Collapsible IDA: Collapsing Parental Sets for Locally Estimating Possible Causal Effects

Yue Liu, Zhuangyan Fang, Yangbo He∗, Zhi Geng

Abstract

It is clear that some causal effects cannot be identified from observational data when the causal directed acyclic graph is absent. In such cases, IDA is a useful framework which estimates all possible causal effects by adjusting for all possible parental sets. In this paper, we combine the adjustment set selection procedure with the original IDA framework. Our goal is to find a common set that can be subtracted from all possible parental sets without influencing the back-door adjustment. To this end, we first introduce graphical conditions to decide whether a treatment’s neighbor or parent in a completed partially directed acyclic graph (CPDAG) can be subtracted and then provide a procedure to construct a subtractable set from those subtractable vertices. We next combine the procedure with the IDA framework and provide a fully local modification of IDA. Experimental results show that, with our modification, both the number of possible parental sets and the size of each possible parental set enumerated by the modified IDA decrease, making it possible to estimate all possible causal effects more efficiently.

1 INTRODUCTION

Causal directed acyclic graphs are often used to give interpretable and compact representations of causal relations and the generative mechanisms of observational data [Pearl 1995; Spirtes et al. 2000; Geng et al. 2019]. If the underlying causal DAG is provided [He & Geng 2008; Hauser & Bühmann 2012], the causal effect of a treatment on a target can be estimated from observational data via the back-door adjustment [Pearl 2009], or more generally, via the covariate adjustment [Shpitser et al. 2010; Perkovic et al. 2015, 2017; Perkovic et al. 2018]. However, in some situations, based on observational data one can only obtain a set of statistically equivalent DAGs, forming a Markov equivalence class represented by a completed partially directed acyclic graph (CPDAG) [Meek 1995; Andersson et al. 1997; Spirtes et al. 2000; Chickering 2002]. Since the causal effects of a treatment on a target may vary in Markov equivalent DAGs, it is challenging to estimate causal effects with a CPDAG only.

The recent progress in causal inference shows that some causal effects can be uniquely identified from observational data without a fully specified causal DAG [Perkovic et al. 2017; Perkovic et al. 2018; Jaber et al. 2019; Perkovic 2019]. Despite these criteria, there are still many causal effects that cannot be identified. To deal with this problem, Maathuis et al. (2009) proposed an alternative framework called intervention do-calculus (IDA), which enumerates all possible causal effects of a treatment on a target. Since knowing the parental set of a treatment is enough for the back-door adjustment, IDA and its generalizations only enumerate possible parental sets instead of all equivalent DAGs [Maathuis et al. 2009; Nandy et al. 2017; Perkovic et al. 2017], making them suitable for sparse DAGs.

Though enumerating possible parental sets is sufficient for estimating all possible causal effects, with limited samples adjusting for possible parental sets may still be challenging, since the total number of possible parental sets and the size of each possible parental set could be very large. There are many papers studying the adjustment set selection problem [Kuroki & Cai 2004; VanderWeele & Shpitser 2011; Henckel et al. 2019; Andrea & Ezequiel 2019], but it is difficult to combine them with the IDA framework directly without breaking the local nature of IDA, since most of them focus on the case where the causal effect can be uniquely identified.

*Correspondence to: heyb@pku.edu.cn.
In this paper, we consider the problem of finding a common set that can be subtracted from all possible parental sets simultaneously without affecting the back-door adjustment. This problem is similar to the one considered in [VanderWeele & Shpitser (2011); Henckel et al. (2019); Andrea & Ezequiel (2019)], but the major difference is that their work focuses on pruning each possible parental set separately. We first introduce a new concept called uniform collapsibility, which basically states that a set of possible parental sets is uniformly collapsible over a set \( Z \), if after subtracting \( Z \) from all of those possible parental sets, the remaining parts are still back-door adjustment sets. Next, given a CPDAG, we provide graphical conditions to decide whether each subset of treatment’s neighbors and parents in the CPDAG can be subtracted. Based on these results, we provide a modification of the original IDA which includes the adjustment set selection procedure while keeping the local nature of IDA. Experimental results show that, with our modification, both the number of possible parental sets and the size of each possible parental set enumerated by the modified IDA decrease, making it possible to estimate all possible causal effects more efficiently.

2 PRELIMINARIES

In this section, we review some basic concepts.

2.1 NOTATION AND DEFINITIONS

Let \( G = (V, E) \) denote a graph. Two vertices are adjacent if there is an edge between them. If \( X_i \rightarrow X_j \), then \( X_i \) is a parent of \( X_j \) and \( X_j \) is a child of \( X_i \). If \( X_i \sim X_j \), then they are neighbors of each other. A graph is called directed (undirected, or partially directed) if the edges in the graph are directed (undirected, or a mixture of directed and undirected). We agree that directed and undirected graphs are also partially directed. The skeleton of a (partially) directed graph is the undirected graph obtained by replacing all directed edges with undirected ones. If \( U \rightarrow W \leftarrow V \) and \( U, V \) are not adjacent in \( G \), then \( (U, W, V) \) forms a v-structure collided on \( W \). A path in a graph is a sequence of distinct vertices such that any two consecutive vertices are adjacent in the graph. Let \( \pi = (X_0, X_1, \ldots, X_n) \) be a path in \( G \), if \( X_{i-1} \rightarrow X_i \) or \( X_{i-1} \sim X_i \) for all \( i = 1, 2, \ldots, n \), then \( \pi \) is a partially directed path from \( X_0 \) to \( X_n \). If all edges on a partially directed path are directed (undirected), then the path is directed (undirected). If there is a directed path from \( X_i \) to \( X_j \) or \( X_i \sim X_j \), then \( X_i \) is an ancestor of \( X_j \) and \( X_j \) is a descendant of \( X_i \). Given a graph \( G \), the parents, children, neighbors, ancestors, and descendants of a set \( X \) are the union of those of each \( X \in X \) in \( G \), and are denoted by \( pa(X, G) \), \( ch(X, G) \), \( ne(X, G) \), \( an(X, G) \) and \( de(X, G) \), respectively. \( G \) will be omitted from these notations if the context is clear. A (directed) cycle is a (directed) path that starts and ends with the same vertex. A directed graph without directed cycle is called a directed acyclic graph (DAG).

2.2 CAUSAL GRAPHICAL MODELS

Based on the notion of d-separation [Pearl, 2009] or see, e.g. Appendix A.1, a DAG encodes a set of conditional independence relationships. DAGs encoding the same conditional independencies are called Markov equivalent and form a Markov equivalence class. Two equivalent DAGs have the same skeleton and the same v-structures [Pearl et al. 1989]. A Markov equivalence class can be uniquely represented by a completed partially directed acyclic graph (CPDAG) \( G^* \). As proved by Andresson et al. (1997), \( G^* \) is a chain graph. We use \( chcomp(X, G^*) \) to denote the chain component containing \( X \) in \( G^* \), and use \( [G^*] \) or \( [G] \) to denote the Markov equivalence class represented by \( G^* \) or containing \( G \), respectively. It can be shown that the skeleton of a CPDAG \( G^* \) is the same as the skeleton of every DAG in \( [G^*] \), and an edge is directed in a CPDAG if and only if it is directed in every DAG in \( [G^*] \) [Pearl et al. 1989].

