Contents

Preface

This volume contains all papers presented at the 28'th Conference on Uncertainty in Artificial Intelligence (UAI), held at Catalina Island in California, August 15-17, 2012. Papers appearing in this volume were subjected to a rigorous review process: 304 papers were submitted, but only 95 were accepted (24 for oral presentation, 18 for poster spotlight presentation, and 53 for poster presentation). We are confident that the proceedings, like past UAI Conference Proceedings, will become an important archival reference for the field.

We are pleased to announce that the best paper award was given to T. Claassen and T. Heskes for their paper entitled "A Bayesian Approach to Constraint Based Causal Inference". Also, the best student paper award was given to R. Grosse (co-authored with R. Salakhutdinov, W. Freeman, and J. Tenenbaum) for their paper entitled "Exploiting compositionality to explore a large space of model structures".

In addition to the presentation of technical papers, we were very pleased to have the following distinguished invited speakers: Tom Mitchell (Carnegie Mellon University), Bill Macready (D-Wave systems), Pedro Felzenszwalb (Brown University), Alex Gray (Georgia Tech), and Judea Pearl (UCLA). Also, we were happy to have, as Banquet Speaker, Alison Gopnik (UC Berkeley).

UAI 2012 also hosted a tutorial day (organized by Irina Rish), covering the following topics: "Copulas in Machine learning" by Gal Elidan, "Determinantal point processes" by Alex Kulesza and Ben Taskar, "Graphical models for causal inference" by Karthika Mohan and Judea Pearl, and "Continuous-time Markov models" by Christian Shelton and Gianfranco Ciardo.

This year UAI also hosted a new series of one-day workshops (organized by Ruslan Salakhutdinov) covering the following topics: "Causal Structure Learning", "StarAI – Statistical Relational AI", "Uncertainty in Natural Intelligence", and "Bayesian Modeling Applications".

Nando de Freitas and Kevin Murphy (Program Co-Chairs)
Fabio Cozman (Conference Chair)
David Heckerman (Local Arrangements Chair)

Acknowledgements

The success of a rigorously reviewed conference hinges upon the diligent efforts of many parties. We assembled a Senior Program Committee and a Program Committee with internationally renowned experts in the range of specialties covered by UAI. At least three Program Committee members (or in some cases, auxiliary reviewers) reviewed each paper. Despite the time pressure imposed by rigid conference deadlines, these individuals did their best to supply balanced, fair, and helpful reviews to all authors of submitted papers. Our Program Committee did an outstanding job for which the program chairs and authors alike are quite grateful. The Senior Program Committee acted in a supervisory role, ensuring that paper reviews lived up to UAI standards, moderating discussion among Program Committee members and, ultimately, making recommendations to the program chairs. In some cases Senior Program Committee members wrote supplementary reviews or consulted outside experts to ensure that authors received fair and detailed feedback. We are extremely grateful for their efforts.

Other people who helped

A number of people have made significant contributions towards making UAI 2012 possible. We acknowledge and thank:

- David Heckerman for being local arrangements chair.
- Irina Rish for being tutorial chair.
- Ruslan Salakhutdinov for being workshop chair.
- Prakash Shenoy, for his help with the financial aspects of the conference.
- Teemu Ross, for crucial help in getting support from the Pascal2 Network.
- David Matheson, for his help in various matters, including creating the conference web site, producing the conference booklet, etc.
- Matt Hoffman, for his help in various matters, including the CMT review system, producing the conference proceedings, etc.

- Joelle Pineau, John Langford, and Mahdi Milani Fard for their advice on how to use the CMT paper matching system.
- Suming Chen and Elias Bareinboim, for their help with various matters.
- Laurent Charlin and Richard Zemel for their help with the paper matching process.

Sponsors

Finally, we gratefully acknowledge the generous support provided by our sponsors: Microsoft Research, Google Inc., Artificial Intelligence Journal, Pascal II Network of Excellence, Charles River Analytics, IBM Research.

Invited talks

Babies, brains and Bayes

Alison Gopnik

How do young children learn so much about the world so quickly and accurately? Many researchers have proposed that children implicitly formulate structured hypotheses about the world and then use evidence to test and revise those hypotheses. Ill describe extensive research has shown over the past ten years that even two-year-olds formulate causal hypotheses and test and evaluate them against the data in a normatively accurate way. But this work raises several problems. Where do those hypotheses come from? What algorithms could children implicitly use to approximate ideal Bayesian inference? How can we reconcile childrens striking inferential success with their apparent variability and irrationality? And are there developmental differences in the ways that children and adults learn?

I will suggest that all these questions can be illuminated by thinking about childrens hypothesis generation as a sampling process an idea with a long and successful history in computer science. Preschoolers may use sampling to generate hypotheses, and this may explain both their successful inferences and the variability in their behavior. In fact, in recent research we have discovered that childrens causal learning has some of the signatures of sampling. In particular, the variability in childrens responses reflects the probability of their hypotheses. Moreover, we have shown that children may use a particular type of sampling algorithm. We also found that preschoolers were actually more open-minded learners than older children and adults in some tasks. They seemed more likely to accept a wide range of novel hypotheses. This suggests that they may search at a higher temperature than adults do. From an evolutionary perspective the transition from childhood to adulthood may be natures way of performing simulated annealing.

Never ending learning

Tom Mitchell

We will never really understand machine learning until we can build machines that learn many different things, over years, and become better learners over time.

This talk describes our research to build a Never-Ending Language Learner (NELL) that runs 24 hours per day, forever, learning to read the web. Each day NELL extracts (reads) more facts from the web, and integrates these into its growing knowledge base of beliefs. Each day NELL also learns to read better than yesterday, enabling it to go back to the text it read yesterday, and extract more facts, more accurately. NELL has been running 24 hours/day for over two years now. The result so far is a collection of 15 million interconnected beliefs (e.g., servedWtih(coffee, applePie), isA(applePie, bakedGood)), that NELL is considering at different levels of confidence, along with hundreds of thousands of learned phrasings, morphoogical features, and web page structures that NELL uses to extract beliefs from the web. Track NELL's progress at http://rtw.ml.cmu.edu.

Quantum computing meets machine learning

Bill Macready

Quantum Computing offers the theoretical promise of dramatically faster computation through direct utilization of the underlying quantum aspects of reality. This idea, first proposed in the early 1980s, exploded in interest in 1994 with Peter Shor's discovery of a polynomial time integer factoring algorithm. Today the first experimental platforms realizing small-scale quantum algorithms are becoming commonplace. Interestingly, machine learning may be the killer app for quantum computing. We will introduce quantum algorithms, with focus on a recent quantum computational model that will be familiar to researchers with a background in graphical models. We will show how a particular quantum algorithm – quantum annealing – running on current quantum hardware can be applied to certain optimization problems arising in machine learning. In turn, we will describe a number of challenges to further progress in quantum computing, and suggest that machine learning researchers may be well-positioned to drive the first real-world applications of quantum annealing.

Graphical models for computer vision

Pedro Felzenszwalb

Graphical models provide a powerful framework for expressing and solving a variety of inference problems. The approach has had an enormous impact in computer vision. In this talk I will review some of the developments that have enabled this impact, focusing on efficient algorithms that exploit the structure of vision problems. I will discuss several applications including the low-level vision problem of image restoration, the mid-level problem of segmentation and the high-level problem of model-based recognition. I will also discuss some of the current challenges in the area.

Machine Learning on (Astronomically) Large Datasets

Alexander Gray

There is much talk of big data these days, surrounding a seismic shift currently underway in industry. Much of what is being discussed today is reminiscent of, and perhaps can be informed by, efforts beginning at least two decades ago in astronomy – which was forced into that pioneering position by some unique scientific constraints and motivating problems that we'll discuss. So what are the best ideas that have been developed over the years for doing machine learning on massive datasets? Toward scaling up the most popular textbook machine learning methods across seven basic types of statistical tasks, we'll first identify seven main types of computational bottlenecks. Then we'll consider seven cross-cutting classes of computational techniques which characterize the current fastest algorithms for these bottlenecks, discussing their strengths and weaknesses. We'll end with some exhortations regarding where more foundational research is needed.

Invited and Not-for-publication papers

The *Do*-Calculus Revisited
Judea Pearl
Keynote Lecture, August 17, 2012
UAI-2012 Conference, Catalina, CA

Abstract

The *do*-calculus was developed in 1995 to facilitate the identification of causal effects in non-parametric models. The completeness proofs of [Huang and Valtorta, 2006] and [Shpitser and Pearl, 2006] and the graphical criteria of [Tian and Shpitser, 2010] have laid this identification problem to rest. Recent explorations unveil the usefulness of the *do*-calculus in three additional areas: mediation analysis [Pearl, 2012], transportability [Pearl and Bareinboim, 2011] and meta-synthesis. Meta-synthesis (freshly coined) is the task of fusing empirical results from several diverse studies, conducted on heterogeneous populations and under different conditions, so as to synthesize an estimate of a causal relation in some target environment, potentially different from those under study. The talk surveys these results with emphasis on the challenges posed by meta-synthesis. For background material, see ⟨http://bayes.cs.ucla.edu/csl_papers.html⟩.

1 Introduction

Assuming readers are familiar with the basics of graphical models, I will start by reviewing the problem of nonparametric identification and how it was solved by the *do*-calculus and its derivatives. I will then show how the *do*-calculus benefits mediation analysis (Section 2) , transportability problems (Section 3) and meta-synthesis (Section 4).

1.1 Causal Models, interventions, and Identification

Definition 1. *(Structural Equation Model) [Pearl, 2000, p. 203].*
A structural equation model (SEM) M is defined as follows:

1. *A set U of background or exogenous variables, representing factors outside the model, which nevertheless affect relationship within the model.*
2. *A set $V = \{V_1, \ldots, V_n\}$ of observed endogenous variables, where each V_i is functionally dependent on a subset PA_i of $U \cup V \backslash \{V_i\}$.*
3. *A set F of functions $\{f_1, \ldots, f_n\}$ such that each f_i determines the value of $V_i \in V, v_i = f_i(pa_i, u)$.*
4. *A joint probability distribution $P(u)$ over U.*

When an instantiation $U = u$ is given, together with F, the model is said to be "completely specified" (at the unit level) when the pair $\langle P(u), F\rangle$ is given, the model is "fully specified" (at the population level). Each fully specified model defines a *causal diagram* G in which an arrow is drawn towards V_i from each member of its parent set PA_i.

Interventions and counterfactuals are defined through a mathematical operator called $do(x)$, which simulates physical interventions by deleting certain functions from the model, replacing them with a constant $X = x$, while keeping the rest of the model unchanged. The resulting model is denoted M_x.

The postintervention distribution resulting from the action $do(X = x)$ is given by the equation

$$P_M(y|do(x)) = P_{M_x}(y) \tag{1}$$

In words, in the framework of model M, the postintervention distribution of outcome Y is defined as the probability that model M_x assigns to each outcome level $Y = y$. From this distribution, which is readily computed from any fully specified model M, we are able to assess treatment efficacy by comparing aspects of this distribution at different levels of x. Counterfactuals are defined similarly through the equation $Y_x(u) = Y_{M_x}(u)$ (see [Pearl, 2009, Ch. 7]).

The following definition captures the requirement that a causal query Q be estimable from the data:

Definition 2. *(Identifiability) [Pearl, 2000, p. 77]. A causal query $Q(M)$ is identifiable, given a set of assumptions A, if for any two (fully specified) models M_1 and M_2 that satisfy A, we have*

$$P(M_1) = P(M_2) \Rightarrow Q(M_1) = Q(M_2) \qquad (2)$$

In words, the functional details of M_1 and M_2 do not matter; what matters is that the assumptions in A (e.g., those encoded in the diagram) would constrain the variability of those details in such a way that equality of Ps would entail equality of Qs. When this happens, Q depends on P only, and should therefore be expressible in terms of the parameters of P.

1.2 The Rules of *do*-calculus

When a query Q is given in the form of a *do*-expression, for example $Q = P(y|do(x), z)$, its identifiability can be decided systematically using an algebraic procedure known as the *do*-calculus [Pearl, 1995]. It consists of three inference rules that permit us to map interventional and observational distributions whenever certain conditions hold in the causal diagram G.

Let X, Y, Z, and W be arbitrary disjoint sets of nodes in a causal DAG G. We denote by $G_{\overline{X}}$ the graph obtained by deleting from G all arrows pointing to nodes in X. Likewise, we denote by $G_{\underline{X}}$ the graph obtained by deleting from G all arrows emerging from nodes in X. To represent the deletion of both incoming and outgoing arrows, we use the notation $G_{\overline{X}\underline{Z}}$.

The following three rules are valid for every interventional distribution compatible with G.

Rule 1 (Insertion/deletion of observations):

$$P(y|do(x), z, w) = P(y|do(x), w) \quad \text{if } (Y \perp\!\!\!\perp Z|X, W)_{G_{\overline{X}}} \qquad (3)$$

Rule 2 (Action/observation exchange):

$$P(y|do(x), do(z), w) = P(y|do(x), z, w) \quad \text{if } (Y \perp\!\!\!\perp Z|X, W)_{G_{\overline{X}\underline{Z}}} \qquad (4)$$

Rule 3 (Insertion/deletion of actions):

$$P(y|do(x), do(z), w) = P(y|do(x), w) \quad \text{if } (Y \perp\!\!\!\perp Z|X, W)_{\overline{XZ(W)}}, \qquad (5)$$

where $Z(W)$ is the set of Z-nodes that are not ancestors of any W-node in $G_{\overline{X}}$.

To establish identifiability of a query Q, one needs to repeatedly apply the rules of *do*-calculus to Q, until the final expression no longer contains a *do*-operator[1]; this renders it estimable from non-experimental data, and the final *do*-free expression can serve as an *estimator* of Q. The *do*-calculus was proven to be complete to the identifiability of causal effects [Shpitser and Pearl, 2006; Huang and Valtorta, 2006], which means that if the *do*-operations cannot be removed by repeated application of these three rules, Q is not identifiable.

Parallel works by [Tian and Pearl, 2002] and [Shpitser and Pearl, 2006] have led to graphical criteria for verifying the identifiability of Q as well as polynomial time algorithms for constructing an estimator of Q. This, from a mathematical viewpoint, closes the chapter of nonparametric identification of causal effects.

2 Using *do*-Calculus for Identifying Direct and Indirect Effects

Consider the mediation model in Fig. 1(a). (In this section, M stands for the mediating variable.) The *Controlled Direct Effect* (CDE) of X on Y is defined as

$$CDE(m) = E(Y|do(X = 1, M = m)) - E(Y|do(X = 0, M = m))$$

and the *Natural Direct Effect* (NDE) is defined by the counterfactual expression

$$NDE = E(Y_{X=1, M_{X=0}}) - E(Y_{X=0})$$

The natural direct effect represents the effect transmitted from X and Y while keeping some intermediate variable M at whatever level it attained prior to the transition [Robins and Greenland, 1992; Pearl, 2001].

Since CDE is a *do*-expression, its identification is fully characterized by the *do*-calculus. The NDE, however, is counterfactual and requires more intricate conditions, as shown in Pearl (2001). When translated to graphical language these conditions read:

Assumption-Set A [Pearl, 2001]

There exists a set W of measured covariates such that:

A-1 No member of W is a descendant of X.

A-2 W blocks all back-door paths from M to Y, disregarding the one through X.

A-3 The W-specific effect of X on M is identifiable using *do*-calculus.

[1] Such derivations are illustrated in graphical details in [Pearl, 2009, p. 87].

A-4 The W-specific joint effect of $\{X, M\}$ on Y is identifiable using *do*-calculus.

The bulk of the literature on mediation analysis has chosen to express identification conditions in the language of "ignorability" (i.e., independence among counterfactuals) which is rather opaque and has led to significant deviation from assumption set A.

A typical example of overly stringent conditions that can be found in the literature reads as follows:

> "Imai, Keele and Yamamoto (2010) showed that the sequential ignorability assumption must be satisfied in order to identify the average mediation effects. This key assumption implies that the treatment assignment is essentially random after adjusting for observed pretreatment covariates and that the assignment of mediator values is also essentially random once both observed treatment and the same set of observed pretreatment covariates are adjusted for." [Imai, Jo, and Stuart, 2011]

When translated to graphical representation, these conditions read:

Assumption-Set B

There exists a set W of measured covariates such that:

B-1 No member of W is a descendant of X.

B-2 W blocks all back-door paths from X to M.

B-3 W and X block all back-door paths from M to Y.

We see that assumption set A relaxes that in B in two ways.

First, we need not insist on using "the same set of observe pretreatment covariates," two separate sets can sometimes accomplish what the same set does not. Second, conditions A-3 and A-4 invoke *do*-calculus and thus open the door for identification criteria beyond back-door adjustment (as in B-2 and B-3).

In the sequel we will show that these two features endow A with greater identification power. (See also [Shpitser, 2012].)

2.1 Divide and conquer

Fig. 2 demonstrates how the "divide and conquer" flexibility translates into an increase identification power. Here, the $X \rightarrow M$ relationship requires an adjustment

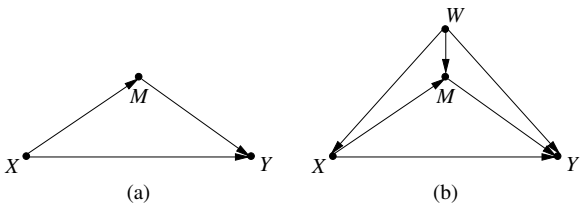

Figure 1: (a) The basic unconfounded mediation model, showing the treatment (X) mediator (M) and outcome (Y). (b) The mediator model with an added covariate (W) that confounds both the $X \rightarrow M$ and the $M \rightarrow Y$ relationships.

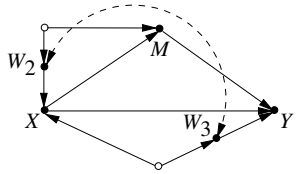

Figure 2: A mediation model with two dependent confounders, permitting the decomposition of Eq. (6). Hollow circles stand for unmeasured confounders. The model satisfies condition A but violates condition B.

for W_2, and the $X \rightarrow Y$ relationship requires an adjustment for W_3. If we make the two adjustments separately, we can identify NDE by the estimand:

$$NDE = \sum_m \sum_{w_2, w_3} P(W_2 = w_2, W_3 = w_3) \\ [E(Y \mid X = 1, M = m, W_3 = w_3)] \\ - [E(Y \mid X = 0, M = m, W_3 = w_3,)] \\ P(M = m \mid X = 0, W_2 = w_2) \qquad (6)$$

However, if we insist on adjusting for W_2 and W_3 simultaneously, as required by assumption set B, the $X \rightarrow M$ relationship would become confounded, by opening two colliders in tandem along the path $X \rightarrow W_3 \leftrightarrow W_2 \leftarrow M$. As a result, assumption set B would deem the NDE to be unidentifiable; there is no covariates set W that simultaneously deconfounds the two relationships.