Let \( G = (V, E) \) be a DAG and \( f \) be a distribution over \( V \). We use \( \{X \perp \perp Y \mid Z\}_{G} \) to denote that \( X \) and \( Y \) are d-separated by \( Z \) in \( G \), and use \( \{X \perp \perp Y \mid Z\}_{f} \) to denote that \( X \) and \( Y \) are independent conditioning on \( Z \) w.r.t. \( f \). We say that \( f \) is Markovian to \( G \) if \( \{X \perp \perp Y \mid Z\}_{G} \) implies \( \{X \perp \perp Y \mid Z\}_{f} \). Any distribution \( f \) Markovian to a DAG \( G \) can be factorized as,

\[
f(x_1, \ldots, x_n) = \prod_{i=1}^{n} f(x_i\mid pa(x_i, G)).
\]

A causal graphical model consists of a DAG and a distribution Markovian to that DAG.

2.3 INTERVENTION CALCULUS

In order to obtain the effect of an intervention on a target variable [Pearl, 2009] employed the do-operator to formulate the post-intervention distribution as follows:

\[
f(x_1, \ldots, x_n|do(X_j = x'_j)) = \left\{ \begin{array}{ll} \prod_{i=1}^{n} f(x_i|pa(x_i))|_{x_j=x'_j}, & \text{if } x_j = x'_j, \\ 0, & \text{otherwise}. \end{array} \right. \tag{1}
\]

Here, \( f(x_1, \ldots, x_n|do(X_j = x'_j)) \) is the post-intervention distribution over \( V = \{X_1, \ldots, X_n\} \) after intervening on \( X_j \), by forcing \( X_j \) to equal \( x'_j \). The post-intervention distribution \( f(x_1|do(X_j = x_j)) \) is defined by integrating
out all variables other than \( x_i \) in \( f(x_1, \ldots, x_n | do(X_j = x_j)) \). Given a treatment \( X \) and a target \( Y \), if there exists an \( x \neq x' \) such that \( f(y | do(X = x)) \neq f(y | do(X = x')) \), then \( X \) has causal effect on \( Y \) \cite{Pearl2009}. It is common to summarise the distribution generated by an intervention by its mean \cite{Maathuis2009, Spirtes2000}, i.e., the mean of \( Y \) w.r.t. \( f(y | do(X = x)) \), which is denoted by \( E(Y | do(X = x)) \). \( E(Y | do(X = x)) \) is a function of \( x \). If \( X \) is continuous, or more precisely, \( E(Y | do(X = x)) \) is differentiable w.r.t. \( x \), then we can define the average causal effect (ACE) of \( do(X = x) \) on \( Y \), i.e., \( ACE(Y | do(X = x)) \), by

\[
ACE(Y | do(X = x)) = \frac{\partial E(Y | do(X = x))}{\partial x}.
\]

If \( X \) is discrete or \( E(Y | do(X = x)) \) is not differentiable w.r.t. \( x \), we can set a reference value \( x_0 \) and define

\[
ACE(Y | do(X = x)) = E(Y | do(X = x)) - E(Y | do(X = x_0)).
\]

In general, the post-intervention distribution \( f(y | do(X = x)) \) is not identical to the conditional distribution \( f(y | X = x) \), meaning that we cannot estimate \( f(y | do(X = x)) \) by \( f(y | X = x) \). Fortunately, Pearl \cite{Pearl2009} showed that, if \( f \) is Markovian to \( G \), then for any \( Y \notin pa(X, G) \), we have \( f(y | do(X = x), pa(x, G)) = f(y | X = x, pa(x, G)) \). Therefore,

\[
f(y | do(X = x)) = \int f(y | do(X = x), pa(x)) f(pa(x)) d(pa(x)) \quad (2)
\]

Here, \( pa(x) \) is an abbreviation for \( pa(x, G) \). Equation (2) shows that, if we know \( pa(X, G) \), then we can estimate \( f(y | do(X = x)) \) from observational data. In fact, Equation (2) is a special case of so-called back-door adjustment \cite{Pearl2009}, and \( pa(X, G) \) is a back-door adjustment set. The general definition of back-door adjustment set is given as follows \cite{Pearl2009, Definition 3.3.1}:

**Definition 1 (Back-Door Adjustment Set)** Let \( W \) be a variable set and \( X, Y \notin W \) be two distinct variables in a DAG \( G \). Then we say that \( W \) is a back-door adjustment set for \( (X, Y) \) w.r.t. \( G \) if:

1. no node in \( W \) is a descendant of \( X \); and
2. \( W \) blocks every path between \( X \) and \( Y \) that contains an arrow into \( X \).

Pearl \cite{Pearl2009} showed that, if \( W \) is a back-door adjustment set, then \( f(y | do(X = x), w) = f(y | X = x, w) \) and

\[
f(y | do(X = x)) = \int f(y | w, x) f(w) dw.
\]

**Algorithm 1** The IDA algorithm

**Require:** A CPDAG \( G^* \), a variable \( X \) and a target \( Y \) in \( G^* \).

**Ensure:** A multi-set \( \Theta \) which stores all possible causal effects of \( X \) on \( Y \).

1. Initialize \( \Theta = \emptyset \).
2. for each \( S \subseteq ne(X, G^*) \) such that \( S \) is a clique do
3. estimate the causal effect \( \theta \) of \( X \) on \( Y \) by adjusting \( S \cup pa(X, G^*) \), and add \( \theta \) to \( \Theta \).
4. end for
5. return \( \Theta \).

Given a DAG \( G \) and a variable \( X \) in \( G \), we define the manipulated graph \( G_X \) as the subgraph of \( G \) by deleting all directed edges pointing at \( X \) \cite{Spirtes2000, Pearl2009}. Manipulated graphs are important in causal inference, as one can see that if \( f \) is Markovian to \( G \), then \( f(\cdot | do(X = x)) \) is Markovian to \( G_X \).

### 2.4 THE IDA FRAMEWORK

The back-door adjustment provides an efficient way to compute post-intervention distributions. However, a causal DAG must be prespecified. In general, due to the existence of Markov equivalent DAGs, it is possible that one can only obtain a CPDAG from observational data instead of a DAG. Much research has been devoted to estimating post-intervention distributions and causal effects when the DAG is absent \cite{Maathuis2015, Perkovic2015, Perkovic2017}. However, in some cases, the causal effect of a treatment on a target may not be identifiable. For example, if the causal effects of a treatment on a target vary in different equivalent DAGs, then it is impossible to estimate the true causal effect without knowing the underlying causal DAG.

To deal with the unidentifiable cases, Maathuis et al. \cite{Maathuis2009} proposed an alternative framework called intervention do-calculus when the DAG is absent (IDA) (see Algorithm 1 for the details). For a treatment and a target, IDA estimates all possible causal effects of the treatment on the target, by using Equation (2) to compute the causal effect w.r.t. each of the equivalent DAGs. Since Equation (2) only requires the parental set of \( X \) in each DAG, to avoid enumerating equivalent DAGs, IDA enumerates all possible parental sets by using the following lemma.

**Lemma 1** \cite{Maathuis2009, Lemma 3.1} Let \( G^* \) be a CPDAG, \( X \) be a vertex of \( G^* \), and \( S \subseteq ne(X, G^*) \). We note that, although Maathuis et al. \cite{Maathuis2009} assumed a linear Gaussian model and used ACE to summarize the causal effects, but IDA can be easily extended beyond those assumptions. Similarly, the results in our paper do not need such assumptions either.
Then there is a DAG $G \in [G^*] \text{ such that } pa(X, G) = pa(X, G^*) \cup S \text{ if and only if orienting } S \rightarrow X \text{ for every } S \in S \text{ in } G^* \text{ does not introduce any new } v\text{-structure.}$

Henckel et al. (2019) and Andrea & Ezequiel (2019). From this we can prove that the condition in Lemma 1 holds if and only if $S$ is a clique, i.e., $S$ is either an empty set, or a singleton set, or for any two distinct vertices $S, S' \in S,$ $S$ and $S'$ are adjacent in $G^*.$ Clearly, enumerating possible parental sets is more efficient than enumerating DAGs (He et al., 2015). However, when the size of $\text{ne}(X, G^*)$ is large, it may take a long time to finish enumeration. Moreover, if the sample size is small, the estimation of $f(Y|do(X = x))$ may have a large variance. In the following, we will provide a method to reduce both the number of possible parental sets and the size of each possible parental set.

3 Uniform Collapsibility for Possible Parental Sets

As discussed in Section 2.4 our goal is to reduce both the number of possible parental sets and the size of each possible parental set when estimating all possible causal effects. The start point is Equation (2). For a DAG $G,$ if we can find a subset $Z$ of $pa(x, G),$ such that

$$f(y|X = x, pa(x, G)) = f(y|X = x, pa(x, G) \setminus Z),$$

then we can estimate $f(y|do(X = x))$ by adjusting for $pa(x, G) \setminus Z$:

$$f(y|do(X = x)) = \int f(y|do(X = x, pa(x)) f(pa(x)) \, d(pa(x))$$

$$= \int f(y|X = x, pa(x)) f(pa(x)) \, d(pa(x))$$

$$= \int f(y|X = x, pa(x) \setminus Z) f(pa(x) \setminus Z) \, d(pa(x) \setminus Z).$$

Since $pa(x, G) \setminus Z$ contains less variables, adjusting for $pa(x, G) \setminus Z$ may lead to a more accurate estimation (Henckel et al., 2019; Andrea & Ezequiel, 2019).

3.1 Collapsibility

To formulate the idea given at the beginning, we introduce the following concept.

Definition 2 (Collapsibility) Let $X, Y$ be distinct vertices in a DAG $G$ such that $Y \notin pa(X, G),$ and $W$ is a back-door adjustment set for $(X, Y)$ w.r.t. $G.$ We say that $W$ is collapsible over $Z \subseteq W$ (or onto $W \setminus Z$ w.r.t. $G$ and $(X, Y),$ if either $W = \emptyset,$ or $Z \neq \emptyset$ and $W \setminus Z$ is a back-door adjustment set for $(X, Y)$ w.r.t. $G.$

In Definition 2 if $Z = \{Z\}$ is a singleton set, we simply say that $W$ is collapsible over $Z$ w.r.t. $G$ and $(X, Y).$ Moreover, if $W$ is collapsible over $Z,$ then $Z$ is called subtractable from $W.$ Back to the IDA framework, if $pa(X, G)$ is collapsible over $Z(G),$ then estimating $f(y|do(X = x))$ by adjusting for $pa(X, G) \setminus Z(G)$ may improve the efficiency and accuracy of the estimation (Henckel et al., 2019; Andrea & Ezequiel, 2019).

Example 1 Figure 1 shows how to collapse $pa(X, G)$ for estimating all possible causal effects under the IDA framework. The CPDAG $G^*$ is shown in Figure 1(a) and Figures 1(b)-1(d) enumerate all equivalent DAGs. Since $\text{ne}(X, G^*) = \{A, B\}$ and $pa(X, G^*) = \emptyset,$ all possible parental sets of $X$ are $\{A\}, \{B\}$ and $\emptyset,$ which correspond to Figures 1(b)-1(d) respectively. However, in Figure 1(b) $pa(X, G_1)$ is collapsible over $A.$ Therefore, $f(y|do(X = x)) = \int f(y|X = x, a) f(a) \, da = f(y|X = x),$ meaning that the post-intervention distribution is reduced to the conditional distribution. On the other hand, since neither $\{B\}$ in $G_2$ nor $\emptyset$ in $G_3$ is collapsible, the final possible back-door adjustment sets are $\{B\}$ and $\emptyset.$

Example 1 shows that collapsing $pa(X, G)$ can indeed reduce both the number of possible parental sets and the size of each parental set when estimating all possible causal effects. However, as shown in Example 1 for different $G$’s, $pa(X, G)$’s may be collapsible over different
Let \( W \)’s. Thus, we need a simple rule to check whether a set can be subtracted from \( \text{pa}(X, G) \).

**Proposition 1** Suppose that \( X \) and \( Y \notin \text{pa}(X, G) \) are distinct vertices in a DAG \( G \), and \( Z(G) \) is a subset of \( \text{pa}(X, G) \). Then \( \text{pa}(X, G) \) is collapsible over \( Z(G) \) w.r.t. \( G \) and \( (X, Y) \) if and only if \( \{Z(G) \perp Y \mid X \cup \text{pa}(X, G) \setminus Z(G)\}_G \).

All detailed proofs of the theoretical results in this paper are present in Appendix A. The sufficiency of Proposition 1 follows from [Henckel et al. (2019)] Lemma D.1. In fact, we can also prove that,

**Proposition 2** With the assumptions in Proposition 1, \( \text{pa}(X, G) \) is collapsible over \( Z(G) \) w.r.t. \( G \) and \( (X, Y) \) if and only if \( \{Z(G) \perp Y \mid X \cup \text{pa}(X, G) \setminus Z(G)\}_G \).

[Henckel et al. (2019)] Algorithm 1 also provided an algorithm to construct a subtractable set. However, combining this algorithm with IDA locally is still challenging. In fact, it may take much more effort to find \( Z(G) \) than simply adjusting for \( \text{pa}(X, G) \). Therefore, in this paper, we focus on another strategy. We would like to find a fixed variable set \( Z \) which can be subtracted from all possible parental sets.

### 3.2 UNIFORM COLLAPSIBILITY

In this section, we introduce a new concept called uniform collapsibility for a set of back-door adjustment sets.

**Definition 3** (Uniform Collapsibility) Let \( Z \) be a variable set, and \( X, Y \notin Z \) are two distinct vertices in a CDAG \( G^* \) and \( Y \notin \text{pa}(X, G^*) \). Given a set of back-door adjustment sets \( W = \{W(G) \mid G \in [G^*] \) and \( Y \notin \text{pa}(X, G) \} \), where \( W(G) \) is a back-door adjustment set for \( (X, Y) \) w.r.t. \( G \), we say that \( W \) is uniformly collapsible over \( Z \) w.r.t. \( G^* \) and \( (X, Y) \), if \( W(G) \) is collapsible over \( W(G) \cap Z \) w.r.t. \( G \) and \( (X, Y) \) for every \( W(G) \in W \).