2.2 Going beyond back-door adjustment

Figure 3 displays a model for which the natural direct effect achieves its identifiability through multi-step adjustment (in this case using the front-door procedure), permitted by A, though not through a single-step adjustment, as demanded by B. In this model, the null set $W = \{0\}$ satisfies conditions B-1 and B-3, but not condition B-2; there is no set of covariates that would enable us to deconfound the treatment-mediator relationship. Fortunately, condition A-3 requires only

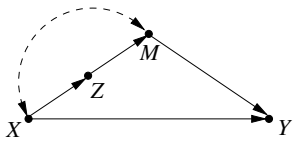

Figure 3: Measuring Z permits the identification of the effect of X on M through the front-door procedure.

that we identify the effect of X on M by *some* do-calculus method, not necessarily by rendering X random or unconfounded (or ignorable). The presence of observed variable Z permits us to identify this causal effect using the front-door condition [Pearl, 1995; 2009].

In Fig. 4, the front-door estimator needs to be applied to both the $X \rightarrow M$ and the $X \rightarrow Y$relationships. In addition, conditioning on W is necessary, in order to satisfy condition A-2. Still, the identification of $P(m|do(x), w)$ and $E(Y|do(m, x), w)$ presents no special problems to students of causal inference [Shpitser and Pearl, 2006].

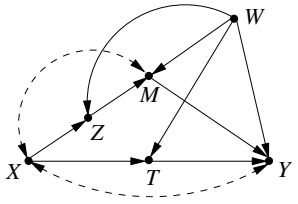

Figure 4: Measuring Z and T permits the identification of the effect of X on M and X on Y for each specific w and leads to the identification of the natural direct effect.

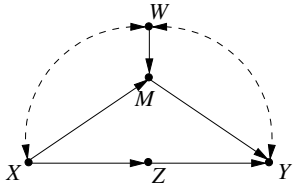

Figure 5: NDE is identified by adjusting for W and using Z to deconfound the $X \rightarrow Y$ relationship.

Figure 5, demonstrates the role that an observed covariate (Z) on the $X \rightarrow Y$ pathway can play in the identification of natural effects. In this model, conditioning on W deconfounds both the $M \rightarrow Y$ and $Y \rightarrow M$ relationships but confounds the $X \rightarrow Y$ relationship. However the W-specific joint effect of $\{X, M\}$ on Y is identifiable through observations on Z (using the front-door estimand).

In Fig. 6, a covariate Z situated along the path from M to Y leads to identifying NDE. Here the mediator$\rightarrow$ outcome relationship is unconfounded (once we fix X), so, we are at liberty to choose $W = \{0\}$ to satisfy condition A-2. The treatment$\rightarrow$ mediator relationship is confounded, and requires an adjustment for T (so does the treatment-outcome relationship). However, conditioning on T will confound the $\{MX\} \rightarrow Y$ relationship (in violation of condition A-4). Here, the presence of Z comes to our help, for it permits us to estimate $P(Y \mid do(x, m), t)$ thus rendering NDE identifiable.

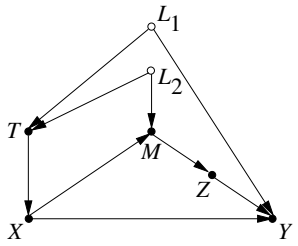

Figure 6: The confounding created by adjusting for T can be removed using measurement of Z.

3 Using *do*-Calculus to Decide Transportability

In applications involving identifiability, the role of the *do*-calculus is to remove the *do*-operator from the query expression. We now discuss a totally different application, to decide if experimental findings can be transported to a new, potentially different environment, where only passive observations can be perforemed. This problem, labeled "transportability" in [Pearl and Bareinboim, 2011] can also be reduced to syntactic operation using the *do*-calculus but here the aim will be to separate the *do*-operator from a set S of variables, that indicate disparities between the two environment.

We shall motivate the problem through the following three examples.

Example 1. *We conduct a randomized trial in Los Angeles (LA) and estimate the causal effect of exposure X on outcome Y for every age group $Z = z$ as depicted in Fig. 7(a). We now wish to generalize the results to the population of New York City (NYC), but data alert us to the fact that the study distribution $P(x, y, z)$ in LA is significantly different from the one in NYC (call the latter $P^*(x, y, z)$). In particular, we notice that the average age in NYC is significantly higher than that in LA. How are we to estimate the causal effect of X on Y in NYC, denoted $P^*(y|do(x))$.*

Example 2. *Let the variable Z in Example 1 stand for subjects language proficiency, and let us assume that*

Z does not affect exposure (X) or outcome (Y), yet it correlates with both, being a proxy for age which is not measured in either study (see Fig. 7(b)). Given the observed disparity $P(z) \neq P^*(z)$, how are we to estimate the causal effect $P^*(y|do(x))$ for the target population of NYC from the z-specific causal effect $P(y|do(x), z)$ estimated at the study population of LA?

Example 3. *Examine the case where Z is a X-dependent variable, say a disease bio-marker, standing on the causal pathways between X and Y as shown in Fig. 7(c). Assume further that the disparity $P(z) \neq P^*(z)$ is discovered in each level of X and that, again, both the average and the z-specific causal effect $P(y|do(x), z)$ are estimated in the LA experiment, for all levels of X and Z. Can we, based on information given, estimate the average (or z-specific) causal effect in the target population of NYC?*

To formalize problems of this sort, Pearl and Bareinboim devised a graphical representation called "selection diagrams" which encodes knowledge about differences between populations. It is defined as follows:

Definition 3. *(Selection Diagram).*
Let $\langle M, M^* \rangle$ be a pair of structural causal models (Definition 1) relative to domains $\langle \Pi, \Pi^* \rangle$, sharing a causal diagram G. $\langle M, M^* \rangle$ is said to induce a selection diagram D if D is constructed as follows:

1. *Every edge in G is also an edge in D;*
2. *D contains an extra edge $S_i \rightarrow V_i$ whenever there exists a discrepancy $f_i \neq f_i^*$ or $P(U_i) \neq P^*(U_i)$ between M and M^*.*

In summary, the S-variables locate the mechanisms where structural discrepancies between the two populations are suspected to take place. Alternatively, the absence of a selection node pointing to a variable represents the assumption that the mechanism responsible for assigning value to that variable is the same in the two populations, as shown in Fig. 7.

Using selection diagrams as the basic representational language, and harnessing the concepts of intervention, *do*-calculus, and identifiability (Section 1), we can now give the notion of transportability a formal definition.

Definition 4. *(Transportability)*
Let D be a selection diagram relative to domains $\langle \Pi, \Pi^* \rangle$. Let $\langle P, I \rangle$ be the pair of observational and interventional distributions of Π, and P^* be the observational distribution of Π^*. The causal relation $R(\Pi^*) = P^*(y|do(x), z)$ is said to be transportable from Π to Π^* in D if $R(\Pi^*)$ is uniquely computable from P, P^*, I in any model that induces D.

Theorem 1. *Let D be the selection diagram characterizing two populations, Π and Π^*, and S a set of selection variables in D. The relation $R = P^*(y|do(x), z)$ is transportable from Π to Π^* if the expression $P(y|do(x), z, s)$ is reducible, using the rules of do-calculus, to an expression in which S appears only as a conditioning variable in do-free terms.*

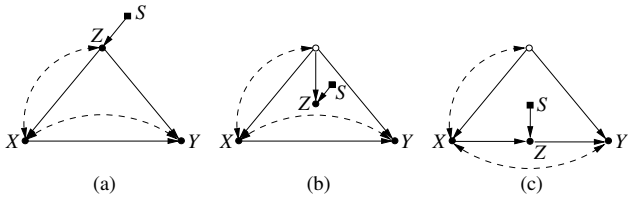

Figure 7: Selection diagrams depicting Examples 1–3. In (a) the two populations differ in age distributions. In (b) the populations differs in how Z depends on age (an unmeasured variable, represented by the hollow circle) and the age distributions are the same. In (c) the populations differ in how Z depends on X.

This criterion was proven to be both sufficient and necessary for causal effects, namely $R = P(y|do(x))$ [Bareinboim and Pearl, 2012b]. Theorem 1 does not specify the sequence of rules leading to the needed reduction when such a sequence exists. [Bareinboim and Pearl, 2012b] established a complete and effective graphical procedure of confirming transportability which also synthesizes the transport formula whenever possible. For example, the transport formulae derived for the three models in Fig. 7 are (respectively):

$$P^*(y|do(x)) = \sum_z P(y|do(x), z)P^*(z) \tag{7}$$

$$P^*(y|do(x)) = p(y|do(x)) \tag{8}$$

$$P^*(y|do(x)) = \sum_z P(y|z, x)P^*(z|x) \tag{9}$$

Each transport formula determines for the investigator what information need to be taken from the experimental and observational studies and how they ought to be combined to yield an unbiased estimate of R.

4 From "Meta-analysis" to "Meta-synthesis"

"Meta analysis" is a data fusion problem aimed at combining results from many experimental and observational studies, each conducted on a different population and under a different set of conditions, so as to synthesize an aggregate measure of effect size that is "better," in some sense, than any one study in isolation. This fusion problem has received enormous attention in the health and social sciences, where data are scarce and experiments are costly.

Unfortunately, current techniques of meta-analysis do little more than take weighted averages of the various studies, thus averaging apples and oranges to infer properties of bananas. One should be able to do better. Using "selection diagrams" to encode commonalities among studies, we should be able to "synthesize" an estimator that is guaranteed to provide unbiased estimate of the desired quantity based on information that each study share with the target environment. The basic idea is captured in the following definition and theorem.

Definition 5. *(Meta-identifiability):*
A relation R is said to be "meta-identifiable" from a set of populations $(\Pi_1, \Pi_2, \ldots, \Pi_K)$ to a target population Π^* iff it is identifiable from the information set $I = \{I(\Pi_1), I(\Pi_2), \ldots, I(\Pi_K), I(\Pi^*)\}$, where $I(\Pi_k)$ stands for the information provided by population Π_k.

Theorem 2. *(Meta-identifiability):*
Given a set of studies $\{\Pi_1, \Pi_2, \ldots, \Pi_K\}$ characterized by selection diagrams $\{D_1, D_2, \ldots, D_K\}$ relative to a target population Π^*, a relation $R(\Pi^*)$ is "meta-identifiable" if it can be decomposed into a set of subrelations of the form:

$$R_k = P(V_k|do(W_k), Z_k) \qquad k = 1, 2, \ldots, K$$

such that each R_k is transportable from some D_k.

Theorem 2 reduces the problem of Meta synthesis to a set of transportability problems, and calls for a systematic way of decomposing R to fit the information provided by I.

Exemplifying meta-synthesis

Consider the diagrams depicted in Fig. 8, each representing a study conducted on a different population and under a different set of conditions. Solid circles represent variables that were measured in the respective study and hollow circles variables that remained unmeasured. An arrow ■→ represents an external influence affecting a mechanism by which the study population is assumed to differ from the target population Π^*, shown in Fig. 8(a). For example, Fig. 8(c) represents an observational study on population Π_c in which variables X, Z and Y were measured, W was not measured and the prior probability $P_c(z)$ differs from that of the target population $P^*(z)$. Diagrams (b)–(f) represent observational studies while (g)–(j) stand for experimental studies with X randomized (hence the missing arrows into X).

Despite differences in populations, measurements and conditions, each of the studies may provide information that bears on the target relation $R(\Pi^*)$ which, in this example, we take to be the causal effect of X on Y, $P^*(y|do(x))$ or; given the structure of Fig. 8(a),

$$R(\Pi^*) = P^*(y|do(x)) = \sum_z P^*(y|x,z)P^*(z).$$

While $R(\Pi^*)$ can be estimated directly from some of the studies, (e.g., (g)) or indirectly from others (e.g., (b) and (d)), it cannot be estimated from those studies in which the population differs substantially from Π^*, (e.g., (c), (e), (f)). The estimates of R provided by the former studies may differ from each other due to sampling variations and measurement errors, and can be aggregated in the standard tradition of meta analysis. The latter studies, however, should not be averaged with the former, since they do not provide unbiased estimates of R. Still, they are not totally useless, for they can provide information that renders the former estimates more accurate. For example, although we cannot identify R from study 8(c), since $P_c(z)$ differs from the unknown $P^*(z)$, we can nevertheless use the estimates of $P_c(x|z), P_c(y|z,x)$ that 8(c) provides to improve the accuracy of $P^*(x|z)$ and $P^*(y|z,x)$[2] which may be needed for estimating R by indirect meth-

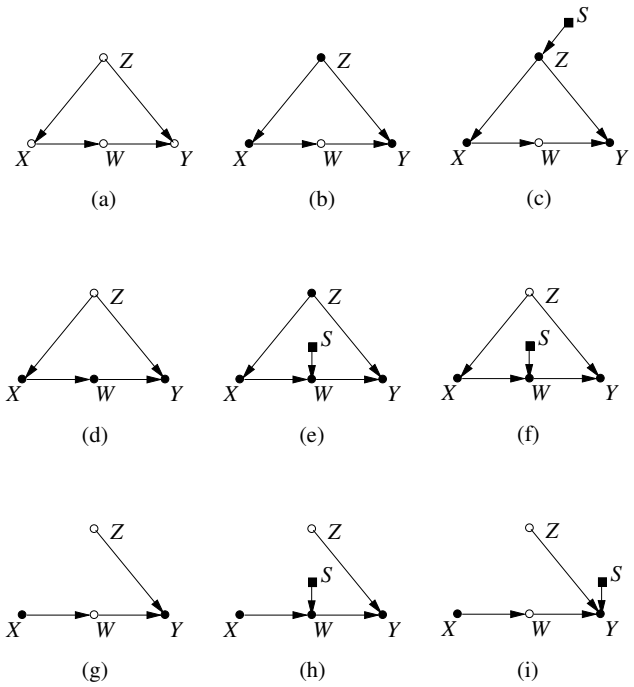

Figure 8: Diagrams representing 8 studies ((b)–(i)) conducted under different conditions on different populations, aiming to estimate the causal effect of X on Y in the target population, shown in 8(a).

[2]The absence of boxed arrows into X and Y in Fig. 8(c) implies the equalities

$$P_c(x|z) = P^*(x|z) \text{ and } P_c(y|z,x) = P^*(y|z,x).$$

ods. For example, $P^*(y|z,x)$ is needed in study 8(b) if we use the estimator $R = \sum_z P^*(y|x,z)P^*(z)$, while $P^*(x|z)$ is needed if we use the inverse probability estimator $R = \sum_z P^*(x,y,z)/P^*(x|z)$.

Similarly, consider the randomized studies depicted in 8(h) and 8(i). None is sufficient for identifying R in isolation yet, taken together, they permit us to borrow $P_i(w|do(x))$ from 8(i) and $P_h(y|w,do(x))$ from 8(h) and synthesize a bias-free estimator:

$$\begin{aligned} R &= \sum_w P^*(y|w,do(x))P^*(w|do(x)) \\ &= \sum_w P_h(y|w,do(x)P_i(w|do(x)) \end{aligned}$$

The challenge of meta synthesis is to take a collection of studies, annotated with their respective selection diagrams (as in Fig. 8), and construct an estimator of a specified relation $R(\Pi^*)$ that makes maximum use of the samples available, by exploiting the commonalities among the populations studied and the target population Π^*. As the relation $R(\Pi^*)$ changes, the synthesis strategy will change as well.

It is hard not to speculate that data-pooling strategies based on the principles outlined here will one day replace the blind methods currently used in meta analysis.

Knowledge-guided Domain Adaptation

It is commonly assumed that causal knowledge is necessary only when interventions are contemplated and that in purely predictive tasks, probabilistic knowledge suffices. When dealing with generalization across domains, however, causal knowledge can be valuable, and in fact necessary even in predictive or classification tasks.

The idea is simple; causal knowledge is essentially knowledge about the mechanisms that remain *invariant* under change. Suppose we learn a probability distribution $P(x,y,z)$ in one environment and we ask how this probability would change when we move to a new environment that differs slightly from the former. If we have knowledge of the causal mechanism generating P, we could then represent where we suspect the change to occur and channel all our computational resources to re-learn the local relationship that has changed or is likely to have changed, while keeping all other relationships invariant.

For example, assume that $P^*(x,y,z)$ is the probability distribution in the target environment and our interest lies in estimating $P^*(x|z)$ knowing that the causal diagram behind P is the chain $X \to Y \to Z$, and that the process determining Y, represented by $P^*(y|x)$, is the only one that changed. We can simply re-learn $P^*(y|x)$ and estimate our target relation $P^*(x|z)$ without measuring Z in the new environment. (This is done using $P^*(x,y,z) = P(x)P^*(y|x)P(z|y)$ with the first and third terms transported from the source environment.)

In complex problems, the savings gained by focusing on only a small subset of variables in P^* can be enormous, because any reduction in the number of measured variables translates into substantial reduction in the number of samples needed to achieve a given level of prediction accuracy.

As can be expected, for a given transported relation, the subset of variables that can be ignored in the target environment is not unique, and should therefore be chosen so as to minimize both measurement costs and sampling variability. This opens up a host of new theoretical questions about transportability in causal graphs. For example, deciding if a relation is transportable when we forbid measurement of a given subset of variables in P^* [Pearl and Bareinboim, 2011], or deciding how to pool studies optimally when sample size varies drastically from study to study [Pearl, 2012].

Conclusions

The *do*-calculus, which originated as a syntactic tool for identification problems, was shown to benefit three new areas of investigation. Its main power lies in reducing to syntactic manipulations complex problems concerning the estimability of causal relations under a variety of conditions.

In Section 2 we demonstrated that going beyond standard adjustment for covariates, and unleashing the full power of *do*-calculus, can lead to improved identification power of natural direct and indirect effects. Section 3 demonstrated how questions of transportability can be reduced to symbolic derivations in the *do*-calculus, yielding graph-based procedures for deciding whether causal effects in the target population can be inferred from experimental findings in the study population. When the answer is affirmative, the procedures further identify what experimental and observational findings need be obtained from the two populations, and how they can be combined to ensure bias-free transport.

In a related problem, Bareinboim and Pearl (2012b) show how the *do*-calculus can be used to decide whether the effect of X on Y can be estimated from experiments on a different set, Z, that is more accessible

to manipulations. Here the aim is to transform *do*-expressions to sentences that invoke only $do(z)$ symbols.

Finally, in Section 4, we tackled the problem of data fusion and showed that principled fusion (which we call meta-synthesis) can be reduced to a sequence of syntactic operations each involving a local transportability exercise. This task leaves many questions unsettled, because of the multiple ways a give relation can be decomposed.

Abstract

We present a set of high-probability inequalities that control the concentration of weighted averages of multiple (possibly uncountably many) simultaneously evolving and interdependent martingales. Our results extend the PAC-Bayesian analysis in learning theory from the i.i.d. setting to martingales opening the way for its application in reinforcement learning and other interactive learning domains, as well as many other domains in probability theory and statistics, where martingales are encountered.

We also present a comparison inequality that bounds the expectation of a convex function of a martingale difference sequence shifted to the $[0, 1]$ interval by the expectation of the same function of independent Bernoulli variables. This inequality is applied to derive a tighter analog of Hoeffding-Azuma's inequality.

For the complete paper see Seldin et al. (2012).