If \( W \) is uniformly collapsible over \( Z \), then \( Z \) is called uniformly subtractable from \( W \). Clearly, \( W \) is uniformly collapsible over any \( Z \) such that \( W(G) \cap Z = \emptyset \) for every \( G \in [G^*] \). We call such \( Z \) trivial. Conversely, if there exists a non-trivial set which is uniformly subtractable from \( W \), then the size of at least one back-door adjustment set in \( W \) can be reduced. Next example shows that non-trivial sets do exist for some CDAGs.

**Example 2** Consider the CDAG \( G^* \) shown in Figure 2(a) and two equivalent DAGs in Figures 2(b) and 2(c). Let \( W = \{\emptyset, \{A\}\} \). Clearly, \( \emptyset \) and \( \{A\} \) are back-door adjustment sets for \( (X, Y) \) w.r.t. \( G_1 \) and \( G_2 \) respectively. Since \( \{A\} \) is collapsible over \( \{A\} \) in \( G_2 \) based on Proposition 1, and \( \emptyset \) is collapsible over \( \emptyset \cap \{A\} \) in \( G_1 \), \( W \) is uniformly collapsible over \( \{A\} \). After collapsing \( W \), we only need adjust for \( \emptyset \) in the IDA framework.

Conversely, for some CDAGs, such non-trivial subtractable sets may not exist. For example, if we consider the CDAG in Figure 2(d), then \( W = \{\emptyset, \{A\}\} \) is not uniformly collapsible over \( A \) w.r.t. \( G^{**} \) and \( (X, Y) \).

### 3.3 CHARACTERIZATIONS AND CONSTRUCTIONS

Based on the IDA framework, our goal is to characterize and construct a set \( Z \) which is uniformly subtractable from \( W = \{\text{pa}(X, G) \mid G \in [G^*] \) and \( Y \notin \text{pa}(X, G) \} \).

The road map is as follows: we first discuss when a single vertex can be uniformly subtracted from \( W \) (Theorems 1 and 2), then we consider how to construct a larger subtractable set from those singleton sets (Theorems 3).

The first result, which is given in Theorem 1, provides a sufficient and necessary condition under which a single vertex in \( \text{ne}(X, G) \) is uniformly subtractable from \( W = \{\text{pa}(X, G) \mid G \in [G^*] \) and \( Y \notin \text{pa}(X, G) \} \).

**Theorem 1** Suppose that \( G^* \) is a CDAG, and \( X, Y, Z \) are three distinct vertices in \( G^* \) such that \( Y \notin \text{pa}(X, G^*) \) and \( Z \in \text{ne}(X, G^*) \). Let \( W = \{\text{pa}(X, G) \mid G \in [G^*] \) and \( Y \notin \text{pa}(X, G) \} \), then the following statements are equivalent.

1. \( W \) is uniformly collapsible over \( Z \) w.r.t. \( G^* \) and \( (X, Y) \).
2. \( \{Z \perp Y \mid X \cup \text{pa}(X, G) \setminus Z\}_G \) holds for every \( \text{pa}(X, G) \in W \).
3. \( \{Z \perp Y \mid X \cup \text{pa}(X, G) \setminus Z\}_{G^*} \) holds for every \( \text{pa}(X, G) \in W \).
We first show that statement (4) is not sufficient. To show that statement (4) is not necessary either, let us consider the singleton subsets of $\text{pa}(X,G^*)$. The fourth statement in Theorem 1 gives a necessary and sufficient graphical criterion to decide whether a singleton subset of $\text{ne}(X,G^*)$ is uniformly collapsible over $\mathcal{W}$. Note that, if none of the paths from $Z$ to $Y$ is partially directed, then $\mathcal{W}$ is also uniformly collapsible over $Z$. We also note that, the graphical criterion only holds for $Z \in \text{ne}(X,G^*)$. If $Z \in \text{pa}(X,G^*)$, the criterion is neither sufficient nor necessary. Below we give an example.

Example 3 Figure 3(a) shows a CPDAG $G^*_1$ containing directed edges only. Figure 3(c) shows another CPDAG $G^*_2$ in which only $A$ and $B$ are connected by an undirected edge. Since $G^*_1$ has no undirected edge, the only DAG in the Markov equivalence class represented by $G^*_1$ is itself. Thus, the corresponding manipulated graph is $G^*_{1,X}$, as shown in 3(e). Similarly, the corresponding manipulated graphs of the DAGs in $G^*_2$ are shown in 3(d), where $A - B$ in $G^*_{2,X}$ can be oriented as $A \rightarrow B$ or $A \leftarrow B$.

We first show that statement (4) is not sufficient. As shown in Figure 3(a), all partially directed paths from $A$ to $Y$ pass through $X$. However, by proposition 1, $A$ is not subtractable from $\{A, B, C\}$, as $A \rightarrow B \leftarrow D \rightarrow Y$ is a $d$-connected path given $B, C$ and $X$ in both $G^*_1$ and $G^*_{1,X}$. To show that statement (4) is not necessary either, let us consider Figures 3(c) and 3(d). Although $A \rightarrow B \rightarrow Y$ is a partially directed path from $X$ to $Y$ which bypasses $X$, $A$ is $d$-separated from $Y$ given $B, C$ and $X$ in both $G^*_2$ and $G^*_{2,X}$. Thus, $A$ is subtractable.

Next, we consider the singleton subsets of $\text{pa}(X,G^*)$. It can be shown that,

$\text{Example 4 In this example, we show that the condition in Theorem 2 is not necessary. As shown in Figures 3(c) and 3(d), $A$ is a parent of $X$ in $G^*$, and $A \rightarrow B \rightarrow Y$ is a path from $A$ to $Y$ bypassing $X$. However, as discussed in Example 3, $\{A, B, C\}$ is uniformly collapsible over $A$.

Since $\text{pa}(X,G^*) \subset \text{pa}(X,G^*) \cup \text{ne}(X,G^*)$ for any $G^* \in \mathcal{G}^*$, we do not have to consider $Z \in \text{ch}(X,G^*)$. Thus, the remaining problem is how to construct a subtractable set containing more than just one vertex. The following Theorem 3 provides an answer.

Theorem 3 Suppose that $G^*$ is a CPDAG, $X$ and $Y$ are two distinct vertices in $G^*$ and $Y \notin \text{pa}(X,G^*)$, and $Z_1, Z_2$ are two subsets of variables such that at least one of them is a subset of $\text{ne}(X,G^*)$. Let $W = \{\text{pa}(X,G) \mid G \in [G^*] \text{ and } Y \notin \text{pa}(X,G)\}$, if $W$ is uniformly collapsible over both $Z_1$ and $Z_2$ w.r.t. $G^*$ and $(X,Y)$, then $W$ is uniformly collapsible over $Z_1 \cup Z_2$ w.r.t. $G^*$ and $(X,Y)$.

Based on the above theorems, we have,

Corollary 1 Suppose that $G^*$ is a CPDAG, $X$ and $Y$ are two distinct vertices in $G^*$ and $Y \notin \text{pa}(X,G^*)$. Let $Z_{\text{ne}} \subset \text{ne}(X,G^*)$ and $Z_{\text{pa}} \subset \text{pa}(X,G^*)$ be the sets
Algorithm 2 The collapsible IDA algorithm

Require: A CPDAG $G^*$, a variable $X$ and a target $Y$ in $G^*$.

Ensure: A multi-set $Θ$ which stores all possible causal effects of $X$ on $Y$.

1: Initialize $Θ = \emptyset$,
2: find all vertices in $\text{ne}(X, G^*)$ from which there is no partially directed path to $Y$ in $G^*$ that bypasses $X$, and denote them by $Z_{ne}$.
3: if $Z_{ne}$ is not identical to $\text{ne}(X, G^*)$, then
4: set $Z_{pa} = \emptyset$,
5: else
6: find all vertices in $pa(X, G^*)$ from which every path to $Y$ passes through $X$, and denote them by $Z_{pa}$.
7: end if
8: for each $S \subseteq \text{ne}(X, G^*) \setminus Z_{ne}$ such that $S$ is a clique, do
9: estimate the causal effect $θ$ of $X$ on $Y$ by adjusting for $S \cup pa(X, G^*) \setminus Z_{pa}$, and add $θ$ to $Θ$,
10: end for
11: return $Θ$.

of vertices satisfying the graphical criteria in Theorems 4 and 2, respectively. Then $W = \{pa(X, G) \mid G \in \mathcal{G}^* \text{ and } Y \notin pa(X, G)\}$ is uniformly collapsible over $Z_1 \cup Z_2$ w.r.t. $G^*$ and $(X, Y)$.

Hence, with Corollary 1, we can separately find all singleton sets satisfying the graphical criteria in Theorems 4 and 2, respectively, then the union of these singleton sets is a non-trivial set which $W$ is uniformly collapsible over.

4 ALGORITHM

In this section, we apply the theoretical results given in the last section to modifying IDA. The proposed algorithm, which is called collapsible IDA, is shown in Algorithm 2.

In Algorithm 2, we first use the graphical criterion provided in Theorem 1 to find $Z_{ne}$. If $Z_{ne}$ is not identical to $\text{ne}(X, G^*)$, then based on Proposition 3, $pa(X, G^*)$ is not collapsible. Thus, we simply let $Z_{pa} = \emptyset$. On the other hand, if $Z_{ne} = \text{ne}(X, G^*)$, we construct $Z_{pa}$ based on Theorem 2. Notice that, other criteria in [Henckel et al., 2019, Section 3.2] can also be applied to this case. Finally, we enumerate all subsets of $\text{ne}(X, G^*) \setminus Z_{ne}$ in order to find all cliques, and for each clique $S$, we estimate one possible causal effect by adjusting for $S \cup pa(X, G^*) \setminus Z_{pa}$.

To avoid enumerating all partially directed paths from $Z$ to $Y$ when building $Z_{ne}$, we can use the following proposition to further reduce the complexity.

Proposition 4 Given a CPDAG $G^*$ and three distinct vertices $X$, $Y$ and $Z$ in $\text{ne}(X, G^*)$. Then, every partially directed path from $Z$ to $Y$ passes through $X$ in $G^*$ if and only if for any $U \in \text{chcomp}(X, G^*) \cap \text{an}(Y, G^*)$, every partially directed path from $Z$ to $U$ passes through $X$ in $G^*$.

Note that any vertex is an ancestor of itself, thus for any $U \in \text{ne}(X, G^*) \cap \text{an}(Y, G^*)$, $W$ is not uniformly collapsible over $U$ since there is a zero-length path from $U$ to itself, which definitely bypasses $X$. The next example shows the usefulness of Proposition 4.

Example 5 Figure 4 shows an example of finding $Z_{ne}$ with Proposition 2. The CPDAG $G^*$ is shown in Figure 4(a). Since $\text{ne}(X, G^*) = \{A, B, E\}$ and $pa(X, G^*) = \emptyset$, all possible parental sets of $X$ are $\{A\}$, $\{B\}$, $\{E\}$ and $\emptyset$. The partially directed paths given in Figures 4(b) to 4(e) enumerate all the cases. Note that $\text{chcomp}(X) \cap \text{an}(Y) = \{A, B\}$, thus $W$ is not uniformly collapsible over $A, B$. On the other hand, all undirected paths from $E$ to $A, B$ pass through $X$, hence, $W$ is uniformly collapsible over $E$. In fact, $X \leftarrow A \rightarrow C \rightarrow Y$ is a back-door path in $G_5^*$, and $X \leftarrow B \rightarrow D \rightarrow Y$ is a back-door path in $G_4^*$. Therefore, both $A$ and $B$ are needed in some back-door adjustment sets.

The major difference between the collapsible IDA and the original IDA is that, the collapsible IDA only enumerates the subsets of $\text{ne}(X, G^*) \setminus Z_{ne}$, while IDA enumerates the subsets of $\text{ne}(X, G^*)$. This modification can reduce both the number of possible parental sets and the size of each possible parental set.

When implementing Algorithm 2, one may use a simple trick to combine the collapsible IDA and the original IDA together. In fact, after line 7 in Algorithm 2 we can remove all edges between $Z_{ne} \cup Z_{pa}$ and $X$, and the resulting graph is a partially directed graph denoted by $H$. Next, we can simply call IDA with the input graph $H$, input treatment $X$, and input target $Y$. Although $H$ is not a CPDAG as required by IDA, from the construction given above, it is straightforward to verify that the resulting multi-set is identical to the one returned by Algorithm 2.

5 SIMULATIONS

In this section, we use simulated data to compare our method with IDA [Maathuis et al., 2009]. The input CPDAG is either the true CPDAG [Perkovic et al., 2017], or the one learned from data using the PC algorithm [Maathuis et al., 2009]. All experiments were implemented with R and run on a computer with 2.50GHz CPU and 8 GB of memory. PC and IDA were called from pcalg R-package [Kalisch et al., 2012]. All
statistical independence tests were performed under the significance level $\alpha = 0.001$.

The data was generated as follows. We first sampled a random DAG $G$ with 50 vertices and expected degree $d \in \{1, 2, 3, 4, 5\}$ based on a Erdős-Rényi random graph model. Then we generated a joint Gaussian distribution Markovian to this DAG as follows. For each directed edge $X_i \rightarrow X_j$, we first independently draw an edge weight $\beta_{ij}$ from a Uniform($[0.5, 2]$) or a Uniform($[-2, -0.5] \cup [0.5, 2]$). The DAG $G$ together with these edge weights $\{\beta_{ij}\}$ gives a distribution over the variable set through the following equations:

$$X_j = \sum_{X_i \in \text{pa}(X_j)} \beta_{ij} X_i + \epsilon_j, \quad j = 1, \ldots, n,$$

where $\epsilon_1, \ldots, \epsilon_n$ i.i.d. $\sim N(0, 1)$. After obtaining the distribution, we randomly generated two data sets with sample size $N_1 = 1000$ and $N_2 \in \{20, 50\}$, respectively. The first data set was used to learn the CPDAG and the second was used to estimate all possible causal effects. Finally, we sampled an $X$ and used the original IDA and the collapsible IDA (‘CIDA’ for short) to estimate all possible effects of $X$ on all other variables. The input CPDAG was set to be the true one representing the Markov equivalence class containing $G$, or the one learned by the PC algorithm. All experiments were repeated 100 times.