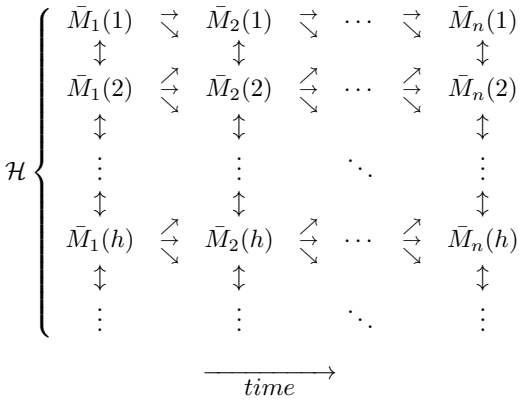

Figure 1: Illustration of an infinite set of simultaneously evolving and interdependent martingales. For a fixed h, the sequence $\bar{M}_1(h), \bar{M}_2(h), \ldots, \bar{M}_n(h)$ is a martingale. $\mathcal{H}$ is a set (possibly uncountably infinite) that indexes the individual martingales. The arrows represent the dependencies between the values of the martingales: the value of the h-th martingale at time i, denoted by $\bar{M}_i(h)$, depends on $\bar{M}_j(h')$ for all $j \leq i$ and $h' \in \mathcal{H}$ (everything that is "before" and "concurrent" with $\bar{M}_i(h)$ in time; some of the arrows are omitted for clarity). A mean value of the martingales with respect to a distribution ρ over $\mathcal{H}$ (or a probability density function, if $\mathcal{H}$ is uncountably infinite) is given by $\langle \bar{M}_n, \rho \rangle$. Our high-probability inequalities bound $|\langle \bar{M}_n, \rho \rangle|$ simultaneously for a large class of ρ.

Nested Markov Properties for Acyclic Directed Mixed Graphs

Ilya Shpitser
ishpitse@hsph.harvard.edu

Abstract

Directed acyclic graph (DAG) models may be characterized in four different ways: via a factorization, the d-separation criterion, the moralization criterion, and the local Markov property. As pointed out by Robins [2, 1], Verma and Pearl [6], and Tian and Pearl [5], marginals of DAG models also imply equality constraints that are not conditional independences. The well-known 'Verma constraint' is an example. Constraints of this type were used for testing edges [3], and an efficient variable elimination scheme [4]. Using acyclic directed mixed graphs (ADMGs) we provide a graphical characterization of the constraints given in [5] via a nested Markov property that uses a 'fixing' transformation on graphs. We give four characterizations of our nested model that are analogous to those given for DAGs. We show that marginal distributions of DAG models obey this property.

Abstract

This paper introduces a novel approach for learning to rank (LETOR) based on the notion of monotone retargeting. It involves minimizing a divergence between all monotonic increasing transformations of the training scores and a parameterized prediction function. The minimization is both over the transformations as well as over the parameters. It is applied to Bregman divergences, a large class of "distance like" functions that were recently shown to be the unique class that is statistically consistent with the normalized discounted gain (NDCG) criterion [19]. The algorithm uses alternating projection style updates, in which one set of simultaneous projections can be computed independent of the Bregman divergence and the other reduces to parameter estimation of a generalized linear model. This results in easily implemented, efficiently parallelizable algorithm for the LETOR task that enjoys global optimum guarantees under mild conditions. We present empirical results on benchmark datasets showing that this approach can outperform the state of the art NDCG consistent techniques.

1 Introduction

Structured output space models [1] have dominated the task of learning to rank (LETOR). Regression based models have been justifiably superseded by pairwise models [11], which in turn are being gradually displaced by list-wise approaches [6, 17]. This trend has on one hand greatly improved the quality of the predictions obtained but on the other hand has come at the cost of additional complexity and computation. The cost functions of structured models are often defined directly on the combinatorial space of permutations, which significantly increase the difficulty of learning and optimization compared to regression based approaches. We propose an approach to the LETOR task that retains the simplicity of the regression based models, is simple to implement, is embarrassingly parallelizable, and yet is a function of ordering alone. Furthermore, MR enjoys strong guarantees of convergence, statistical consistency under uncertainty and a global minimum under mild conditions. Our experiments on benchmark datasets show that the proposed approach outperforms state of the art models in terms of several common LETOR metrics.

We adapt regression to the LETOR task by using Bregman divergences and monotone retargeting (MR). MR is a novel technique that we introduce in the paper and Bregman divergences [5] are a family of "distance like" functions well studied in optimization [8], statistics and machine learning [2] due to their one to one connections with modeling uncertainty using exponential family distributions. Bregman divergences are the unique class of strongly statistically consistent surrogate cost functions for the NDCG criterion [19], a de facto standard of ranking quality. In addition to these statistical properties, Bregman divergences have several properties useful for optimization and specifically useful for ranking. The LETOR task decomposes into subproblems that are equivalent to estimating (unconstrained as well as constrained) generalized linear models. The Bregman divergence machinery provides easy to implement, scalable algorithms for them, with a user chosen level of granularity of parallelism. We hope the reader will appreciate the flexibility of choosing an appropriate divergence to encode desirable properties on the rankings while enjoying the strong guarantees that come with the family.

We introduce MR by first discussing direct regression of rank scores and highlighting its primary deficiency: its attempt to fit the scores exactly. An exact fit is unnecessary since any score that induces the correct ordering is sufficient. MR addresses this problem by searching for a order preserving transformation of the target scores that may be easier for the regressor to fit: hence the name "retargeting".

Let us briefly sketch our line of attack. In section 2 we

* Both authors contributed equally.

present a method to reduce the optimization over the infinite class of all monotonic increasing functions to that of alternating projection over a finite dimensional vector space. In section 3.2.3 we show when that optimization problem is jointly convex by resolving the question of joint convexity of the Fenchel-Young gap. This result is important in its own right. We introduce Bregman divergences in section 3 and discuss properties that make them particularly suited to the ranking task. We show (i) that one set of the alternating projections can be computed in a Bregman divergence independent fashion 3.2.1, and (ii) separable Bregman divergences allow us to use sorting 3.2.2 that would have otherwise required exhaustive combinatorial enumeration or solving a linear assignment problem repeatedly.

Notation: Vectors are denoted by bold lower case letters, matrices are capitalized. $\boldsymbol{x}^\dagger$ denotes the transpose of the vector $\boldsymbol{x}$, $||\boldsymbol{x}||$ denotes the L_2 norm. $\mathrm{Diag}(\boldsymbol{x})$ denotes a diagonal matrix with its diagonal set to the vector $\boldsymbol{x}$. $\text{Adj-Diff}(\boldsymbol{x})$ denotes a vector obtained by taking adjacent difference of consecutive components of $\left[\begin{smallmatrix}\boldsymbol{x}\\0\end{smallmatrix}\right]$. Thus $\text{Cum-Sum}(\text{Adj-Diff}(\boldsymbol{x})) = \boldsymbol{x}$. A vector $\boldsymbol{x}$ is defined to be in *descending order* if $x_i \geq x_j$ if $i > j$, the set of such vectors is denoted by $\mathcal{R}\!\downarrow$. Vector $\boldsymbol{x}$ is isotonic with $\boldsymbol{y}$ if $x_i \geq x_j$ then $y_i \geq y_j$. The unit simplex is denoted by Δ and the positive orthant by ${\mathbb{R}_+}^d$. $\psi(\cdot)$ is used to denote the Legendre dual of the function $\phi(\cdot)$. Partitions of sets are denoted by Π and P.

2 Monotone Retargeting

We introduce our formulation of learning to rank, this consists of a set of queries $\mathcal{Q} = \{q_1, q_i \ldots q_{|\mathcal{Q}|}\}$ and a set of items $\mathcal{V}$ that are to be ranked in the context of the queries. For every query q_i, there is a subset $\mathcal{V}_i \subset \mathcal{V}$ whose elements have been ordered, based on their relevance to the query. This ordering is customarily expressed via a rank score vector $\tilde{\boldsymbol{r}}_i \in \mathbb{R}^{d_i=|\mathcal{V}_i|}$ whose components $\tilde{r}_{ij}$ correspond to items in $\mathcal{V}_i$. Beyond establishing an order over the set $\mathcal{V}_i$, the actual values of $\tilde{r}_{ij}$ are of no significance. For a query q_i the index j of $\tilde{r}_{ij}$ is local to the set $\mathcal{V}_i$ hence $\tilde{r}_{ij}$ and $\tilde{r}_{kj}$ need not correspond to the same object. We shall further assume, with no loss in generality, that the subscript j is assigned such that $\tilde{r}_{ij}$ is in a descending order for any $\mathcal{V}_i$. Note that $\tilde{\boldsymbol{r}}_i$ induces a partial order if the number of unique values k_i in the vector is less than d_i.

For every query-object pair $\{q_i, v_{ij}\}$ a feature vector $\mathbb{R}^n \ni \boldsymbol{a}_{ij} = F(q_i, v_{ij})$ is pre-computed. The subset of training data pertinent to any query q_i is the pair $\{\tilde{\boldsymbol{r}}_i, \boldsymbol{A}_i\}$ and is called its qset. Thus, the column vector $\tilde{\boldsymbol{r}}_i$ consists of the rank-scores $\tilde{r}_{ij}$ and $\boldsymbol{A}_i$ is a matrix whose j^{th} row is ${\boldsymbol{a}_{ij}}^\dagger$.

Given a loss function $D_i : \mathbb{R}^{|\mathcal{V}_i|} \times \mathbb{R}^{|\mathcal{V}_i|} \mapsto \mathbb{R}_+$ we may define the regression problem $\min_{\boldsymbol{w}} \sum_i D(\tilde{\boldsymbol{r}}_i, f(\boldsymbol{A}_i, \boldsymbol{w}))$ where $f : \mathbb{R}^{|\mathcal{V}_i| \times n} \times \mathbb{R}^n \mapsto \mathbb{R}^{|\mathcal{V}_i|}$ is some fixed parametric form with the parameter $\boldsymbol{w}$. As discussed, this is unnecessarily stringent for ranking. A better alternative is:

$$\min_{\boldsymbol{w}, \boldsymbol{\Upsilon}_i \in \mathcal{M}} \sum_i D_i\big(\tilde{\boldsymbol{r}}_i, \boldsymbol{\Upsilon}_i \circ f(\boldsymbol{A}_i, \boldsymbol{w})\big),$$

where $\boldsymbol{\Upsilon}_i : \mathbb{R}^{|\mathcal{V}_i|} \mapsto \mathbb{R}^{|\mathcal{V}_i|}$ transforms the component of its argument by a fixed monotonic increasing function Υ_i, and $\mathcal{M}$ is the class of all such functions. Now $f(\boldsymbol{A}_i, \boldsymbol{w})$ no longer need to equal $\tilde{\boldsymbol{r}}_i$ point-wise to incur zero loss. It is sufficient for some monotonic increasing transform of $f(\boldsymbol{A}_i, \boldsymbol{w})$ to do so. With no loss in generality of modeling, we may apply the monotonic transform to $\tilde{\boldsymbol{r}}_i$ instead. This avoids the minimization over the function composition, but the need for minimizing over the set of all monotone functions remains. One possible way to eliminate the minimization over the function space is to restrict our attention to some parametric family in $\mathcal{M}$ at the expense of generality. Instead, with no loss in generality, the optimization over the infinite space of functions $\mathcal{M}$ can be converted into one over finite dimensional vector spaces $\mathbb{R}^{|\mathcal{V}_j|}$, provided we have a finite characterization of the constraint set $\mathcal{R}\!\downarrow_i$:

$$\min_{\boldsymbol{w}, \boldsymbol{r} \in \mathcal{R}\downarrow_i} \sum_i D_i(\boldsymbol{r}_i, f(\boldsymbol{A}_i, \boldsymbol{w})) \text{ s.t. } \mathcal{R}\!\downarrow_i = \{\boldsymbol{r}|^{\exists \boldsymbol{M} \in \mathcal{M}}_{\boldsymbol{M}(\tilde{\boldsymbol{r}}_i)=\boldsymbol{r}}\}. \tag{1}$$

The Set $\mathcal{R}\!\downarrow_i$: The convex composition $\boldsymbol{r} = \alpha \boldsymbol{r}_1 + (1-\alpha)\boldsymbol{r}_2$ of two isotonic vectors $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ preserves isotonicity, as does the scaling $\alpha \boldsymbol{r}_1$ for any $\alpha \in \mathbb{R}_+$. Hence the set $\mathcal{R}\!\downarrow_i$ is a convex cone. This makes the problem computationally tractable because the set can be described entirely by its extreme rays, or by the extreme rays of its polar. We claim the set $\mathcal{R}\!\downarrow_i$ can be expressed as the image of the set $\{\mathbb{R}_+\}^{|\mathcal{V}_i|-1} \times \mathbb{R}$ under a linear transformation by a particular upper triangular matrix U with positive entries:

$$\mathcal{R}\!\downarrow_i = U\boldsymbol{x} \quad \text{s.t.} \quad \boldsymbol{x} \in \{\mathbb{R}_+\}^{|\mathcal{V}_i|-1} \times \mathbb{R}$$

The matrix U is not unique and can be generated from any vector $\boldsymbol{v} \in {\mathbb{R}_+}^{|\mathcal{V}_i|}$, but as we shall see, any member from the allowed class of U is sufficient for a *exhaustive* representation of $\mathcal{R}\!\downarrow_i$.

Lemma 1. *The set of all vectors in $\mathbb{R}^d$ that are sorted in a descending order is given by $U\boldsymbol{x}$ s.t. $\boldsymbol{x} \in \{\mathbb{R}_+\}^{|\mathcal{V}_i|-1} \times \mathbb{R}$ where U is a triangular matrix generated from a vector $\boldsymbol{v} \in {\mathbb{R}_+}^d$ such that the i^{th} row $U(i,:)$ is $\{0\}^{i-1} \times \boldsymbol{v}(i:)$*

Proof. Consider solving $U\boldsymbol{x} = \tilde{\boldsymbol{r}}_i$ for any vector $\tilde{\boldsymbol{r}}_i$ sorted in descending order. We have $\boldsymbol{x} = (\mathrm{Diag})^{-1}(\boldsymbol{v}) \times \text{Adj-Diff}(\tilde{\boldsymbol{r}}_i)$ which is in $\{\mathbb{R}_+\}^{|\mathcal{V}_i|-1} \times \mathbb{R}$ □

For regression functions capable of fitting an arbitrary additive offset, no generality is lost by constraining the last component to be non-negative.

In addition to the set $\mathcal{R}\!\downarrow_i$ we shall make frequent use of the set of all discrete probability distributions that are in descending order, i.e. $\mathcal{R}\!\downarrow_i \cap \Delta_i$ that we represent by Δ_o^i.

We give a similar representation of this set by generating an upper triangular matrix T from the vector $\boldsymbol{v}_\Delta = \{1, \frac{1}{2}, \cdots \frac{1}{i} \cdots \frac{1}{d}\}$ and considering $\boldsymbol{x} \in \Delta$.

Lemma 2. *The set Δ_o of all discrete probability distributions of dimension d that are in descending order is the image $T\boldsymbol{x}$ s.t. $\boldsymbol{x} \in \Delta$ where T is an upper triangular matrix generated from the vector $\boldsymbol{v}_\Delta = \{1, \frac{1}{2} \cdots \frac{1}{d}\}$ such that $T(i,:) = \{0\}^{i-1} \times \boldsymbol{v}_\Delta(i:)$*

Proof. The proof follows Lemma (1). $T\boldsymbol{x}$ is in the simplex Δ because it is a convex combination of vectors in Δ. □

With appropriate choices of the distance like function $D_i(\cdot,\cdot)$ and the curve fitting function $f(\cdot,\cdot)$ we can transform (1) into a bi-convex optimization [1] problem over a product of convex sets. We choose $D_i(\cdot,\cdot)$ to be a Bregman divergence $D_\phi\big(\cdot\big|\big|\cdot\big)$, defined in Section 3.1, and $f(\boldsymbol{A}_i, \boldsymbol{w})$ to be $(\nabla\phi)^{-1}(\langle \boldsymbol{A}_i, \boldsymbol{w}\rangle)$, leading to the formulation:

$$\min_{\boldsymbol{w}\in\mathcal{W}, \boldsymbol{r}\in\mathcal{R}\downarrow_i} \sum_{i=1}^{|\mathcal{Q}|} \frac{1}{|\mathcal{V}_i|} D_{\boldsymbol{\phi}}\big(\boldsymbol{r}_i\big|\big|(\nabla\phi)^{-1}(\langle \boldsymbol{A}_i, \boldsymbol{w}\rangle)\big). \quad (2)$$

Coordinate-wise updates of (2) are equivalent to learning canonical GLMs under linear constraints for which scalable techniques are known [9]. The LETOR task has additional structure that allows more efficient solutions.

3 Background

We make heavy use of identities and algorithms associated with Bregman divergences, some that to the best of our knowledge are new e.g. Theorem 2, Lemmata 3, 4 and independent proof of Theorem 1. Theorem 2, and Lemmata 3, and 4 are particularly relevant to ranking. The purpose of this section is to collect these results in a single place.

3.1 Definitions

Bregman Divergence: Let $\boldsymbol{\phi} : \Theta \mapsto \mathbb{R},\ \Theta = \operatorname{dom}\boldsymbol{\phi} \subseteq \mathbb{R}^d$ be a strictly convex, closed function, differentiable on $\operatorname{int}\Theta$. The corresponding Bregman divergence $D_\phi\big(\cdot\big|\big|\cdot\big) : \operatorname{dom}(\boldsymbol{\phi}) \times \operatorname{int}(\operatorname{dom}(\boldsymbol{\phi})) \mapsto \mathbb{R}_+$ is defined as $D_\phi\big(\boldsymbol{x}\big|\big|\boldsymbol{y}\big) \triangleq \boldsymbol{\phi}(\boldsymbol{x}) - \boldsymbol{\phi}(\boldsymbol{y}) - \langle \boldsymbol{x}-\boldsymbol{y}, \nabla\boldsymbol{\phi}(\boldsymbol{y})\rangle$. From strict convexity it follows that $D_\phi\big(\boldsymbol{x}\big|\big|\boldsymbol{y}\big) \geq 0$ and $D_\phi\big(\boldsymbol{x}\big|\big|\boldsymbol{y}\big) = 0$ iff $\boldsymbol{x} = \boldsymbol{y}$. Bregman divergences are (strictly) convex in their first argument, but not necessarily convex in their second.

In this paper we only consider functions of the form $\boldsymbol{\phi}(\cdot) : \mathbb{R}^n \ni \boldsymbol{x} \mapsto \sum_i w_i\phi(x_i)$ that are weighted sums of *identical* scalar convex functions applied to each component. We refer to this class as *weighted, identically separable* (**WIS**) or simply **IS** if the weights are equal. This class has properties particularly suited to ranking. Mahalonobis distance with diagonal W, weighted KL divergence $wKL(\boldsymbol{x}\|\boldsymbol{y})$ and weighted and shifted generalized I-divergence $wGI(\boldsymbol{x}\|\boldsymbol{y})$ are in this family (Table 1).

[1] A biconvex function is a function of two arguments such that with any one of its argument fixed the function is convex in the other argument.

$\boldsymbol{\phi}(\boldsymbol{x})$	$D_\phi\big(\boldsymbol{x}\big\|\big\|\boldsymbol{y}\big)$
$\frac{1}{2}\|\|\boldsymbol{x}\|\|^2_W$	$\frac{1}{2}\|\|\boldsymbol{x}-\boldsymbol{y}\|\|^2_W$
$\sum_i w_i x_i \log x_i\ \boldsymbol{x} \in \Delta$	$wKL(\boldsymbol{x}\|\boldsymbol{y}) = \sum_i w_i x_i \log(\frac{x_i}{y_i})$
$\sum_i w_i(x_i \log x_i - x_i)$ $\boldsymbol{x} \in \mathbb{R}_+{}^d$	$wGI(\boldsymbol{x}\|\boldsymbol{y})$ $= \sum_i w_i\big((x_i-1)\log(\frac{x_i-1}{y_i-1}) - x_i + y_i\big)$

Table 1: Examples of WIS Bregman divergences.