We use the following metrics to assess the results. After estimating all possible causal effects of $X$ on other variables, for each method, we computed the total number of possible causal effects of $X$ on all other variables (denoted by $N_{\text{IDA}}$ or $N_{\text{CIDA}}$), the maximum size of possible parental sets (denoted by $M_{\text{IDA}}$ or $M_{\text{CIDA}}$), and the total estimation bias (denoted by $B_{\text{IDA}}$ or $B_{\text{CIDA}}$). The total estimation bias is defined as

$$B_{\text{method}} = \sqrt{\sum_{Y} \sum_i (PE_{X \rightarrow Y,i} - TE_{X \rightarrow Y})^2},$$

where $PE_{X \rightarrow Y,i}$ is the $i$-th possible effect of $X$ on $Y$ estimated with the input CPDAG and $TE_{X \rightarrow Y}$ is the true effect of $X$ on $Y$ estimated with the underlying DAG. For ease of comparison, we only stored $RN = N_{\text{CIDA}}/N_{\text{IDA}}$, $RM = M_{\text{CIDA}}/M_{\text{IDA}}$ and $RB = B_{\text{CIDA}}/B_{\text{IDA}}$.

Due to page limits, we only show the results for mixed edge weights in Figure 5. Additional results are given in Appendix B. As discussed in Section 4, if the treatment $X$ does not have any neighbors, the number of possible parental sets cannot be reduced. Thus, in Figure 5, we not only report the average quantities over 100 times repetitions (full-samples), but also report the average quantities over the cases where $X$ has neighbors (sub-samples).

From Figure 5, we can draw the following conclusions. (1) For an arbitrary treatment, the total number of possible effects can be reduced by 10%-20% if we use the collapsible IDA, and for a treatment with neighbors, the total number of possible effects can be approximately reduced by 40%-50%. (2) Using the collapsible IDA can significantly reduce the maximum size of parental sets. For an arbitrary treatment, $M_{\text{CIDA}}$ is reduced by 10%-50%, and for a treatment with neighbors, $M_{\text{CIDA}}$ is reduced by 60%-90% compared with $M_{\text{IDA}}$. (3) The estimation bias $B_{\text{CIDA}}$ is reduced by 5%-20% and 10%-30% for an arbitrary treatment and a treatment with neighbors, respectively, compared with $B_{\text{IDA}}$. (4) As the graph becomes dense, the results of the collapsible IDA become less significant.

To explain the above results, we recall that collapsing treatments’ parents in a CPDAG does not reduce the number of possible effects but only reduce the maximum size of a possible parental set, while collapsing treatments’ neighbors can reduce both the number of possible effects and the maximum size of a possible parental set. Therefore, $RM$ is generally lower than $RN$ in the same setting. On the other hand, when the underlying DAG is sparse, the corresponding CPDAG contains many undirected edges. However, when the graph becomes dense, the number of v-structures increases, and thus less undirected edges are in the CPDAG. Therefore, $RN$, $RM$ and $RB$ increase when we increase the expected degree. Finally, when the input CPDAG is learned from data, we
Figure 5: Experimental results. The first two rows report the results for using the true CPDAGs as inputs, while the third row reports the results for using the learned CPDAGs. The first row corresponds to $N_2 = 20$, while the second and the third row correspond to $N_2 = 50$. The edge weights were sampled from $\text{Uniform}([-2, -0.5] \cup [0.5, 2])$.

empirically find that there are many falsely discovered v-structures in the learned graphs. Consequently, the difference between the collapsible IDA and the original IDA, as well as the distance between two lines in each figure is narrowed.

6 CONCLUDING REMARKS

IDA is a general framework for estimating all possible causal effects of a treatment on a target when the true effect is not identifiable. In this paper, we combine the adjustment set selection procedure with the IDA framework, by providing a method to subtract a common set from all possible parental sets without influencing the back-door adjustment and estimating possible causal effects. With our modification, both the number of possible parental sets and the size of each possible parental set enumerated by IDA decrease, while the local nature of IDA remains unchanged.

There are many possible future directions. For example, how to extend our work to more generalized graphs such as maximal PDAGs is interesting (Perković et al., 2017). Besides, as discussed in Henckel et al. (2019), Andrea & Ezequiel (2019), some additional covariates are beneficial for efficiency, and thus should be included. Therefore, how to extend our work to identify those variables locally and apply them to the IDA framework is also useful.

Acknowledgements

We would like to thank the anonymous reviewers for their constructive suggestions. We would also like to thank Assoc. Prof. Jiji Zhang from Lingnan University for many helpful comments. This work was supported by National Key R&D Program of China (2018YFB1004300), NSFC (11671020, 11771028).

This material is supplementary to ‘Collapsible IDA: Collapsing Parental Sets for Locally Estimating Possible Causal Effects’.

A PROOFS

In this section, we present the proofs of the results in the main text.

A.1 PRELIMINARIES

Given a DAG $\mathcal{G}$ and a path $\pi$, if there are two directed edges $U \rightarrow W$ and $V \rightarrow W$ on $\pi$, then $W$ is called a collider on $\pi$. A path $(X_1, X_2, \ldots, X_n)$ is called unshielded if $X_1$ is not adjacent to $X_{i+2}$ for $i = 1, 2, \ldots, n-2$. Given a path $\pi = (X_1, X_2, \ldots, X_j, \ldots, X_n)$, the subpath of $\pi$ from $X_j$ to $X_k$ is the subsequence $(X_j, \ldots, X_k)$ and is denoted by $\pi(X_j, X_k)$. A path from $X_j$ to $X_k$ in $\mathcal{G}$ is called d-connected or active given $S \subset V$ if every non-collider on the path is in $\text{an}(S, \mathcal{G})$ (Pearl [1988]). Otherwise, the path is called d-separated or blocked by $S$. If there is no d-connected path from node set $X$ to node set $Y$ given $S$, then $X$ and $Y$ are d-separated given $S$. As discussed in the main text, a Markov equivalence class can be uniquely represented by a CPDAG $\mathcal{G}^*$. As proved by Andersson et al. [1997], a CPDAG $\mathcal{G}^*$ is a chain graph. A chain graph consists of both directed and undirected edges but no partially directed cycles containing directed edges (Lauritzen & Richardson [2002]). In the following proofs, we simply use ‘partially directed circles’ to refer to those partially directed cycles that contain directed edges. After deleting all directed edges from a CPDAG, we obtain several disconnected undirected subgraphs, which are called chain components. Meek [1995] Lemma 1) showed that, if $Y \in \text{pa}(X, \mathcal{G}^*)$, then $Y \in \text{pa}(X', \mathcal{G}^*)$ for every $X' \in \text{chcomp}(X, \mathcal{G}^*)$.

To prove our main results, the following lemma is useful.

**Lemma 2** Given a CPDAG $\mathcal{G}^*$, if there is a partially directed path from $X$ to $Y$ where the first edge is directed, then there is a directed path from $X$ to $Y$ in the CPDAG.

**Proof.** There is no loss of generality in assuming that the path has the following form: $X = X_0 \rightarrow X_1, \ldots, X_{i,1} \rightarrow \ldots \rightarrow X_{i,k_i} \rightarrow \ldots \rightarrow X_{i+1,k_{i+1}} \rightarrow \ldots 

A.2 PROOF OF PROPOSITION 1

**Proof.** The sufficiency follows from Henckel et al. [2019] Lemma D.1), thus we only prove the necessity, i.e., $\text{pa}(X, \mathcal{G})$ is collapsible over $Z(\mathcal{G})$ w.r.t. $\mathcal{G}$ and $(X, Y)$ implies $(Z(\mathcal{G}) \perp Y \mid X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G}))_\mathcal{G}$. In the following paper, we call a path from $X$ to $Y$ that contains an arrow into $X$ a back-door path.