Bregman Projection: Given a closed convex set $\mathcal{S}$, the Bregman-projection of $\boldsymbol{q}$ on $\mathcal{S}$ is $\operatorname{Proj}^\phi(q,\mathcal{S}) \triangleq \operatorname{Argmin}_{\boldsymbol{p}} D_\phi\big(\boldsymbol{p}\big|\big|\boldsymbol{q}\big)\ \boldsymbol{p} \in S$.

A function $\phi(\cdot)$ has **modulus of strong convexity** s if $\phi(\alpha\boldsymbol{x}+(1-\alpha)\boldsymbol{y}) \leq \alpha\phi(\boldsymbol{x})+(1-\alpha)\phi(\boldsymbol{y}) - \frac{s}{2}\alpha(1-\alpha)||\boldsymbol{x}-\boldsymbol{y}||^2$. For a twice differentiable $\phi(\boldsymbol{x})$ this means that eigenvalues of its Hessian are lower bounded by s.

The **Legendre conjugate** $\psi(\cdot)$ of the function $\phi(\cdot)$ is defined as $(\phi)^*(\boldsymbol{x}) \triangleq \psi(\boldsymbol{x}) \triangleq \sup_{\boldsymbol{\lambda}}(\langle\boldsymbol{\lambda},\boldsymbol{x}\rangle - \phi(\boldsymbol{\lambda}))$. If $\phi(\cdot)$ is a convex function of Legendre type [21], as will always be the case in this paper, $\big((\phi)^*\big)^*(\cdot) = \phi(\cdot)$ and $(\nabla\phi(\cdot))^{-1} = \nabla\psi(\cdot)$ is a one to one mapping.

The **Fenchel-Young** inequality (3) is fundamental to convex analysis and plays an important role in our analysis.

$$\psi(\boldsymbol{y}) + \phi(\boldsymbol{x}) - \langle\boldsymbol{y},\boldsymbol{x}\rangle \geq 0. \quad (3)$$

3.2 Properties

The convexity of (2) in $\boldsymbol{r}$ and $\boldsymbol{w}$ (separately) can be proven by verifying the identity (by evaluating its LHS):

$$D_\psi\big(\nabla\phi(\boldsymbol{y})\big|\big|\nabla\phi(\boldsymbol{x})\big) = D_\phi\big(\boldsymbol{x}\big|\big|\boldsymbol{y}\big). \quad (4)$$

3.2.1 Universality Of Minimizers

A mean-variance like decomposition (described in the appendix, Theorem (3)) holds for all Bregman divergences. It plays a critical role in Theorem 1 that has significant impact in facilitating the solution of the LETOR problem.

Theorem 1. *For $\mathcal{R}\downarrow\ \subset\ \mathbb{R}^d$ the entire set of vectors with descending ordered components, the minimizer $\boldsymbol{y}^* = \operatorname{Argmin}_{\boldsymbol{y}\in\mathcal{R}\downarrow} D_\phi\big(\boldsymbol{x}\big|\big|\boldsymbol{y}\big)$ is independent of $\boldsymbol{\phi}(\cdot)$ if $\boldsymbol{\phi}(\cdot)$ is WIS.*

Proof: sketched in the appendix.

Following our independent proof of Theorem 1, we have since come across an older proof [20] in the context of maximum likelihood estimators of exponential family models under conic constraints that were developed prior to the

popularity of Bregman divergences. Whereas the older proof uses Moreau's cone decomposition[21], ours uses Theorem 3 (in appendix) and yields a much shorter proof.

Corrolary 1. *If* $\operatorname{dom}\psi(\cdot) = \mathbb{R}^d$ *where* $\psi(\cdot)$*is the Legendre conjugate of the WIS convex function* $\boldsymbol{\phi}(\cdot)$ *then* $\operatorname{Argmin}_{\boldsymbol{y}\in\mathcal{R}\downarrow\cap\operatorname{dom}\phi} D_\phi\big(\boldsymbol{y}\big|\big|(\nabla\phi)^{-1}(\boldsymbol{x})\big) = (\nabla\boldsymbol{\phi})^{-1}(\boldsymbol{y}^*)$ *where* $\boldsymbol{y}^* = \operatorname{Argmin}_{\boldsymbol{y}\in\mathcal{R}\downarrow} ||\boldsymbol{x}-\boldsymbol{y}||^2$.

Corollary (1) implies that for choices of convex function $\boldsymbol{\phi}(\cdot)$ indicated, the minimization over $\boldsymbol{r}_i \in \mathcal{R}\downarrow \cap \operatorname{dom}\boldsymbol{\phi}$ can be obtained by transforming the equivalent squared loss minimizer by $(\nabla\boldsymbol{\phi})^{-1}(\cdot)$. The squared loss minimization is not only simpler but its implementation can now be shared across all different $\boldsymbol{\phi}(\cdot)$s where Corollary 1 applies. This class of convex functions is the same as "essentially smooth" [21]. Three such functions are listed in Table 1.

3.2.2 Optimality of Sorting

For any sorted vector $\boldsymbol{x}$, finding the permutation of $\boldsymbol{y}$ that minimizes $D_\phi\big(\boldsymbol{x}\big|\big|\boldsymbol{y}\big)$ shows up as a subproblem in our formulation that needs to be solved in an inner loop. Thus solving it efficiently is critical and this is yet another instance where Bregman divergences are very useful.

For an arbitrary divergence function the search over the optimal permutation is a *non-linear assignment* problem that can be solved only by exhaustive enumeration. For an arbitrary separable divergence the optimal permutation may be found by solving a linear assignment problem, which is an integer linear program and hence also expensive to solve (especially in an inner loop, as required in our algorithm).

On the other hand, if $\boldsymbol{\phi}(\cdot)$ is IS, the solution is remarkably simple, as shown in Lemma 3 where $\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]$ denotes a vector in $\mathbb{R}^2$ with components x_1 and x_2.

Lemma 3. *If* $x_1 \geq x_2$ *and* $y_1 \geq y_2$ *and* $\boldsymbol{\phi}(\cdot)$ *is IS, then* $D_\phi\big(\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]\big|\big|\left[\begin{smallmatrix}\boldsymbol{y}_1\\ \boldsymbol{y}_2\end{smallmatrix}\right]\big) \leq D_\phi\big(\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]\big|\big|\left[\begin{smallmatrix}\boldsymbol{y}_2\\ \boldsymbol{y}_1\end{smallmatrix}\right]\big)$ *and* $D_\phi\big(\left[\begin{smallmatrix}\boldsymbol{y}_1\\ \boldsymbol{y}_2\end{smallmatrix}\right]\big|\big|\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]\big) \leq D_\phi\big(\left[\begin{smallmatrix}\boldsymbol{y}_2\\ \boldsymbol{y}_1\end{smallmatrix}\right]\big|\big|\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]\big)$

Proof.
$D_\phi\big(\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]\big|\big|\left[\begin{smallmatrix}\boldsymbol{y}_1\\ \boldsymbol{y}_2\end{smallmatrix}\right]\big) - D_\phi\big(\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]\big|\big|\left[\begin{smallmatrix}\boldsymbol{y}_2\\ \boldsymbol{y}_1\end{smallmatrix}\right]\big) = \langle(\nabla\phi(y_2) - \nabla\phi(y_1)), x_1 - x_2\rangle\,.$
There exists $c \geq 0$ s.t. $x_1 - x_2 = c(y_1 - y_2)$. Proof follows from monotonicity of $\nabla\phi$, ensured by convexity of ϕ. We can exchange the order of the arguments using (4). □

Using induction over d for $\boldsymbol{y} \in \mathbb{R}^d$ the optimal permutation is obtained by sorting. Not only is Lemma 3 extremely helpful in generating descent updates, it has fundamental consequences in relation to the local and global optimum of our formulation (see Lemma 4).

3.2.3 Joint Convexity and Global Minimum

Using Legendre duality one recognizes that equation (2) quantifies the gap in the Fenchel-Young inequality (3).

$$D_{\boldsymbol{\phi}}\big(\boldsymbol{r}_i\big|\big|(\nabla\phi)^{-1}\left(\boldsymbol{A}_i\boldsymbol{w}\right)\big) = \psi(\boldsymbol{A}_i\boldsymbol{w}) + \phi(\boldsymbol{r}_i) - \langle\boldsymbol{r}_i, \boldsymbol{A}_i\boldsymbol{w}\rangle\,.$$

Although this clarifies the issue of separate convexity in $\boldsymbol{w}$ and $\boldsymbol{r}_i$, the conditions under which joint convexity is obtained is not obvious. Joint convexity, if ensured, guarantees global minimum even for a coordinate-wise minimization because our constraint set is a product of convex sets. We resolve this important question in Theorem 2.

Theorem 2. *The gap in the Fenchel-Young inequality* $\psi(\boldsymbol{y}) + \phi(\boldsymbol{x}) - \langle\boldsymbol{x}, \boldsymbol{w}\rangle$ *for any twice differentiable strictly convex* $\phi(\cdot)$ *with a differentiable conjugate* $(\phi)^*(\cdot) = \psi(\cdot)$ *is jointly convex if and only if* $\phi(\boldsymbol{x}) = c||\boldsymbol{x}||^2$ *for all* $c > 0$.

Proof: sketched in the appendix.

3.3 Algorithms

Now we discuss Bregman's algorithm associated with Bregman divergences. The original motivation for introducing [5] Bregman divergence was to generalize alternating orthogonal projection. A significant advantage of the algorithm is its scalability and suitability for parallelization. It solves the following (Bregman projection) problem:

$$\min_{\boldsymbol{x}} D_\phi\big(\boldsymbol{x}\big|\big|\boldsymbol{y}\big) \text{ s.t. } \boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b} \tag{5}$$

Bregman's algorithm:

Initialize: $\boldsymbol{\lambda}^0 \in \mathbb{R}+^d$ and z^0 such that
$\nabla\phi(z^0) = \left[\boldsymbol{A}^\dagger|\nabla\phi(\boldsymbol{y})\right]\left[\boldsymbol{\lambda}^{0\dagger}, 1\right]^\dagger$

Repeat: Till convergence

Update: Apply **Sequential** or **Parallel Update**

Solve: $\nabla\phi(z^{t+1}) = \left[\boldsymbol{A}^\dagger|\nabla\phi(\boldsymbol{y})\right]\left[\boldsymbol{\lambda}^{t+1\dagger}, 1\right]^\dagger$

Sequential Bregman Update:

Select i: Let $\mathcal{H}_i = \{\boldsymbol{z}|\,\langle\boldsymbol{a}_i, \boldsymbol{z}\rangle \leq b_i\}$

If in violation: Compute $\operatorname{Proj}^\phi\left(\boldsymbol{z}^t, \mathcal{H}_i\right)$ i.e.
$\nabla\phi(\operatorname{Proj}^\phi\left(\boldsymbol{z}^t, \mathcal{H}_i\right)) = \nabla\phi(\boldsymbol{z}^t) + c_i^t\boldsymbol{a}_i,$

Update: $\boldsymbol{\lambda}^{t+1} = \boldsymbol{\lambda}^t + c_i^t\mathbf{1}_i$

Parallel Bregman Update:

For all i **in parallel:** Compute $\operatorname{Proj}^\phi\left(\boldsymbol{z}^t, \mathcal{H}_i\right), c_i^t$

Update: $\boldsymbol{\lambda}_i^{t+1} = \boldsymbol{\lambda}^t + c_i^t\mathbf{1}_i$

Synchronize: $\boldsymbol{\lambda}^{t+1} = \nabla^{-1}\phi(\sum_i \nabla\phi(\boldsymbol{\lambda_i}^{t+1}))$

4 LETOR with Monotone Retargeting

Our cost function is an instantiation of (2) with a WIS Bregman divergence. In addition, we include regularization and a query specific offset. Note that the cost function (2) is not invariant to scale. For example squared Euclidean, KL

divergence and generalized I-divergence are homogeneous functions of degree 2, 1 and 1 respectively. Thus the cost can be reduced just by scaling its arguments down, without actually learning the task. To remedy this, we restrict the $\boldsymbol{r}_i$s from shrinking below a pre-prescribed size. This is accomplished by constraining $\boldsymbol{r}_i$s to lie in an appropriate closed convex set separated from the origin, for example, an unit simplex or a shifted positive orthant. This yields:

$$\min_{\beta_i,\boldsymbol{w},\boldsymbol{r}_i\in\mathcal{R}\downarrow_i\cap\mathcal{S}_i}\sum_{i=1}^{|\mathcal{Q}|}\frac{1}{|\mathcal{V}_i|}D_{\boldsymbol{\phi}}\big(\boldsymbol{r}_i\Big|\Big|(\nabla\phi)^{-1}\left(\boldsymbol{A}_i\boldsymbol{w}+\beta_i\mathbf{1}\right)\big)+\frac{C}{2}||\boldsymbol{w}||^2, \quad (6)$$

or equivalently

$$\min_{\beta_i,\boldsymbol{w},\boldsymbol{r}_i\in\mathcal{R}\downarrow_i\cap\mathcal{S}_i}\sum_{i=1}^{|\mathcal{Q}|}\frac{1}{|\mathcal{V}_i|}D_{\boldsymbol{\psi}}\big(\boldsymbol{A}_i\boldsymbol{w}+\beta_i\mathbf{1}\Big|\Big|\nabla\phi\left(\boldsymbol{r}_i\right)\big)+\frac{C}{2}||\boldsymbol{w}||^2, \quad (7)$$

where $\mathcal{S}_i$ are bounded sets excluding $\mathbf{0}$, chosen to suit the divergence. The parameter C is the regularization parameter. In non-transductive settings, the query specific offsets β_i will not be available for the test queries. This causes no difficulty because β_i does not affect the relative ranks over the documents. We update the $\boldsymbol{r}_i$'s and $\{\boldsymbol{w},\{\beta_i\}\}$ alternately. Note that each is a Bregman projection.

If $\mathcal{S}_i=\operatorname{dom}\boldsymbol{\phi}$ and $\operatorname{dom}\boldsymbol{\psi}=\mathbb{R}^d$, the optimization over $\boldsymbol{r}_i$ reduces to an order constrained least squares problem (corrolary-1). Examples of such matched pairs are (i) $wKL\left(\cdot\|\cdot\right)$ and Δ_i, and (ii) shifted $wGI\left(\cdot\|\cdot\right)$ and $\mathbf{1}+{\mathbb{R}_+}^d$. A well studied, scalable algorithm for the ordered least squares problem is pool of adjacent violators (PAV) algorithm [3]. One can verify that PAV, like Bregman's algorithm (5) is a dual feasible method. One may also use Lemma 1 to solve it as a non-negative least squares problem for which several scalable algorithm exists [15].

To be able to use Bregman's algorithm it is essential that $\mathcal{R}\downarrow_i$ be available as an intersection of linear constraints, as is readily obtained for any prescribed total order, as shown:

$$\mathcal{R}\downarrow_i=\{r_{i,j+1}-r_{i,j}\leq 0\}_{\forall j\in\mathcal{J}_i},$$
$$\Delta_i^o=\mathcal{R}\downarrow_i\cap\{\sum_j r_{ij}=1\}\cap\{r_{i,d_i}>0\}. \quad (8)$$

Partial orders are discussed in section 4.1.

The advantages of the Bregman updates (3.3), are that they are easy to implement (more so when $\operatorname{Proj}^{\phi}\left(\cdot,\cdot\right)$ is available in closed form e.g. squared Euclidean), have minimal memory requirements, and hence they scale readily and allow easy switch from a sequential to a parallel update.

The parallel Bregman updates applied to (2), (8) clearly exposes massive amounts of fine grained parallelism at the level of individual inequalities in $\mathcal{R}\downarrow_i$ or Δ_i^o, and is well suited for implementation on a GPGPU[18]. We note further that the optimization for $\boldsymbol{r}_i$ is independent for each query, thus can be embarrassingly parallelized.

For optimizing over $\boldsymbol{w}$ one may use several techniques available for parallelizing a sum of convex functions, for example parallelize the gradient computation across the terms or use more specialized technique such as alternating direction of multipliers [4]. Further, $\{\boldsymbol{w},\{\beta_i\}\}$ can be solved jointly simply by augmenting the feature matrix $\boldsymbol{A}_i$ with $\mathbf{1}$. We hope the readers will appreciate this flexibility of being able to exploit parallelism at different levels of granularity of choice.

4.1 Partial Order

Recall that a partial order is induced if the number of unique rank scores k_i in $\tilde{\boldsymbol{r}_i}$ is less than d_i. In this case our convention of indexing $\mathcal{V}_i$ in a descending order is ambiguous. To resolve this, we break ties arbitrarily. Consider a subset of $\mathcal{V}_i$ whose elements have the same training rank-score. We distinguish between two modeling choices: (a) the items in that subset are not really equivalent, but the training set used a resolution that could not make fine distinctions between the items,[2] we call this the "hidden order" case, and (b) the items in the subset are indeed equivalent and the targets are constrained to reflect the same block structure, we call this case "block equivalent" and can model it appropriately. Although we have removed the discussion on the latter in the interest of space, this too can be modeled efficiently by MR.

4.1.1 Partially Hidden Order

In this model we assume that the items are totally ordered, though the finer ordering between similar items is not visible to the ranking algorithm. Let $P_i=\{P_{ik}\}_{k=1}^{k_i}$ be a partition of the index set of $\mathcal{V}_i$, such that all items in P_{ik} have the same training rank-score. We denote their sizes by $d_{ik}=|P_{ik}|$. The sets $\mathcal{V}_i$ effectively get partitioned further into $\{P_{ik}\}_{k=1}^{k_i}$ by the $k_i<d_i$ unique scores given to each of its members. Though such a score specifies an order between items from any two different sets P_{ij} and P_{il}, the order within any set P_{ik} remains unknown. This is very common in practice and is usually an artifact of the high cost of acquiring training data in a totally ordered form. The optimization problem may be solved using either an inner or an outer representation of the constraint sets.

Outer representation: Recall that Bregman's algorithm 3.3 is better suited for the outer representation (8).