Suppose that $(Z(\mathcal{G}) \perp Y \mid X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G}))_\mathcal{G}$ does not hold, then there exists a d-connected path $\pi$ from $X$ to $Y$ such node, say $Z_\pi$, must be in $Z(\mathcal{G})$. Therefore, the subpath $\pi(Z_\pi, Y)$ is a d-connected path given $X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$ in $\mathcal{G}$, which is strictly shorter than $\pi$. This leads to a contradiction.

If there is a d-connected path $\pi$ from some $Z \in Z(\mathcal{G})$ to $Y$ given $X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$, then $\pi'$ is a d-connected path from $X$ to $Y$ given $X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$. On the other hand, if there is a collider on $\pi$ which is not an ancestor of $\text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$, then this collider must be an ancestor of $X$ since $\pi$ is d-connected given $X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$. Let $W$ denote the first collider on $\pi$ from $Y$’s side that is not an ancestor of $\text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$, then $W$ has a directed path, denoted by $\rho$, to $X$ which does not contain any node in $\text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$. Concatenating $\rho$ and the subpath $\pi(W, Y)$ from $W$ to $Y$ leads to a d-connected back-door path from $X$ to $Y$ given $\text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$. □

A.3 PROOF OF PROPOSITION 2

**Proof.** We first prove the sufficiency. Suppose that there is a d-connected back-door path $\pi$ from $X$ to $Y$ given $\text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$. Since $\pi$ is d-separated by $\text{pa}(X, \mathcal{G})$, there exists a non-collider $Z'$ on $\pi$ which is also in $Z(\mathcal{G})$. Consider the subpath $\pi(Z', Y)$. Clearly, every non-collider on $\pi(Z', Y)$ is in $X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$, and every collider on $\pi(Z', Y)$ is in $\text{an}(\text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G}), \mathcal{G})$. Note that $X \cup \text{an}(\text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G}), \mathcal{G}) = X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G}), \mathcal{G})$, $\pi(Z', Y)$ is d-connected given $X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$ in $\mathcal{G}_X$.

Next we prove the necessity. Suppose that there is a d-connected path $\pi$ from a vertex $Z \in Z(\mathcal{G})$ to $Y$ given $X \cup \text{pa}(X, \mathcal{G}) \setminus Z(\mathcal{G})$ in $\mathcal{G}_X$. Clearly, $X$ is not on $\pi$ since $X$ cannot be a collider in $\mathcal{G}_X$. We combine $X \leftarrow Z$ with $\pi$ and the resulting path $\pi'$ is a back-door path in $\mathcal{G}$. Clearly, every non-collider on $\pi'$ is not in $X \cup$.
pa(X, G) \ Z(G), and every collider on π' is in an(X ∪ pa(X, G) \ Z(G), G), and thus in X ∪ an(pa(X, G) \ Z(G), G). Therefore, π' is a d-connected back-door path from X to Y given pa(X, G) \ Z(G).

A.4 PROOF OF THEOREM 1

Proof. According to Propositions[1] and 2 statements (1), (2) and (3) are clearly equivalent. In the following, we will show that statements (2) and (4) are equivalent.

Statement (2) ⇒ statement (4). Suppose that (4) does not hold, then there is a partially directed path π from Z to Y which bypasses X in CPDAG G*.

Let U denote the last node on π from Z’s side which is also in chcomp(X, G*).

If U = Z, then π is a partially directed path from Z to Y where the first edge is directed. According to Lemma[3] there is a directed path ρ from Z to Y in G*. However, since Z ∈ ne(X, G) and G* does not contain any partially directed cycles, none of the vertices in pa(X, G*) ∪ ne(X, G*) \ X except for Z is on ρ. On the other hand, for any DAG G in the Markov equivalence class represented by G*, pa(X, G) ⊂ pa(X, G*) ∪ ne(X, G*).

Therefore, none of the vertices in pa(X, G) \ X except for Z is on ρ. Since the corresponding path of ρ in G is also directed, ρ is a directed path from Z to Y in G* given pa(X, G) \ X. If U ≠ Z, then the subpath π(Z, U) is a directed path from U to Z, since both U, Z are in chcomp(X, G*) and G* does not contain any partially directed cycles. Note that π(Z, U) does not contain X. Let σ denote the shortest undirected path from Z to U which does not contain X, σ is clearly unshielded. According to Lemma[1] there is a DAG G1 ∈ [G*] such that pa(X, G1) = Z ∪ pa(X, G*) and ch(X, G1) = ne (X, G*) ∪ ch(X, G*) \ Z. Based on [Meek, 1995], there is no collider on the corresponding path of σ in G1. If U = Y, then the corresponding path of σ in G1 is a d-connected path from Z to Y given X ∪ pa(X, G1) \ Z. If U ≠ Y, by the same argument given for U = Z, one can prove that U ∈ an(Y, G*), which means U ∈ an(Y, G1). Concatenating σ and any directed path from U to Y in G1 would result a d-connected path from Z to Y given X ∪ pa(X, G1) \ Z in G1.

Statement (2) ⇔ statement (4). Conversely, suppose that there is a DAG G2 ∈ [G*] in which Y ∉ pa(X, G2) and there is a d-connected path π from Z to Y given X ∪ pa(X, G2) \ Z. If X is on π, then X must be a collider on π. Let P denote the vertex adjacent to X on the subpath π(X, Y). P is a parent of X. Since Y ∉ pa(X, G2), P ≠ Y. Therefore, P ∈ pa(X, G2) is a non-collider on π, meaning that π is blocked by X ∪ pa(X, G2) \ Z, which leads to a contradiction. Now suppose X is not on π. If every node on π is also a member of chcomp(X, G*), then π in G* is a partially directed path from Z to Y bypassing X. Otherwise, let U1 be the first node on π from Z’s side which is not in chcomp(X, G*), and U2 be the node adjacent to U1 on the subpath π(Z, U1).

By assumption, U2 ∈ chcomp(X, G*), and either U1 → U2 or U2 → U1 in G*. If U1 → U2 in G*, then U1 is also a parent of X in G*, which means U1 ≠ Y and π is blocked by X ∪ pa(X, G2) \ Z in G2. This is contradicted to the assumption. Since the definitions of U1 and U2 indicate that π(Z, U2) in G* is unshielded, if U2 → U1 in G* and π(U2, Y) in G2 does not contain a collider, then π2 in G* is a partially directed path bypassing X. If U2 → U1 in G* and π(U2, Y) in G2 contains a collider, then the first collider on π(U2, Y) from U2’s side, denoted by W, is an ancestor of X ∪ pa(X, G2) \ Z in G2. Therefore, there is a directed path ρ from U1 to X in G2. However, concatenating π(Z, U2), U2 → U1, ρ and X → Z will lead to a partially directed cycle in G*, which is impossible. This completes the proof of (2) ⇔ (4).

A.5 PROOF OF PROPOSITION 3

Proof. If W is not uniformly collapsible over Z, then by Theorem[1], there is a partially directed path from Z to Y bypassing X. For any W ∈ pa(X, G*), W ∈ pa(Z, G*). Therefore, similar to the proof of Lemma[2], there is a directed path πW from W to Y in G* which does not contain X, and the vertex adjacent to W on πW is in chcomp(X, G*). This means every vertex on πW except for W is a non-collider and not in pa(X, G*), since otherwise, there would be a partially directed cycle in G*. On the other hand, based on Lemma[1] there is a DAG G ∈ [G*] such that pa(X, G) = pa(X, G*) and ch(X, G1) = ne(X, G*) ∪ ch(X, G*) \ Z. In G, πW is a d-connected path from W to Y given X ∪ pa(X, G) \ W. This completes the proof.

A.6 PROOF OF THEOREM 2

Proof. By proposition[1] we can conversely suppose that there is a DAG G in the Markov equivalence class represented by CPDAG G* such that Y ∉ pa(X, G) and there is at least one d-connected path from some node Z ∈ pa(X, G*) to Y given X ∪ pa(X, G) \ Z in G. Let π be the shortest one among these d-connected paths. If X is on π, then X is a collider on π. Since Y ∉ pa(X, G), the node adjacent to X on the subpath π(X, Y) must be Z. Therefore, the subpath π(Z, Y) is a d-connected path given X ∪ pa(X, G) \ Z in G, which is strictly shorter than π. This is contradicted to our assumption. Therefore, π is a path from Z to Y not containing X.

A.7 PROOF OF THEOREM 3

Proof. Without loss of generality, we suppose that Z1 is
a subset of \( ne(X, G^*) \). Then for any DAG \( G \in [G^*] \), it is clear that \( pa(X, G) \cap ne(X, G^*) \) is a clique. Hence, \( \{pa(X, G) \cap ne(X, G^*)\} \setminus Z_1 \) is also a clique. According to Lemma 1 in the main text, there exists a DAG \( G_1 \in [G^*] \) such that \( pa(X, G_1) = pa(X, G) \setminus Z_1 \). Now we have,

\[
P(Y|X, pa(X, G)) = P(Y|X, pa(X, G) \setminus Z_1)
\]

\[
= P(Y|X, pa(X, G_1))
\]

\[
= P(Y|X, pa(X, G_1) \setminus Z_2)
\]

\[
= P(Y|X, \{pa(X, G) \setminus Z_1 \cup Z_2\}).
\]

Finally, using Theorem 1, \( W \) is uniformly collapsible over \( Z_1 \cup Z_2 \) w.r.t. \( G^* \) and \( (X,Y) \).

□

A.8 PROOF OF PROPOSITION 4

Proof. If there is a partially directed path \( \pi \) from \( Z \) to \( Y \) passing through \( X \), according to Lemma 2 the last node from \( Z \)'s side on which is also in \( chcomp(X, G^*) \) is an ancestor of \( Y \) in \( G^* \). Denote this node by \( U \), then the subpath \( \pi(Z, U) \) is undirected in \( G^* \), which is also a partially directed path passing through \( X \). Conversely, if there is a partially directed path from \( Z \) to some node \( U \in \{chcomp(X, G^*) \cap \{Y \} \} \) passing through \( X \), since \( U \in \{Y \} \), it is clear that \( Z \) has a partially directed path to \( Y \) passing \( X \) in \( G^* \).

□

B ADDITIONAL RESULTS

In this section, we present the additional experimental results for positive edge weights. The results, which are shown in Figure 6 are similar to those given in the main text. We notice that the error bars of the reported metrics on full-samples shown in Figures 5 and 6 are wide, and the value of 1 is included many times. One may expect that the large standard errors can be reduced by increasing the sample size. However, this might be impossible. In fact, the reason for large standard errors is because the distributions of the metrics are multimodal. For example, the distribution of \( RN \) has one peak near 1, representing the cases where \( X \) has no neighbor. Other peaks are possibly less than 1, representing the cases where \( X \) has neighbors (i.e. sub-samples). Thus, the large standard errors of the reported metrics may not be reduced by increasing the sample size.

C FURTHER DISCUSSIONS

In this section, we discuss some worth-noting problems which are related to the main results in our paper.

We greatly appreciate the anonymous reviewers for raising these interesting problems.

Complexity The complexity of CIDA is an important concern. Compared with IDA, CIDA needs to identify which set is subtractable, which may bring additional costs. However, our simulations showed that the time for finding \( Z_{ne} \) and \( Z_{pa} \) is negligible compared to the total time. In fact, let \( |V| = n \), then one can use Depth-First-Search to find \( Z_{ne} \) and \( Z_{pa} \), which is \( O(n^3) \). Although it brings additional costs, it also brings gains since one may enumerate fewer subsets of \( ne(X, G^*) \). Let \( |ne(X, G^*)| = m \) and \( |Z_{ne}| = k \), then the computational gains are about \( O(2^m - 2^m-k) \), which are generally greater than the costs.

The Local Nature of CIDA In the main text, we claim that our proposed CIDA is a ‘local’ algorithm and it keeps the ‘local nature’ of IDA. The word of local was used in Maathuis et al. (2009) to address that IDA does not enumerate all DAGs or run Meeks rules (Meek, 1995), which depends on an entire CPDAG, to check if a set can be a possible parental set of a treatment \( X \). Currently, the methods of listing all DAGs in a Markov equivalence class are called global, and the methods of running Meeks rules are called semi-local (e.g., joint-IDA (Nandy et al., 2017) and semi-local IDA (Perkovic et al., 2017)). In our Algorithm 2, Meeks rules are not needed, and the global structure is needed only once before the for-loop (lines 8-10). Thus, we say that Algorithm 2 is local.

The Maximality of Subtractable Sets Given a set \( \mathcal{W} \) of back-door adjustment sets, one may wondering whether there is a maximal uniformly subtractable set \( Z \) from \( \mathcal{W} \) in the sense that for any other uniformly subtractable set \( Z' \) from \( \mathcal{W} \), it holds that \( Z' \subseteq Z \). The answer to this question is negative. Consider the CPDAG \( C \rightarrow X \leftarrow A \rightarrow B \rightarrow Y \) and \( D \rightarrow B \). This CPDAG is also a DAG. Clearly, \( \{A, B\} \) is a back-door adjustment set for the treatment \( X \) and the response \( Y \). Let \( W = \{\{A, B\}\} \), then \( W \) is uniformly collapsible over \( A \) or \( B \) but not both of them. However, if \( W = \{pa(X, G) \mid G \in [G^*] \text{ and } Y \notin pa(X, G)\} \), then the answer is yes. Studying the maximality of subtractable sets is an interesting topic, and we will explore it in future.

Efficiency Gains In the main text, we informally state that uniformly collapsing adjustment sets could bring efficiency gains. In fact, according to Andrea & Ezequiel (2019) Lemma 2), if \( Z \) includes a subset of \( pa(X, G^*) \), then uniformly subtracting \( Z \) has efficiency gains; if \( Z \) does not include any node in \( pa(X, G^*) \), then in the multi-set of possible causal effects, there is at least one estimate has efficiency gains and one estimate has no efficiency gains.
Figure 6: Experimental results. The edge weights were sampled from Uniform([0.5, 2]).