Denote the set of rank-score vectors having the same partially ordered structure as $\tilde{\boldsymbol{r}_i}$ by $\mathfrak{R}_i$. For partial order we may describe $\mathfrak{R}_i$ by linear inequalities as follows:

$$\{r_{im}>r_{in}\}_{j=1}^{k_i-1}\forall_{i\in[1,|\mathcal{Q}|]},\ m\in P_{ij},\ n\in P_{i,j+1},$$

with each j generating $d_{ij}d_{i,j+1}$ inequalities, which is very high. The proliferation of inequalities may be reduced by

[2] or that, we only care to reduce the error of predicting $r_{ij}>r_{ik}$ when $\tilde{r}_{ij}<\tilde{r}_{ik}$, note the strict inequality.

$$\boldsymbol{x}_i^{t+1} = \underset{\boldsymbol{x}\in\Delta}{\text{Argmin}}\, D_{\boldsymbol{\phi}}\left(T\boldsymbol{x}\middle|\middle|(\nabla\phi)^{-1}\left(\mathbb{P}_i^t\boldsymbol{A}_i\boldsymbol{w}^t+\beta_i^t\right)\right)\ \ \forall i \tag{10}$$

$$\mathbb{P}_i^{t+1} = \underset{\pi}{\text{Argmin}}\, D_{\boldsymbol{\phi}}\left(T\boldsymbol{x}_i^{t+1}\middle|\middle|(\nabla\phi)^{-1}\left(\pi\boldsymbol{A}_i\boldsymbol{w}^t+\beta_i^t\right)\right)\ \ \forall i \tag{11}$$

$$\boldsymbol{w}^{t+1}, \{\beta_i^{t+1}\} = \tag{12}$$
$$\underset{\boldsymbol{w},\{\beta_i\}}{\text{Argmin}} \sum_{i=1}^{|\mathcal{Q}|} D_{\boldsymbol{\phi}}\left(T\boldsymbol{x}^{t_i+1}\middle|\middle|(\nabla\phi)^{-1}\left(\mathbb{P}_i^{t+1}\boldsymbol{A}_i\boldsymbol{w}+\beta_i^t\right)\right)+\frac{C}{2}||\boldsymbol{w}||^2$$

Figure 1: Algorithm for Partially Hidden Order

introducing auxiliary variables $\{\bar{r}_{i,l}\}_{l=1}^{k_i-1}$ and the following inequalities:

$$\{\bar{r}_{i,j+1} > r_{iP_{ij}} > \bar{r}_{i,j}\}\forall_{i\in[1,|\mathcal{Q}|]}. \tag{9}$$

However, since Bregman's algorithms are essentially coordinate-wise ascent methods, their convergence may slow unless fine grained parallelism can be exploited. For commodity hardware, an alternative to the exterior point methods are interior point methods that use an inner representation of the convex constraint set.

Inner representation: For our experiments we use the updates in figure 1. In particular, we use the method of D proximal gradients for (10) where the proximal term is a Bregman divergence defined by a convex function whose domain is the required constraint set [13], [22], [16]. This automatically enforces the required constraints.

To handle partial order we introduce a block-diagonally restricted permutation matrix $\mathbb{P}_i$ that can permute indices in each P_{ij} independently. Since the items in P_{ij} are not equivalent they are available for re-ordering as long as that minimizes the cost (6). Block weighted IS Bregman divergences have the special property that sorting minimizes the divergence over all permutations (Lemma 3). Thus update (11) can be accomplished by sorting.

The updates (10), (11) and (12) each reduce the lower bounded cost (6), and therefore the algorithm described in figure 1 converges. However, the vital question about whether the updates converge to a stationary point remains.

Convergence to a Stationary Point If repeated application of (10) and (11) (sorting) for a fixed $\boldsymbol{w}^{t+1}, \{\beta_i^{t+1}\}$ achieves the minimum then convergence to the stationary point is guaranteed. Thus we explore the question whether (11) and (10) together achieves a local minimum.

The tri-factored form $\boldsymbol{r}_i\mathbb{P}_iU\boldsymbol{x}_i$ is a cause for concern. Somewhat re-assuring is the fact that the range of $\mathbb{P}_iU\boldsymbol{x}_i$ is $\mathfrak{R}_i$ which again is a convex cone and that the tri-factored representation of any point in that cone is described uniquely. This however is not sufficient to ensure that a minimum is achieved by (10) and (11) because though the constraint set is convex, the cost function (6) is not convex in the tri-factored parameterization. Worse still, the parameterization is discontinuous because of the discrete nature of $\mathbb{P}$.

While one may address the discreteness problem via a real-relaxation of $\mathbb{P}$ to doubly stochastic matrices, the local minima attained in such a case will be in the interior of the Birkhoff polytope and not at the vertices that (11) sorting would have obtained. Therefore such a convex relaxation cannot answer the question whether (10) and sorting achieves the local minimum. Thus it is surprising that sorting followed by the $\boldsymbol{x}_i$ updates does achieve the local minimum of (6) on the cone $\mathfrak{R}_i$, as a consequence of the following Lemma.

Lemma 4. *Let vectors* $\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]$ *and* $\left[\begin{smallmatrix}\boldsymbol{y}_1\\ \boldsymbol{y}_2\end{smallmatrix}\right]$ *be conformally partitioned. Let* $\left[\begin{smallmatrix}\boldsymbol{y}_1\\ \boldsymbol{y}_2\end{smallmatrix}\right]^* = \underset{\boldsymbol{y}_i'\in\Pi(\boldsymbol{y}_1),\ \boldsymbol{y}_1'\geq\boldsymbol{y}_2'}{\text{Argmin}} D_\phi\left(\left[\begin{smallmatrix}\boldsymbol{y}'_1\\ \boldsymbol{y}'_2\end{smallmatrix}\right]\middle|\middle|\left[\begin{smallmatrix}\boldsymbol{x}_1\\ \boldsymbol{x}_2\end{smallmatrix}\right]\right)$ *where* $\Pi(\boldsymbol{y}_i)$ *is the set of all permutations of the vector* $\boldsymbol{y}_i$*. If the Bregman divergence* $D_\phi\left(\cdot\middle|\middle|\cdot\right)$ *is conformally separable then* $\boldsymbol{y}_i^*$ *is isotonic with* $\boldsymbol{x}_i$ $\forall i = 1, 2$

Proof. The proof is by contradiction. Assume $\boldsymbol{y}_i^*$ is a minimizer that is not isotonic with $\boldsymbol{x}_i$, then one may permute $\boldsymbol{y}_i^*$ to match the order of $\boldsymbol{x}_i$ to obtain a reduced cost, yielding a contradiction. □

The utility of Lemma 4 is that in spite of the caveats mentioned it can correctly identify the internal ordering of the components of the left hand side that achieves the minimum for a fixed $\boldsymbol{w}^{t+1}, \{\beta_i^{t+1}\}$, given a fixed right hand side. With the knowledge of the order obtained, one may then compute the actual values with relative ease with (10).

5 Experiments

We evaluated the ranking performance of the proposed monotone retargeting approach on the benchmark LETOR 4.0 datasets (MQ2007, MQ2008) [23] as well as the OHSUMED dataset [12]. Each of these datasets is pre-partitioned into five-fold validation sets for easy comparison across algorithms. For OHSUMED, we used the *QueryLevelNorm* partition. Each dataset contains a set of queries, where each document is assigned a relevance score from irrelevant ($r = 0$) to relevant ($r = 2$).

All algorithms were trained using a regularized linear ranking function, with a regularization parameter chosen from the set $C \in \{10^{-50}, 10^{-20}, 10^{-10}, 10^{-5}, 10^{0}, 10^{1}\}$. The best model was identified as the model with highest mean average precision (MAP) on the validation set. All presented results are of average performance on the test set. As the baseline, we implemented the NDCG consistent re-normalization approach in [19] (using the NDCG$_m$ normalization) for the squared loss and the I-divergence (generalized KL-divergence). ListNet was implemented [7] as the KL divergence baseline since their normalization has

no effect on KL-divergence. MR was implemented using the *partially hidden order* monotone retargeting approach (Section 4.1). We compared the performance of MR (Normalized MR) to the MR method with the normalization $\frac{1}{|\mathcal{V}_i|}$ removed (Unnormalized MR).

The algorithms were implemented in Python and executed on a 2.4GHz quad-core Intel Xeon processor without paying particular attention to writing optimized code. Ample room for improvement remains. Square loss was the fastest with respect to average execution times per iteration at 0.58 seconds whereas KL achieved 1.01 seconds per iteration and I-div 1.14 seconds per iteration. We found that although MQ2007 is more than 4 times larger than MQ2008, MQ2007 only required about twice the time execution on average, highlighting the scalability of MR. On average SQ, KL and I-div took 99, 90 and 65 iterations.

Table 5 compares the algorithms in terms of expected reciprocal return (ERR) [10], Mean average precision (MAP) and NDCG. Unnormalized KL divergence cost function led to the best performance across datasets. The most significant gains over the baseline were for the I-divergence cost function. Monotone retargeting showed consistent performance gains over the baseline across metrics (NDCG, ERR, Precision), suggesting the effectiveness of MR for improving the overall ranking performance.

Figure 2 shows a subset of performance comparisons using the NDCG@N and Precision@N metrics. Our experiments show a significant improvement in performance on the range of datasets and cost functions. Across datasets, the difference between the baseline and our results were most significant with the I-divergence (generalized KL divergence) cost function.

There are two things worth taking special note of: (i) Although the baseline algorithms were proposed specifically for improving NDCG performance, MR improves the ranking accuracy further, even in terms of NDCG. (ii) MR seems to be consistently peaking early. This property is particularly desirable and is encoded specifically in the cost functions such as NDCG and ERR. In our initial formulation we used WIS Bregman divergence so that the weights could be tuned to obtained the early peaking behavior. However that proved unnecessary because even the unweighted model produced satisfactory performance. The effect of query length normalization was, however, inconsistent. Some of our results were insensitive to it, whereas other results were adversely affected. We conjecture that it is an artifact of using the same amount of regularization as in the un-normalized case.

6 Conclusion and Related Work

One technique that shares our motivation of learning to rank is ordinal regression [14] which optimizes parameters

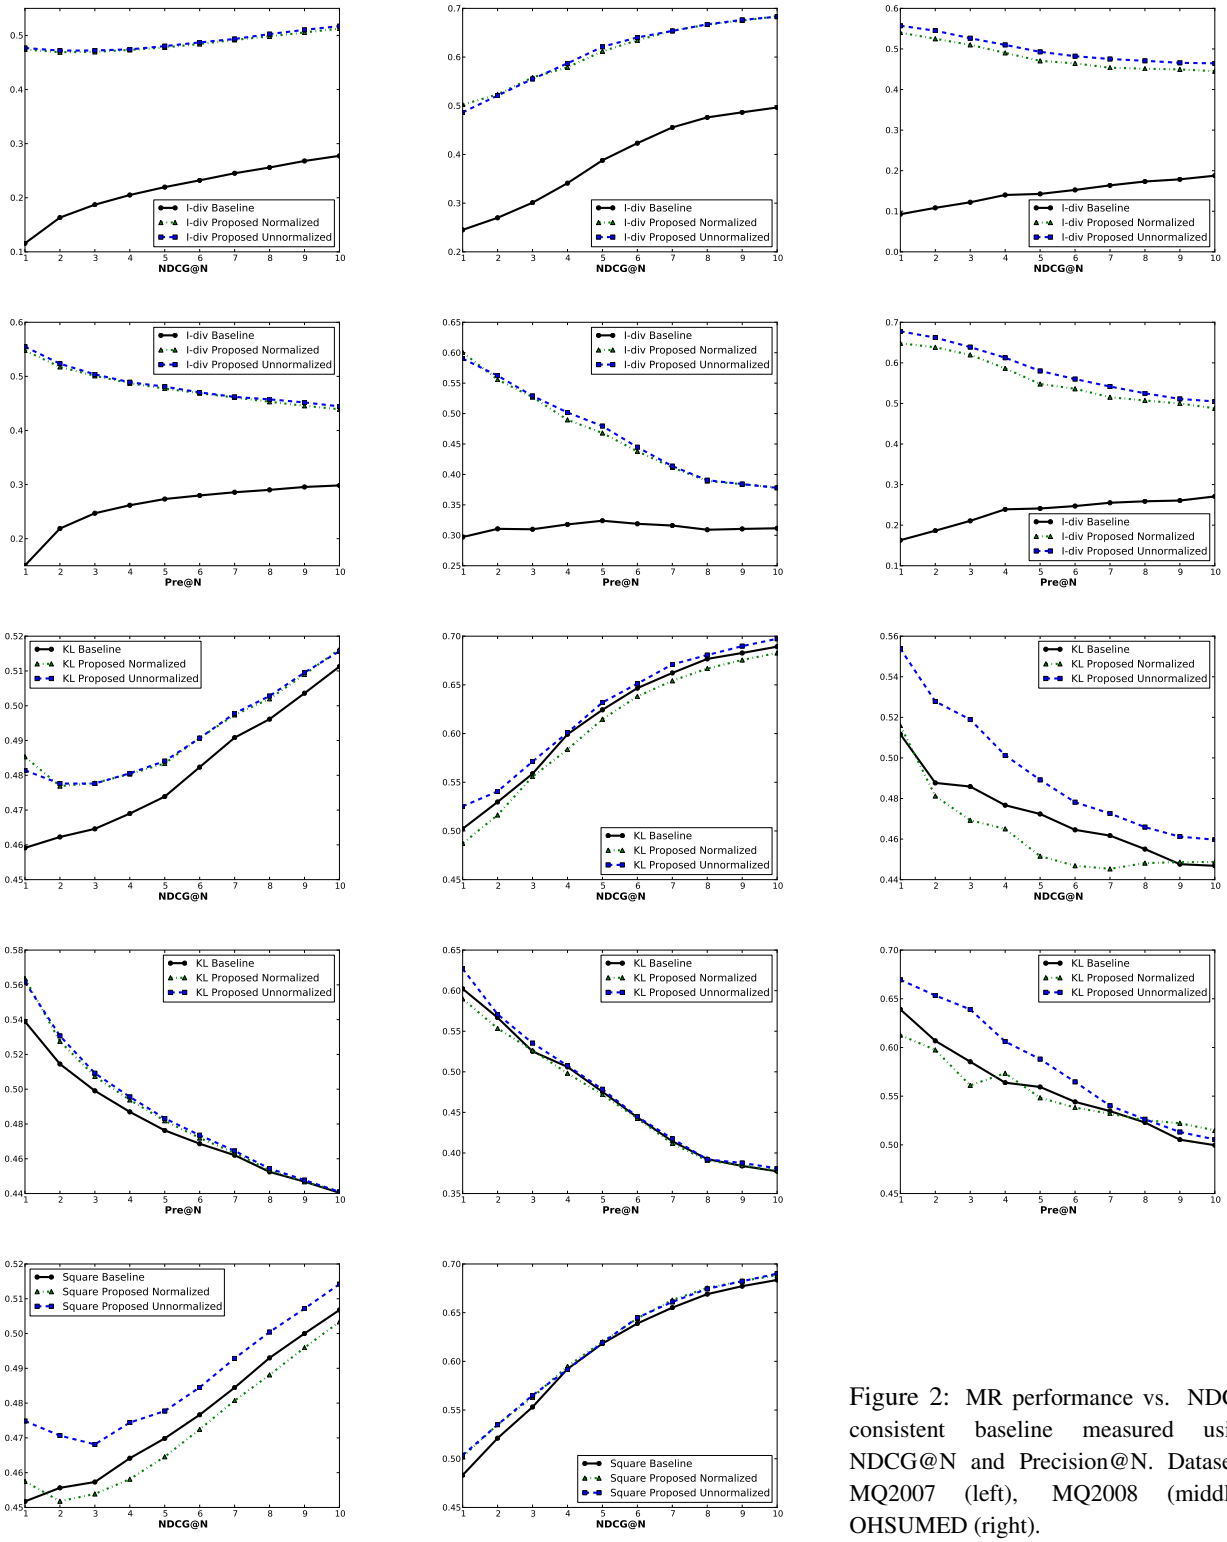

Figure 2: MR performance vs. NDCG consistent baseline measured using NDCG@N and Precision@N. Datasets: MQ2007 (left), MQ2008 (middle), OHSUMED (right).

of a regression function as well as thresholds. Unfortunately we do not have space for a full literature survey and only mention a few key differences. The log-likelihood of the classic ordinal regression methods are a sum of logarithms of differences of monotonic functions and are much more cumbersome to optimize over. To our knowledge they do not share the strong guarantees that MR with Bregman divergences enjoys. The prevalent technique there seems to require fixing a finite number of thresholds up-front, an arbitrary choice that MR does not make. However, it is not clear if that is a restriction of ordinal regression or is a prevalent practice.

In this paper we introduced a family of new cost functions for ranking. The cost function takes into account all possible monotonic transforms of the target scores, and we show how such a cost function can be optimized efficiently. Because the sole objective of learning to rank is to output good permutations on unseen data, it is desirable that the cost function be a function of such permutations. Though several permutation dependent cost functions have been proposed, they are extremely difficult to optimize over and one has to resort to surrogates and/or cut other corners. We show that with monotone retargeting with Bregman divergences such contortions are unnecessary. In addition, the proposed cost function and algorithms have very favorable statistical, optimization theoretic, as well as empirically observed properties. Other advantages include extensive parallelizability due to simple simultaneous projection updates that optimize a cost function that is convex not only in each of the arguments separately but also jointly, with a proper choice of the cost function from the family.

A Appendix: Proof Sketches

Theorem 1

Proof. Let the components of $\boldsymbol{y}^*$ take k unique values. Partition the set indexing the components into $\Pi = \{\Pi_i\}_{i=1}^k$ s.t. $\forall_j \in \Pi_i \; y_j^* = c_i \, \forall_{i \in [1,k]}$. Let the scalar mean of $\boldsymbol{x}$ on Π_i be μ_{Π_i}. By (14), $\sum_{j \in \Pi_i} D_\phi(x_j \big|\big| y_j^*) = \sum_{j \in \Pi_i} D_\phi(x_j \big|\big| \mu_{\Pi_i}) + D_\phi(\mu_{\Pi_i} \big|\big| c_i)$. First, we prove by contradiction that $y_j^* = \mu_{\Pi_i} \, \forall_j \in \Pi_i$, otherwise $\exists \; \boldsymbol{y'} \in \mathbb{R}^d$ s.t. $y'_l = y_l^* \; \forall l \notin \Pi_i$, and $\forall_j \in \Pi_i \;\; c_{i+1} \leq y'_j = c' \leq c_{i-1}$ s.t. $D_\phi\big(\mu_{\Pi_i} \big|\big| c'\big) < D_\phi\big(\mu_{\Pi_i} \big|\big| c_i\big)$. Thus $D_\phi\big(\boldsymbol{x} \big|\big| \boldsymbol{y'}\big) < D_\phi\big(\boldsymbol{x} \big|\big| \boldsymbol{y}^*\big)$, clearly a contradiction.

Let $\operatorname{Argmin}_{\boldsymbol{y} \in \mathcal{R}\downarrow} D_\theta\big(\boldsymbol{x} \big|\big| \boldsymbol{y}\big) = \boldsymbol{z}^*$ for $\boldsymbol{\theta} \neq \boldsymbol{\phi}$. Let $\boldsymbol{z}^*$ induce the partition $P = \{P_l\}_{l=1}^m$. If $\Pi = P$ always, then $y_j^* = z_j^*$ completing the proof. Shift the indexing of the partitions to the first j where Π_j, P_j differs. Now with new index, WLOG [3] assume $\Pi_1 \subset P_1$, $P_1 \subset \Pi_1 \cup \Pi_2$. Define $\dot{\Pi}_2 = \Pi_2 \cap P_1, \ddot{\Pi}_2 = \Pi_2 \setminus \dot{\Pi}_2 \neq \emptyset$, else P_1 can be refined into Π_1, Π_2 obtaining a lower cost (by Corollary 3). Let the means of $\dot{\Pi}_2, \ddot{\Pi}_2 = \dot{y}_2, \ddot{y}_2$. By definition y_2^* is their convex combination. Now $\dot{y}_2 \geq \ddot{y}_2$, else one can reduce the cost by refining Π_2 into $\dot{\Pi}_2, \ddot{\Pi}_2$. Therefore $\dot{y}_2 \geq y_2^* \geq \ddot{y}_2$. Note $y_1^* \geq \dot{y}_2$ or else we can refine P_1 into $\Pi_1, \dot{\Pi}_2$. Thus we have $y_1^* \geq \dot{y}_2 \geq \ddot{y}_2$ which is in contradiction with $y_1^* < y_2^*$. □

[3] We encourage the reader to draw a picture for clarity.

Theorem 2

Proof. For succinctness we use the abbreviations: $\boldsymbol{x}(\alpha) = \alpha \boldsymbol{x}_1 + (1-\alpha)\boldsymbol{x}_2$, $\boldsymbol{y}(\alpha) = \alpha \boldsymbol{y}_1 + (1-\alpha)\boldsymbol{y}_2$, $\phi_i = \phi(\boldsymbol{x}_i)$, $\psi_i = \psi(\boldsymbol{x}_i)$, $\Phi(\alpha) = \alpha\phi_1 + (1-\alpha)\phi_2$ and $\Psi(\alpha) = \alpha\psi_1 + (1-\alpha)\psi_2$. Joint convexity is equivalent to $\phi(\boldsymbol{x}(\alpha)) + \psi(\boldsymbol{y}(\alpha)) - \langle \boldsymbol{x}(\alpha), \boldsymbol{y}(\alpha) \rangle \leq \Phi(\alpha) + \Psi(\alpha) - \alpha \langle \boldsymbol{x}_1, \boldsymbol{y}_1 \rangle - (1-\alpha) \langle \boldsymbol{x}_2, \boldsymbol{y}_2 \rangle \;\; \forall \, \boldsymbol{x}_1, \boldsymbol{x}_2 \in \operatorname{dom} \phi, \; \boldsymbol{y}_1, \boldsymbol{y}_2 \in \operatorname{dom} \psi$. Thus we have to show:

$$\phi(\boldsymbol{x}(\alpha)) + \psi(\boldsymbol{y}(\alpha)) \leq \Phi(\alpha) + \Psi(\alpha) + \overbrace{\alpha(1-\alpha) \langle \boldsymbol{x}_1 - \boldsymbol{x}_2, \boldsymbol{y}_1 - \boldsymbol{y}_2 \rangle}^{B} \tag{13}$$

for all arguments in the domain. Assume with no loss in generality that $\phi(\cdot)$ and $\psi(\cdot)$ are strongly convex with modulus of strong convexity $(1+s1), (1-s2)$ with $s1 > -1$, $s2 < 1$, respectively. Reciprocal of the modulus of strong convexity of the Legendre dual is the Lipschitz constant of the gradient of a convex function [21], therefore $(1+s1) \leq \frac{1}{1-s2}$, being the lower and upper bounds of the eigenvalues of the Hessian of $\phi(\cdot)$ respectively. Simplifying expression (13) using our strong convexity assumptions and positivity of $\alpha(1-\alpha)$, we obtain that we have to show $(1+s1)||\boldsymbol{x}_1 - \boldsymbol{x}_2||^2 + (1-s2)||\boldsymbol{y}_1 - \boldsymbol{y}_2||^2 - 2B \leq 0$. Or

$$||(\boldsymbol{x}_1 - \boldsymbol{x}_2) - (\boldsymbol{y}_1 - \boldsymbol{y}_2)||^2 + s1||\boldsymbol{x}_1 - \boldsymbol{x}_2||^2 - s2||(\boldsymbol{y}_1 - \boldsymbol{y}_2)||^2 \leq 0.$$

Let $\boldsymbol{p} = \boldsymbol{x}_1 - \boldsymbol{x}_2$ and $\boldsymbol{q} = \boldsymbol{y}_1 - \boldsymbol{y}_2$. By choosing $(1+s)\boldsymbol{p} = \boldsymbol{q}$ we obtain $s1 > s2 + s1s2$, or equivalently $(1+s1) \geq \frac{1}{1-s2}$. Thus the lower and upper bounds of the eigenvalues of Hessian of $\phi(\cdot)$ must coincide. □

B Appendix: Optimality of Means

Theorem 3. *[2] Let $\boldsymbol{\pi}$ be a distribution over $\boldsymbol{x} \in \operatorname{dom} \phi$ and $\boldsymbol{\mu} = \mathop{\mathbb{E}}_{\boldsymbol{x} \sim \boldsymbol{\pi}} [\boldsymbol{x}]$ then the expected divergence about $\boldsymbol{s}$ is*

$$\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \boldsymbol{\pi}} \Big[D_\phi\big(\boldsymbol{x} \big|\big| \boldsymbol{s}\big) \Big] = \mathop{\mathbb{E}}_{\boldsymbol{x} \sim \boldsymbol{\pi}} \Big[D_\phi\big(\boldsymbol{x} \big|\big| \boldsymbol{\mu}\big) \Big] + D_\phi\big(\boldsymbol{\mu} \big|\big| \boldsymbol{s}\big). \tag{14}$$

From non-negativity of Bregman divergence it follows that

Corrolary 2. *[2]* $\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \boldsymbol{\pi}} [\boldsymbol{x}] = \operatorname*{Argmin}_{\boldsymbol{y} \in \operatorname{dom} \phi} \mathop{\mathbb{E}}_{\boldsymbol{x} \sim \boldsymbol{\pi}} \Big[D_\phi\big(\boldsymbol{x} \big|\big| \boldsymbol{y}\big) \Big]$.

Corrolary 3. *If random variable $\boldsymbol{x}$ takes values in $\mathcal{X} = \mathcal{X}_1 \cup \mathcal{X}_2$ with $\mathcal{X}_1 \cap \mathcal{X}_2 = \emptyset$ then* $\operatorname*{Argmin}_{\boldsymbol{\mu} \in \mathcal{X}} \mathop{\mathbb{E}}_{\boldsymbol{x}|\mathcal{X}} \Big[D_\phi\big(\boldsymbol{x} \big|\big| \boldsymbol{\mu}\big) \Big] \geq$

$$\operatorname*{Argmin}_{\boldsymbol{\mu}_1 \in \mathcal{X}_1} \mathop{\mathbb{E}}_{\boldsymbol{x}|\mathcal{X}_1} \Big[D_\phi\big(\boldsymbol{x} \big|\big| \boldsymbol{\mu}_1\big) \Big] + \operatorname*{Argmin}_{\boldsymbol{\mu}_2 \in \mathcal{X}_2} \mathop{\mathbb{E}}_{\boldsymbol{x}|\mathcal{X}_2} \Big[D_\phi\big(\boldsymbol{x} \big|\big| \boldsymbol{\mu}_2\big) \Big].$$

Abstract

A determinantal point process (DPP) is a random process useful for modeling the combinatorial problem of subset selection. In particular, DPPs encourage a random subset $\boldsymbol{Y}$ to contain a *diverse* set of items selected from a base set $\mathcal{Y}$. For example, we might use a DPP to display a set of news headlines that are relevant to a user's interests while covering a variety of topics. Suppose, however, that we are asked to sequentially select *multiple* diverse sets of items, for example, displaying new headlines day-by-day. We might want these sets to be diverse not just individually but also through time, offering headlines today that are unlike the ones shown yesterday. In this paper, we construct a *Markov* DPP (M-DPP) that models a *sequence* of random sets $\{\boldsymbol{Y}_t\}$. The proposed M-DPP defines a stationary process that maintains DPP margins. Crucially, the induced union process $\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1}$ is also marginally DPP-distributed. Jointly, these properties imply that the sequence of random sets are encouraged to be diverse both at a given time step as well as across time steps. We describe an exact, efficient sampling procedure, and a method for incrementally learning a quality measure over items in the base set $\mathcal{Y}$ based on external preferences. We apply the M-DPP to the task of sequentially displaying diverse and relevant news articles to a user with topic preferences.

1 INTRODUCTION

Consider the combinatorial problem of subset selection. Binary Markov random fields are commonly applied in this setting, and in the case of positive correlations, yield subsets that favor similar items. However, in many applications there is naturally a sense of *repulsion*. For example, repulsive processes arise in nature—trees tend to grow in the least occupied space (Neeff et al., 2005), and ant hill locations are likewise over-dispersed relative to uniform placement (Bernstein and Gobbel, 1979). Likewise, many practical tasks can be posed in terms of diverse subset selection. For example, one might want to select a set of frames from a movie that are representative of its content. Clearly, diversity is preferable to avoid redundancy; likewise, each frame should be of high quality. A motivating example we consider throughout the paper is the task of selecting a diverse yet relevant set of news headlines to display to a user. One could imagine employing binary Markov random fields with negative correlations, but such models often involve notoriously intractable inference problems.

Determinantal point processes (DPPs), which arise in random matrix theory (Mehta and Gaudin, 1960; Ginibre, 1965) and quantum physics (Macchi, 1975), are a class of *repulsive processes* and are natural models for subset selection problems where diversity is preferred. DPPs define the probability of a subset in terms of the determinant of a kernel submatrix, and with an appropriate definition of the kernel matrix they can be interpreted as inherently balancing quality and diversity. DPPs are appealing in practice since they offer interpretability and tractable algorithms for exact inference. For example, one can compute marginal and conditional probabilities and perform exact sampling. DPPs have recently been employed for human pose estimation, search diversification, and document summarization (Kulesza and Taskar, 2010, 2011a,b).

In this paper, our focus is instead on modeling diverse *sequences* of subsets. For example, in displaying news headlines from day to day, one aims to select articles that are relevant and diverse on any given day. Additionally, it is desirable to select articles that are diverse relative to those previously shown. We construct a *Markov* DPP (M-DPP) for a sequence of random sets $\{\boldsymbol{Y}_t\}$. The proposed M-DPP defines a stationary process that maintains DPP margins, implying that $\boldsymbol{Y}_t$ is encouraged to be diverse at time t. Crucially, the induced union process $\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1}$ is also marginally DPP-distributed. Since this property implies the diversity of $\boldsymbol{Z}_t$, in addition to the individual diversity of $\boldsymbol{Y}_t$ and $\boldsymbol{Y}_{t-1}$, we conclude that $\boldsymbol{Y}_t$ is diverse from $\boldsymbol{Y}_{t-1}$.

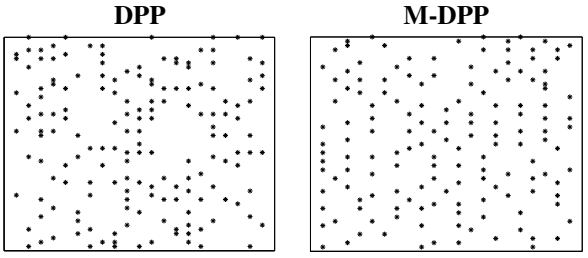

Figure 1: A set of points on a line (y axis) drawn from a DPP independently over time (left) and from a M-DPP (right). While DPP points are diverse only within time steps (columns), M-DPP points are also diverse across time steps.

For an illustration of the improved overall diversity when sampling from a M-DPP rather than independent sequential sampling from a DPP, see Fig. 1.

Our specific construction of the M-DPP yields an exact sampling procedure that can be performed in polynomial time. Additionally, we explore a method for incrementally learning the quality of each item in the base set $\mathcal{Y}$ based on externally provided preferences. In particular, a decomposition of the DPP kernel matrix has an interpretation as defining the quality of each item and pairwise similarities between items. Our incremental learning procedure assumes a well-defined similarity metric and aims to learn features of items that a user deems as preferable. These features are used to define the quality scores for each item. The M-DPP aids in the exploration of items of interest to the user by providing sequentially diverse results.

We study the empirical behavior of the M-DPP on a news task where the goal is to display diverse and high quality articles. Compared to choosing articles based on quality alone or to sampling from an independent DPP at each time step, we show that the M-DPP produces articles that are significantly more diverse across time steps without large sacrifices in quality. Furthermore, within a time step the M-DPP chooses articles with diversity comparable to that of the independent DPP; this is a direct result of the fact that the M-DPP maintains DPP margins. We also consider learning the quality function over time from the feedback of a user with topic preferences. In this setting, the M-DPP returns high quality results that are preferred by the user while simultaneously exploring the topic space more quickly than baseline methods, leading to improved coverage.

2 DETERMINANTAL POINT PROCESSES

A random point process $\mathcal{P}$ on a discrete base set $\mathcal{Y} = \{1, \ldots, N\}$ is a probability measure on the set $2^{\mathcal{Y}}$ of all subsets of $\mathcal{Y}$. Let K be a semidefinite matrix with rows and columns indexed by the elements of $\mathcal{Y}$. $\mathcal{P}$ is called a determinantal point process (DPP) if there exists $K \preceq I$ (all eigenvalues less than or equal to 1) such that if $\boldsymbol{Y}$ is a random set drawn according to $\mathcal{P}$, then for every $A \subseteq \mathcal{Y}$:

$$\mathcal{P}(\boldsymbol{Y} \supseteq A) = \det(K_A) \,. \tag{1}$$

Here, $K_A \equiv [K_A]_{i,j \in A}$ denotes the submatrix of K indexed by elements in A, and we adopt the convention that $\det(K_\emptyset) = 1$. We will refer to K as the marginal kernel. If we think of K_{ij} as measuring the similarity between items i and j, then

$$\mathcal{P}(\boldsymbol{Y} \supseteq \{i, j\}) = K_{ii}K_{jj} - K_{ij}^2 \tag{2}$$

implies that $\boldsymbol{Y}$ is unlikely to contain both i and j when they are very similar; that is, a DPP can be seen as modeling a collection of diverse items from the base set $\mathcal{Y}$.

DPPs can alternatively be constructed via L-ensembles (Borodin and Rains, 2005). An L-ensemble is a probability measure on $2^{\mathcal{Y}}$ defined via a positive semidefinite matrix L indexed by elements of $\mathcal{Y}$:

$$\mathcal{P}_L(\boldsymbol{Y} = A) = \frac{\det(L_A)}{\det(L + I)} \,, \tag{3}$$

where I is the $N \times N$ identity matrix. It can be shown that an L-ensemble is a DPP with marginal kernel $K = L(I+L)^{-1}$. Conversely, a DPP with marginal kernel K has L-ensemble kernel $L = K(I - K)^{-1}$ (when the inverse exists).

An intuitive way to think of the L-ensemble kernel L is as a Gram matrix (Kulesza and Taskar, 2010):

$$L_{ij} = q_i \phi_i^\top \phi_j q_j \,, \tag{4}$$

interpreting $q_i \in \mathbb{R}^+$ as representing the intrinsic *quality* of an item i, and $\phi_i, \phi_j \in \mathbb{R}^n$ as unit length feature vectors representing the *similarity* between items i and j with $\phi_i^\top \phi_j \in [-1, 1]$. Under this framework, we can model quality and similarity separately to encourage the DPP to choose *high quality* items that are *dissimilar* to each other. This is very useful in many applications. For example, in response to a search query we can provide a very relevant (i.e. high quality) but diverse (i.e. dissimilar) list of results.

Conditional DPPs For any $A, B \subseteq \mathcal{Y}$ with $A \cap B = \emptyset$, it is straightforward to show that

$$\mathcal{P}_L(\boldsymbol{Y} = A \cup B | \boldsymbol{Y} \supseteq A) = \frac{\det(L_{A \cup B})}{\det(L + I_{\mathcal{Y} \setminus A})} \,, \tag{5}$$

where $I_{\mathcal{Y} \setminus A}$ is a matrix with ones on the diagonal entries indexed by the elements of $\mathcal{Y} \setminus A$ and zeros elsewhere.

This conditional distribution is itself a DPP over the elements of $\mathcal{Y} \setminus A$ (Borodin and Rains, 2005). In particular, suppose $\boldsymbol{Y}$ is DPP-distributed with L-ensemble kernel L, and condition on the fact that $\boldsymbol{Y} \supseteq A$. Then the set $\boldsymbol{Y} \setminus A$ is DPP-distributed with marginal and L-ensemble kernels

$$K^A = \left[I - (L + I_{\mathcal{Y} \setminus A})^{-1}\right]_{\mathcal{Y} \setminus A} \tag{6}$$

$$L^A = \left(\left[(L + I_{\mathcal{Y} \setminus A})^{-1}\right]_{\mathcal{Y} \setminus A}\right)^{-1} - I \,. \tag{7}$$

Here, $[\cdot]_{\mathcal{Y}\setminus A}$ denotes the submatrix of the argument indexed by elements in $\mathcal{Y} \setminus A$. Thus, DPPs as a class are closed under most natural conditioning operations.

In selecting a diverse collection of elements in $\mathcal{Y}$, a DPP jointly models both the size of a set and its content. In some applications, the goal is to select (diverse) sets of a fixed size. In order to achieve this goal, we can instead consider a fixed-size determinantal point processes, or kDPP (Kulesza and Taskar, 2011a), which gives a distribution over all random subsets $\boldsymbol{Y} \subseteq \mathcal{Y}$ with fixed cardinality k. The L-ensemble construction of a kDPP, denoted $\mathcal{P}_L^k$, gives probabilities

$$\mathcal{P}_L^k(\boldsymbol{Y} = A) = \frac{\det(L_A)}{\sum_{|B|=k} \det(L_B)} \tag{8}$$

for all sets A with cardinality k and any positive semidefinite kernel L. Kulesza and Taskar (2011a) developed efficient algorithms to normalize, sample and marginalize kDPPs using properties of elementary symmetric polynomials.

3 MARKOV DETERMINANTAL POINT PROCESSES (M-DPPS)

In certain applications, such as in the task of displaying news headlines, our goal is not only to generate a diverse collection of items at one time point, but also to generate collections of items at subsequent time points that are both highly relevant and dissimilar to the previous collection. To address these goals, we introduce the Markov determinantal point process (M-DPP), which emphasizes both marginal and conditional diversity of selected items. Harnessing the *quality* and *similarity* interpretation of the DPP in (4), the M-DPP provides a dynamic way of selecting high quality and diverse collections of items as a temporal process.

We constructively define a first-order, discrete-time autoregressive point process on $\mathcal{Y}$ by specifying a Markov transition distribution (and initial distribution). Throughout, we use the notation $\{\boldsymbol{Y}_t\}$, $\boldsymbol{Y}_t \subseteq \mathcal{Y}$, to represent a sequence of sets following a M-DPP. We consider two such constructions: one based on marginal kernels, and the other on L-ensembles. Both yield equivalent stationary processes with DPP margins. Additionally, and quite intuitively, the induced union process $\{\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1}\}$ has DPP margins with a closely related kernel. Combining these two properties, we conclude that the constructed M-DPPs yield a sequence of sets $\{\boldsymbol{Y}_t\}$ that are diverse at any time t and across time steps $t, t-1$.

Marginal construction. Define $\mathcal{P}(\boldsymbol{Y}_1 \supseteq A) = \det(K_A)$ and

$$\mathcal{P}(\boldsymbol{Y}_t \supseteq B | \boldsymbol{Y}_{t-1} \supseteq A) = \frac{\det(K_{A\cup B})}{\det(K_A)} , \tag{9}$$

where $K \prec \frac{1}{2}I$ and $A \cap B = \emptyset$. Throughout, we adopt the implicit constraint that $\boldsymbol{Y}_t \cap \boldsymbol{Y}_{t-1} = \emptyset$. We have immediately the joint probability

$$\mathcal{P}(\boldsymbol{Y}_2 \supseteq B, \boldsymbol{Y}_1 \supseteq A) = \det(K_{A\cup B}) , \tag{10}$$

and therefore

$$\mathcal{P}(\boldsymbol{Y}_2 \supseteq B) = \mathcal{P}(\boldsymbol{Y}_2 \supseteq B, \boldsymbol{Y}_1 \supseteq \emptyset) = \det(K_B) . \tag{11}$$

Inductively, the process is stationary and marginally DPP.

Finally, we have the union of consecutive sets:

$$\begin{aligned}
&\mathcal{P}(\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1} \supseteq C) \\
&\quad = \sum_{A\subseteq C} \mathcal{P}(\boldsymbol{Y}_t \supseteq C \setminus A, \boldsymbol{Y}_{t-1} \supseteq A) = \sum_{A\subseteq C} \det(K_C) \\
&\quad = 2^{|C|} \det(K_C) = \det((2K)_C) .
\end{aligned} \tag{12}$$

That is, $\boldsymbol{Z}_t$ is marginally distributed as a DPP with marginal kernel $2K$. Since a randomly sampled subset of a DPP-distributed set also follows a DPP, marginally we can imagine this process as sampling $\boldsymbol{Z}_t$ and then splitting its elements randomly into two sets, $\boldsymbol{Y}_{t-1}$ and $\boldsymbol{Y}_t$.

L-ensemble construction. The above is appealingly simple, but the marginal form of the conditional in (9) is not particularly conducive to a sequential sampling process. Instead, we can rewrite everything as L-ensembles. Assume that at the first time step $\mathcal{P}(\boldsymbol{Y}_1 = Y_1) = \frac{\det(L_{Y_1})}{\det(L+I)}$ and define the transition distribution as

$$\mathcal{P}(\boldsymbol{Y}_t = Y_t | \boldsymbol{Y}_{t-1} = Y_{t-1}) = \frac{\det(M_{Y_t\cup Y_{t-1}})}{\det(M + I_{\mathcal{Y}\setminus Y_{t-1}})} , \tag{13}$$

for $M = L(I-L)^{-1}$. Note that the transition distribution is essentially a conditional DPP with L-ensemble kernel M (Eq. (5)). M is well-defined as long as $L \prec I$, which is equivalent to $K \prec \frac{1}{2}I$, as in the marginal construction.

Now we have the joint probability

$$\mathcal{P}(\boldsymbol{Y}_2 = Y_2, \boldsymbol{Y}_1 = Y_1) = \frac{\det(M_{Y_1\cup Y_2})}{\det(M + I_{\mathcal{Y}\setminus Y_1})} \frac{\det(L_{Y_1})}{\det(L+I)} . \tag{14}$$

Using the fact that $\det(M + I_{\mathcal{Y}\setminus Y_1})/\det(M+I) = \det(L_{Y_1})$,

$$\mathcal{P}(\boldsymbol{Y}_2 = Y_2, \boldsymbol{Y}_1 = Y_1) = \frac{1}{\det(L+I)} \frac{\det(M_{Y_1\cup Y_2})}{\det(M+I)} . \tag{15}$$

Therefore, marginally,

$$\begin{aligned}
\mathcal{P}(\boldsymbol{Y}_2 = Y_2) &= \sum_{Y_1\subseteq\mathcal{Y}} \frac{1}{\det(L+I)} \frac{\det(M_{Y_1\cup Y_2})}{\det(M+I)} \\
&= \sum_{(Y_1\cup Y_2)\supseteq Y_2} \frac{1}{\det(L+I)} \frac{\det(M_{Y_1\cup Y_2})}{\det(M+I)} \\
&= \frac{\det(M + I_{\mathcal{Y}\setminus Y_2})}{\det(L+I)\det(M+I)} = \frac{\det(L_{Y_2})}{\det(L+I)} .
\end{aligned} \tag{16}$$

Here, we used $\sum_{B \supseteq A} \det(M_B) = \det(M + I_{\mathcal{Y} \setminus A})$, which is immediately derived from (5). By induction, we conclude

$$\mathcal{P}(\boldsymbol{Y}_t = Y_t) = \frac{\det(L_{Y_t})}{\det(L+I)} \,. \tag{17}$$

Thus, our construction yields a stationary process with $\boldsymbol{Y}_t$ marginally distributed as a DPP with L-ensemble kernel L.

One can likewise analyze the margin of the induced union process $\{\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1}\}$:

$$\begin{aligned}
&\mathcal{P}(\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1} = C) \\
&\quad = \sum_{A \subseteq C} \mathcal{P}(\boldsymbol{Y}_t = C \setminus A, \boldsymbol{Y}_{t-1} = A) \\
&\quad = \sum_{A \subseteq C} \frac{1}{\det(L+I)} \frac{\det(M_C)}{\det(M+I)} \\
&\quad = \frac{2^{|C|}}{\det(L+I)} \frac{\det(M_C)}{\det(M+I)} \qquad (18) \\
&\quad = \frac{1}{\det(L+I)} \frac{\det((2M)_C)}{\det(M+I)} \,. \qquad (19)
\end{aligned}$$

Noting that

$$\begin{aligned}
&\det(M+I)\det(L+I) = \det((M+I)(L+I)) \\
&\quad = \det((M+I)(I-(M+I)^{-1}+I)) \\
&\quad = \det(2M+2I-I) = \det(2M+I) \,, \qquad (20)
\end{aligned}$$

we conclude

$$\mathcal{P}(\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1} = C) = \frac{\det((2M)_C)}{\det(2M+I)} \,. \tag{21}$$

We have shown that $\boldsymbol{Z}_t$ is marginally distributed as a DPP with L-ensemble kernel $2M$. The corresponding marginal kernel is

$$\begin{aligned}
2M(2M+I)^{-1} &= 2L(I-L)^{-1}\left[(L+I)(I-L)^{-1}\right]^{-1} \\
&= 2L(L+I)^{-1} = 2K \,. \qquad (22)
\end{aligned}$$

Thus, we have reproduced the same characterization of $\boldsymbol{Z}_t$ as in (12) for the marginal kernel construction.

To summarize the marginal properties of the M-DPP, using the notation $\boldsymbol{Y} \sim L, K$ to denote that $\boldsymbol{Y}$ is from a DPP with L-ensemble kernel L and marginal kernel K, we have:

$$\boldsymbol{Y}_t \sim L, K \tag{23}$$

$$\boldsymbol{Z}_t \sim 2L(I-L)^{-1}, 2K \,. \tag{24}$$

3.1 COMMENTS ON THE M-DPP

While we have shown that the M-DPP subsets are diverse at subsequent time steps, this does not necessarily imply diversity at longer intervals. In fact, it is possible for realizations to have oscillations, where groups of high-quality items recur every two (or more) time steps. However, this is not necessarily a problem in practice for several reasons. First, the M-DPP construction straightfowardly extends to higher order models with longer memory, if desired. Second, it is possible to show that the M-DPP does not *harm* long-term diversity relative to independent sampling from a DPP. If we make a separate copy of each item at each time step, then the M-DPP can be seen as a large DPP on item/time pairs (i,t). Denoting the marginal kernel by $\hat{K}$, the Markov property implies that $\hat{K}_{(i,t)(j,u)}$ is only nonzero when $|t-u| \leq 1$. The probability of item i appearing at any set of time steps, given by the appropriate determinant of $\hat{K}$, can only be reduced by the off-diagonal entries compared to independent DPP samples at each time step. Thus, the M-DPP can only make global repetition less likely. Finally, in our experiments (Sec. 5) we report results that suggest that M-DPP oscillations do not arise in the task we study.

3.2 MARKOV kDPPS

One can also construct a *Markov kDPP* (M-kDPP). Although we define a stationary process, our construction does not yield $\boldsymbol{Y}_t$ marginally kDPP. Instead, the M-kDPP simply ensures that $\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1}$ follows a $2k$DPP. Since $\boldsymbol{Z}_t$ is encouraged to be diverse, the subsets $\boldsymbol{Y}_t$ and $\boldsymbol{Y}_{t-1}$ will likewise be diverse despite not following a kDPP themselves.

We start by defining the margin and transition distributions:

$$\mathcal{P}(\boldsymbol{Y}_{t-1} = Y_{t-1}) = \frac{\sum_{|A|=k} \det(L_{Y_{t-1} \cup A})}{\binom{2k}{k} \sum_{|B|=2k} \det(L_B)} \tag{25}$$

$$\mathcal{P}(\boldsymbol{Y}_t = Y_t | \boldsymbol{Y}_{t-1} = Y_{t-1}) = \frac{\det(L_{Y_{t-1} \cup Y_t})}{\sum_{|A|=k} \det(L_{Y_{t-1} \cup A})} \,, \tag{26}$$

where A and Y_t are disjoint from Y_{t-1}. Then, jointly

$$\mathcal{P}(\boldsymbol{Y}_t = Y_t, \boldsymbol{Y}_{t-1} = Y_{t-1}) = \frac{\det(L_{Y_{t-1} \cup Y_t})}{\binom{2k}{k} \sum_{|B|=2k} \det(L_B)} \,, \tag{27}$$

from which we confirm the stationarity of the process:

$$\mathcal{P}(\boldsymbol{Y}_t = Y_t) = \frac{\sum_{|Y_{t-1}|=k} \det(L_{Y_t \cup Y_{t-1}})}{\binom{2k}{k} \sum_{|B|=2k} \det(L_B)} \,. \tag{28}$$

The implied union process has margins

$$\begin{aligned}
&\mathcal{P}(\boldsymbol{Z}_t \equiv \boldsymbol{Y}_t \cup \boldsymbol{Y}_{t-1} = C) \\
&\quad = \sum_{A \subseteq C, |A|=k} \mathcal{P}(\boldsymbol{Y}_t = C \setminus A, \boldsymbol{Y}_{t-1} = A) \\
&\quad = \sum_{A \subseteq C, |A|=k} \frac{\det(L_C)}{\binom{2k}{k} \sum_{|B|=2k} \det(L_B)} \\
&\quad = \frac{\det(L_C)}{\sum_{|B|=2k} \det(L_B)} \,, \qquad (29)
\end{aligned}$$

which is a $2k$DPP with L-ensemble kernel L.

Algorithm 1 Sampling from a DPP

Input: L-ensemble kernel matrix L
$\{(v_n, \lambda_n)\}_{n=1}^N \leftarrow$ eigenvector/value pairs of L
$J \leftarrow \emptyset$
for $n = 1, \ldots, N$ **do**
  $J \leftarrow J \cup \{n\}$ with prob. $\frac{\lambda_n}{\lambda_n + 1}$
$V \leftarrow \{v_n\}_{n \in J}$
$Y \leftarrow \emptyset$
while $|V| > 0$ **do**
  Select y_i from $\mathcal{Y}$ with $\Pr(y_i) = \frac{1}{|V|} \sum_{v \in V} (v^\top \boldsymbol{e}_i)^2$
  $Y \leftarrow Y \cup \{y_i\}$
  $V \leftarrow V_\perp$, an orthonormal basis for the subspace of V orthogonal to e_i
Output: Y

3.3 SAMPLING FROM M-DPPS AND M-kDPPS

In the previous subsections we showed how our constructions of M-(k)DPPs lead to DPP (and DPP-like) marginals for $\{\boldsymbol{Y}_t\}$ and the union process $\{\boldsymbol{Z}_t\}$. These connections to DPPs give us valuable intuition about the diversity induced both within and across time steps. They serve another purpose as well: since DPPs and kDPPs can be sampled in polynomial time, we can leverage existing algorithms to efficiently sample from M-DPPs and M-kDPPs.

Hough et al. (2006) first described the DPP sampling algorithm shown in Algorithm 1. The first step is to compute an eigendecomposition $L = \sum_{n=1}^N \lambda_n v_n v_n^\top$ of the kernel matrix; from this, a random subset V of the eigenvectors is chosen by using the eigenvalues to bias a sequence of coin flips. The algorithm then proceeds iteratively, on each iteration selecting a new item y_i to add to the sample and then updating V in a manner that de-emphasizes items similar to the one just selected. Note that $\boldsymbol{e}_i$ is the ith elementary basis vector whose elements are all zero except for a one in position i. Algorithm 1 runs in time $O(N^3 + Nk^3)$, where N is the number of available items and k is the cardinality of the returned sample.

To adapt this algorithm for sampling M-DPPs, we will proceed sequentially, first sampling $\boldsymbol{Y}_1$ from the initial distribution and then repeatedly selecting $\boldsymbol{Y}_t$ from the transition distribution given $\boldsymbol{Y}_{t-1}$. The initial distribution is a DPP with L-ensemble kernel L and can therefore be sampled directly using Algorithm 1. As shown in Sec. 3, the transition distribution (13) is a conditional DPP with L-ensemble kernel $M = L(L - I)^{-1}$; using (7), the L-ensemble kernel for $\boldsymbol{Y}_t$ given $\boldsymbol{Y}_{t-1} = Y_{t-1}$ can be written as

$$L^{(t)} = \left((M + I_{\mathcal{Y} \setminus Y_{t-1}})^{-1}_{\mathcal{Y} \setminus Y_{t-1}} \right)^{-1} - I \,. \qquad (30)$$

Thus we can sample simply and efficiently from a M-DPP using Algorithm 2. The runtime is $O(TN^3 + TNk_{\max}^3)$, where $k_{\max}$ is the maximum number of items chosen at a single time step. Note that for constant $k_{\max}$ this is the same runtime as a Kalman filter with a state vector of size N.

Algorithm 2 Sampling from a Markov DPP

Input: matrix L
$M \leftarrow L(L - I)^{-1}$
$Y_1 \leftarrow$ DPP-SAMPLE(L)
for $t = 2, \ldots, T$ **do**
  $L^{(t)} \leftarrow \left((M + I_{\mathcal{Y} \setminus Y_{t-1}})^{-1}_{\mathcal{Y} \setminus Y_{t-1}} \right)^{-1} - I$
  $Y_t \leftarrow$ DPP-SAMPLE$(L^{(t)})$
Output: $\{Y_t\}$

Algorithm 3 Sampling from a kDPP

Input: L-ensemble kernel matrix L, size k
$\{(v_n, \lambda_n)\}_{n=1}^N \leftarrow$ eigenvector/value pairs of L
$J \leftarrow \emptyset$
for $n = N, \ldots, 1$ **do**
  if $u \sim U[0,1] < \lambda_n \frac{e_{k-1}^{n-1}}{e_k^n}$ **then**
    $J \leftarrow J \cup \{n\}$
    $k \leftarrow k - 1$
    if $k = 0$ **then**
      break
{continue with the rest of Algorithm 1}

Kulesza and Taskar (2011a) proved that a modification to the first loop in Algorithm 1 allows sampling from a kDPP with no change in the asymptotic complexity. The result is Algorithm 3; here e_k^n denotes the elementary symmetric polynomial $e_k^n = \sum_{|J|=k} \prod_{n \in J} \lambda_n$, which can be computed efficiently using recursion.

We can now use Algorithm 3 to perform sequential sampling for a M-kDPP. At first glance, the initial distribution (which is not a kDPP) seems difficult to sample; however, from Sec. 3 we know that it can be obtained by harnessing the union process form of (29) and first sampling a $2k$DPP with L-ensemble kernel L and then throwing away half of the resulting items at random. Transitionally, we have a conditional kDPP whose kernel can be computed as in (30). Algorithm 4 summarizes the M-kDPP sampling process, which runs in time $O(TN^3 + TNk^3)$.

Algorithm 4 Sampling from a Markov kDPP

Input: matrix L, size k
$Z_1 \leftarrow k$DPP-SAMPLE$(L, 2k)$
$Y_1 \leftarrow$ random half of Z_1
for $t = 2, \ldots, T$ **do**
  $L^{(t)} \leftarrow \left((L + I_{\mathcal{Y} \setminus Y_{t-1}})^{-1}_{\mathcal{Y} \setminus Y_{t-1}} \right)^{-1} - I$
  $Y_t \leftarrow k$DPP-SAMPLE$(L^{(t)}, k)$
Output: $\{Y_t\}$

4 LEARNING USER PREFERENCES

A broad class of problems suited to M-(k)DPP modeling are also applications in which we would like to learn preferences from a user over time. Recall the news headlines scenario. Here, the goal is to present articles on a daily basis that are both relevant to the user's interests and also non-redundant. With feedback from a user in the form of click-through behavior, we can attempt to simultaneously learn features of the articles that the user regards as preferable. While the diversity offered by a M-DPP is intrinsically valuable for this task, e.g., to keep the user from getting bored, in the context of learning it also has an important secondary benefit: it promotes exploration of the preference space.

Consider the following simple learning setup. At each time step t, the algorithm shows the user a set of k items drawn from some base set $\mathcal{Y}_t$, for instance, articles from the day's news. The user then provides feedback by identifying each shown item as either preferred or not preferred, perhaps by clicking on the preferred ones. The algorithm then incorporates this feedback and proceeds to the next round. The learner has two goals. First, as often as possible at least some of the items shown to the user should be preferred. Second, over the long term, many different items preferred by the user should be shown. In other words, the algorithm should not focus on a small set of preferred items.

Perhaps the most important consideration in this framework is balancing showing articles that the user is known to like (*exploitation*) against showing a variety of articles so as to discover new topics in which the user is also interested (*exploration*). Neither extreme is likely to be successful. However, using the L-ensemble kernel decomposition in (4), a DPP seeks to propose sets of items that are simultaneously high quality and diverse. The M-DPP takes this a step further and encourages diversity from step to step while maintaining DPP margins, exposing the user to an even greater variety of items without significantly sacrificing quality. Thus, we might expect that M-(k)DPPs can be used to enable fast and successful learning in this setting.

The tradeoff between exploration and exploitation is a fundamental issue for interactive learning, and has received extensive treatment in the literature on multi-armed bandits. However, our setup is relatively unusual for two reasons. First, we show multiple items per time step, sometimes called the *multiple plays* setting (Anantharam et al., 1987). Second, we use feature vectors to describe the items we choose, allowing us to generalize to unseen items (e.g., new articles); this is a special case of *contextual bandits* (Langford and Zhang, 2007). Each of these scenarios has received some attention on its own, but it is only in combination that a notion of diversity becomes relevant, since we have both the need to select multiple items as well as a basis for relating them. This combination has been considered recently by Yue and Guestrin (2011), who showed an algorithm that yields bounded regret under the assumption that the reward function is submodular. Here, on the other hand, our goal is primarily to illustrate the empirical effects on learning when the items shown at each time step are sampled from a M-DPP. To that end, we propose a very simple quality learning algorithm that appears to work well in practice. Whether formal regret guarantees can be established for learning with M-DPPs is an open question for future work.

4.1 SETUP

To naturally accommodate user feedback and transfer knowledge across items, we will consider algorithms that learn a log-linear quality model assigning item i the score

$$q_i = \exp(\theta^\top f_i)\ , \tag{31}$$

where $f_i \in \mathbb{R}^m$ is a feature vector for item i and $\theta \in \mathbb{R}^m$ is the parameter vector to be learned. Learning iterates between two distinct steps: (1) sampling articles according to the current quality scores and (2) using user feedback to revise the quality scores via updates to θ.

Let $\theta^{(t)}$ denote the parameter vector prior to time step t and let $q_i^{(t)}$ denote the corresponding quality scores for the items $i \in \mathcal{Y}_t$. We initialize $\theta^{(1)} = \mathbf{0}$ so that $q_i^{(1)} = 1$ for all $i \in \mathcal{Y}_1$. (At this point we are effectively in a purely exploratory mode.) Denote the items preferred by the user at iteration t by $\{a_i^{(t)}\}_{i=1}^{R_t}$, and the non-preferred items by $\{b_i^{(t)}\}_{i=1}^{S_t}$. Inspired by standard online algorithms, we define the parameter update rule as follows:

$$\theta^{(t+1)} \leftarrow \theta^{(t)} + \eta\left(\frac{1}{R_t}\sum_{i=1}^{R_t} f_{a_i^{(t)}} - \frac{1}{S_t}\sum_{i=1}^{S_t} f_{b_i^{(t)}}\right) \tag{32}$$

That is, we add to θ the average features of the preferred items, and subtract from θ the average features of non-preferred items. This increases the quality of the former and decreases the quality of the latter. η is a learning rate hyperparameter. We can then proceed to the next time step, computing the new quality scores $q_i^{(t+1)} = \exp(\theta^{(t+1)\top} f_i)$ for each $i \in \mathcal{Y}_{t+1}$.

The updated quality scores are then used to select subsequent items to be shown to the user. In order to separate the challenges of learning the quality scores, which is not our primary interest, from the benefits of incorporating the M-DPP, we consider five sampling methods:

- **Uniform.** We ignore the quality scores and choose k items uniformly at random without replacement.
- **Weighted.** We draw k items with probabilities proportional to their quality scores without replacement.
- k**DPP.** We sample the set of items from a kDPP with L-ensemble kernel L given by the decomposition in

Algorithm 5 Interactive learning of quality scores

Input: learning rate η
$\theta^{(1)} \leftarrow \mathbf{0}$
for $t = 1, 2, \ldots$ **do**
  $q_i^{(t)} \leftarrow \exp(\theta^{(t)\top} f_i) \quad \forall i \in \mathcal{Y}_t$
  Select items to display given $q_i^{(t)}$
    (using one of the methods described in Sec. 4.1)
  Receive user feedback $\{a_i^{(t)}\}_{i=1}^{R_t}$ and $\{b_i^{(t)}\}_{i=1}^{S_t}$
  $\theta^{(t+1)} \leftarrow \theta^{(t)} + \eta \left(\frac{1}{R_t} \sum_{i=1}^{R_t} f_{a_i^{(t)}} - \frac{1}{S_t} \sum_{i=1}^{S_t} f_{b_i^{(t)}} \right)$

(4), where ϕ is fixed in advance and q_i are the current quality scores.

- k**DPP + heuristic (threshold).** We sample the set of items from a kDPP after removing articles whose similarity to the previously selected articles exceeds a predetermined threshold. At threshold > 1, the heuristic is equivalent to the kDPP.

- **M-kDPP.** We sample the set of items from the M-kDPP transition distribution given the items selected at the previous time step. The L-ensemble transition kernel is as in (30), with L defined as for the kDPP.

The learning algorithm is summarized in Algorithm 5.

4.2 LIKELIHOOD-BASED ALTERNATIVE

Instead of the additive learning rule proposed above, one could instead take advantage of the probabilistic nature of the M-DPP and perform likelihood-based learning, which has associated theoretical guarantees. In particular, based on a sequence of user feedback, we could solve for the penalized DPP maximum likelihood estimate of $q^{(t)} = [q_1^{(t)}, \ldots, q_N^{(t)}]$ as:

$$\arg\max_q \prod_{t=1}^{t} \mathcal{P}_q(\{a_i^{(t)}\} \subseteq \boldsymbol{Y}_t, \{b_i^{(t)}\} \cap \boldsymbol{Y}_t = \emptyset) + \lambda ||q||_2, \tag{33}$$

where $\mathcal{P}_q$ is a DPP with L-ensemble kernel defined by quality scores q and λ is a regularization parameter. We have

$$\mathcal{P}_q(\{a_i^{(t)}\} \subseteq \boldsymbol{Y}_t, \{b_i^{(t)}\} \cap \boldsymbol{Y}_t = \emptyset) = \left(1 - \mathcal{P}_q(\{b_i^{(t)}\} \subseteq \boldsymbol{Y}_t \mid \{a_i^{(t)}\} \subseteq \boldsymbol{Y}_t)\right) \cdot \mathcal{P}_q(\{a_i^{(t)}\} \subseteq \boldsymbol{Y}_t), \tag{34}$$

which has computable terms in a DPP given the quality scores q. The M-DPP has obvious extensions. However, in both cases the objective function is not convex so computations are intensive and only converge to local maxima. Due to its simplicity and good performance in practice (see Sec. 5.2), we use the heuristic algorithm described previously for illustrating the behavior of the M-DPP.

5 EXPERIMENTS

We study the performance of the M-kDPP for selecting daily news items from a selection of over 35,000 New York Times newswire articles obtained between January and June of 2005 as part of the Gigaword corpus (Graff and Cieri, 2009). On each day of a given week, we display 10 articles from a base set of the roughly 1400 articles written that week. This process is repeated for each of the 26 weeks in our dataset. The goal is to choose a collection of articles that is high quality but also diverse, both marginally and between time steps.

To examine performance in the absence of confounding issues of quality learning, we first consider a scenario in which the quality scores are fixed. Here, we measure both the diversity and quality of articles chosen each day by the different methods. We then turn to quality learning based on user feedback to examine how the properties of the M-kDPP influence the discovery of a user's preferences.

5.1 FIXED QUALITY

Similarity To generate similarity features ϕ_i, we first compute standard normalized tf-idf vectors, where the idf scores are computed across all 26 weeks worth of articles. We then compute the cosine similarity between all pairs of articles. Due to the sparsity of the tf-idf vectors, these similarity scores tend to be quite low, leading to poor diversity if used directly as a kernel matrix. Instead, we let the similarity features be given by binary vectors where the jth coordinate of ϕ_i is 1 if article j is among the 150 nearest neighbors of article i in that week based on our cosine distance metric, and 0 otherwise.

Quality In the fixed scenario, we need a way to assign quality scores to articles. A natural approach is to score articles based on their proximity to the other articles; this way, an article that is close to many others (as measured by cosine similarity) is considered to be of high quality. In this data set, for example, we find that there is a large cluster of articles that talk about *politics* and articles that fall under this topic generally have much higher quality than articles that talk about, say, *food*. To model this, we compute quality scores as $q_i = \exp(\alpha d_i)$, where d_i is the sum of the cosine similarities between article i and all other articles in our collection and α is a hyperparameter that determines the dynamic range. We chose $\alpha = 5$ for our data set, although a range of values gave qualitatively similar results.

For each method, we sample sets of articles on a daily basis for each of the 26 weeks. To measure diversity within a time step, we compute the average cosine similarity between articles chosen on a given day. We then subtract the result from 1 so that larger values correspond to greater diversity. Diversity between time steps is obtained by measuring the average cosine similarity between each article at time t and

Table 1: Average Diversity and Quality of Selected Articles

Method	Marginal diversity	1-step diversity	2-step diversity	Quality
M-kDPP	0.899	0.849	0.843	0.654
k-DPP	0.896	0.786	0.779	0.668
k-DPP + heuristic (0.4)	0.904	0.849	0.804	0.651
k-DPP + heuristic (0.2)	0.946	0.891	0.889	0.587
Weighted Rand.	0.750	0.681	0.677	0.756
Uniform Rand.	0.975	0.949	0.947	0.457

the single most similar article at time $t+1$ (or $t+2$ for 2-step diversity), and again subtracting the result from 1. We also report the average quality score of the articles chosen across all 182 days. All measures are averaged over 100 random runs; statistical significance is computed by bootstrapping.

Table 1 displays the results for all methods. The M-kDPP shows a marked increase in between-step diversity, on average, compared to the kDPP and weighted random sampling. All of the differences are significant at 99% confidence. The average marginal diversities for the M-kDPP and kDPP are statistically significantly higher than for weighted random sampling, but are not statistically significantly different from each other. This is to be expected since, as we have seen in Sec. 3, the marginal distribution for the M-kDPP does not greatly differ from the kDPP process. On the other hand, the uniform sampling shows much higher diversity than the other methods, which can be attributed to the fact that it is a purely exploratory method that ignores the quality of the articles it chooses.

Table 1 also shows the average quality of the selected articles. The weighted random sampling chooses, on average, higher quality articles compared to the rest of the methods since it does not have to balance issues of diversity within the set. The kDPP on average chooses slightly higher quality articles than the M-kDPP, perhaps due to the additional between-step diversity sought by the M-kDPP; however, the difference is not statistically significant. It is evident from Table 1 that the M-kDPP achieves a balance between the diversity of the articles it chooses (both marginally and across time steps) and their quality.

As for the kDPP + heuristic baseline, our experiments show that by tuning the threshold carefully we can mimic the performance of the M-kDPP, but without the associated probabilistic interpretation and theoretical properties. When the threshold is too low, quality degrades significantly.

5.2 LEARNING PREFERENCES

We also study the performance of the M-kDPP when learning from user feedback, as outlined in Sec. 4. For simplicity, we use only a week's worth of news articles (1427 articles). To create feature vectors, we first generate topics by running LDA on the entire corpus (Blei et al., 2003). We then manually label the most prevalent 10 topics as *finance*, *health*, *politics*, *world news*, *baseball*, *football*, *arts*, *technology*, *entertainment*, and *justice*, and associate each article with its LDA-inferred mixture of these topics (a 10-dimensional feature vector f_i). We define a synthetic user by a sparse topic preference vector (0.7 for *finance*, 0.2 for *world news*, 0.1 for *politics*, and 0 for all other topics), and preselect as "preferred" the 200 articles whose feature vectors f_i maximize the dot product with the user preference vector.

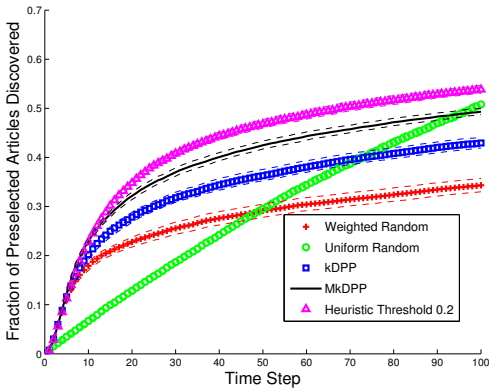

Figure 2: Performance of the methods at recovering the preselected preferred articles. Solid lines indicate the mean over 100 random runs, and dashed lines indicate the corresponding confidence intervals, computed by bootstrapping.

Similar to our previous experiment, we define the similarity features between articles to be binary vectors based on 50 nearest neighbors using the tf-idf cosine distances. The quality is defined as in Sec. 4, $q_i^{(t)} = \exp(\theta^{(t)\top} f_i)$, where f_i is the feature vector of article i (based on the mixture of topics) normalized to sum to 1. We set the learning rate $\eta = 2$; however, varying η did not change the qualitative behavior of each method, only the time scale at which these behaviors became noticeable. We also note that although we base the similarity on 50 nearest neighbors, the results were not sensitive to the size of this neighborhood.

The goal of this experiment is to illustrate how the different methods balance between exploring the space of all articles to discover the 200 preselected articles (*recall*) and exploiting a learned set of features to keep showing preferred articles (*precision*). On one end of the spectrum, uniform sampling simply explores the space of articles without taking advantage of the user feedback, leading to high recall and low precision. On the other end, the weighted random sampling fully exploits the learned preference in selecting articles, but does not have a mechanism to encourage exploration. We demonstrate that the M-kDPP balances these two extremes, taking advantage of the user feedback while also exploring diverse articles.

Results We use each method to select 10 articles per day over a period of 100 days, using the current quality scores $q^{(t)}$ on each day t. We measure recall by keeping track of the fraction of preselected preferred articles (out of the 200 total) that have been displayed so far. We also compute, out

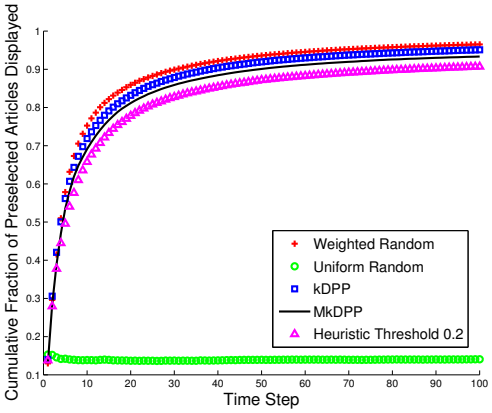

Figure 3: Cumulative fraction of preferred articles displayed to the user.

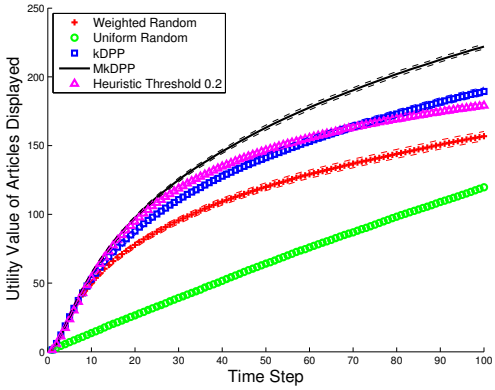

Figure 4: Performance measured by a marginally decreasing utility function.

of the 10 articles shown on a given day, the fraction that are preferred. This serves as a measure of precision. All measures are averaged over 100 random runs.

Figure 2 shows the recall performance of the methods we tested. Uniform sampling discovers the articles at a somewhat linear rate of about 5% per day; given a larger base set relative to the size of the preferred set, however, we would expect a slower rate of discovery. The methods that incorporate user feedback discover a larger set of preferred articles more rapidly by harnessing learned features of the user's interests. The M-kDPP dominates both the kDPP and weighted random sampling in this metric since it encourages exploration by introducing both marginal and between-step diversity of displayed articles. In contrast, the kDPP does not penalize repeating similar marginally diverse sets and the weighted random sampling does not have any explicit mechanism for exploration. It takes uniform random sampling nearly 100 time steps to discover the same number of unique preferred articles as the M-kDPP. For the sake of clarity, we omit the results of kDPP + heuristic with threshold 0.4 since they are not statistically significantly different from the M-kDPP. The supplementary material includes a randomly selected example of the articles displayed on days 99 and 100 for the various methods.

Figure 3 shows the cumulative fraction of displayed articles that were preferred, reflecting precision. (The supplement includes a sample non-cumulative version of Figure 3.) All methods besides uniform sampling quickly achieve high precision. Weighted random sampling displays the largest number of preferred articles per day, almost always having precision of at least 0.9. However, as we have observed, this large precision is at the cost of lower recall. In particular, weighted random sampling quickly homes in on features related to a small subset of preferred articles, thereby increasing the probability of them being repeatedly selected with no force to counteract this behavior. As expected, by only requiring marginal diversity, the kDPP achieves slightly higher precision than the M-kDPP on average (both typically above 0.8), but again at the cost of reduced exploration. Overall, the differences in precision between these methods are not large. In many applications, having 8 out of 10 results preferred may be more than sufficient.

Finally, to examine the balance between exploration and exploitation, we compute a metric based on the idea of marginally decreasing utility. Under this metric, at every time step, the user experiences a utility of 1 for each preferred article shown for the first time. If a previously displayed preferred article is once again chosen, the user gets a utility of $\frac{1}{l+1}$ where l is the number of times that article has appeared in the past. The underlying assumption is that a user benefits from seeing preferred articles, but in decreasing amounts as the same articles are repeatedly displayed. Figure 4 shows the performance of the methods under this utility metric; the M-kDPP scores highest.

6 CONCLUSION

We introduced the Markov DPP, a combinatorial process for modeling diverse sequences of subsets. By establishing the theoretical properties of this process, such as stationary DPP margins and a DPP union process, we showed how our construction yields sets that are diverse at each time step as well as from one time step to the next, making it appropriate for interactive tasks like news recommendation. Additionally, by explicitly connecting with DPPs, further properties of M-DPPs are straightforwardly derived, such as the marginal and conditional expected set cardinality.

We showed how to efficiently sample from a M-DPP, and found empirically that the model achieves an improved balance between diversity and quality compared to baseline methods. We also studied the effects of the M-DPP on learning, finding significant improvements in recall at minimal cost to precision for a news task with user feedback.

Abstract

Empty taxi cruising represents a wastage of resources in the context of urban taxi services. In this work, we seek to minimize such wastage. An analysis of a large trace of taxi operations reveals that the services' inefficiency is caused by drivers' greedy cruising behavior. We model the existing system as a continuous time Markov chain. To address the problem, we propose that each taxi be equipped with an intelligent agent that will guide the driver when cruising for passengers. Then, drawing from AI literature on multi-agent planning, we explore two possible ways to compute such guidance. The first formulation assumes fully cooperative drivers. This allows us, in principle, to compute system-wide optimal cruising policy. This is modeled as a Markov decision process. The second formulation assumes rational drivers, seeking to maximize their own profit. This is modeled as a stochastic congestion game, a specialization of stochastic games. Nash equilibrium policy is proposed as the solution to the game, where no driver has the incentive to singly deviate from it. Empirical result shows that both formulations improve the efficiency of the service significantly.

1 INTRODUCTION

Taxis are a major mode of transport in every urban city in the world. In Singapore, as of April 2009, there were about 24,000 taxis and 87,000 licensed drivers, providing around 850,000 trips daily. These are operated by a small number of companies. The largest company, ComfortDelgro, operates over 15,000 taxis, and captures the majority of the market share in terms of ridership. Like many congested cities in the world, commuters in Singapore often view taxis as a more efficient mode of transport compared to private cars. Data from the Singapore Land Transport Authority (the regulatory agency for land transportation) show that taxis on average chalk up higher mileage than private cars, with single-shift taxis traveling some 120,000 km a year. More than a third of this travel is empty cruising, as shown in the next section, see (Tan et al., 2009) as well, which represents a significant wastage of resources.

Taxi services have been studied extensively in the literature. Research has been conducted to investigate the services' demand-supply interaction and the resulting market equilibrium (Cairns and Liston-Heyes, 1996; Yang et al., 2002). These studies aim to predict the economic consequences of regulatory policies, such as entry restriction and fare control. At the operational level, quantitative models have been built to capture, for example, passengers' and drivers' bilateral searching behavior (Wong et al., 2005). While these models tend to be descriptive, our work is operative by nature. We seek to provide solutions to a specific problem, namely, we improve the inefficiency of existing cruising policy by providing alternative policies derived from multi-agent planning and decision making models. We believe the public transport arena offers a rich domain for application of multi-agent concepts and methodologies.

We start by analyzing a dataset obtained from a major taxi operator, which traces the movement of a large number of taxis in Singapore. Using the data for the month of July 2009, our analysis shows that the current system's inefficiency, measured in terms of cruising hours, is due to the inherently greedy behavior of drivers. This, in turn, is caused by the lack of visibility in regards to the distribution of cruising taxis on the network at different time periods. We then model the existing taxi service by a continuous-time Markov chain, whose parameters are derived from the dataset. The result is used as the baseline for empirical com-

parison with our approach.

We proceed to propose two models: a cooperative and a non-cooperative model. In our formulations, each driver is endowed with a guidance agent that provides suggestions on how to cruise in search of passengers. In the first formulation, we assume that each driver is fully cooperative, and therefore willing to follow a centralized policy (that could be suboptimal for him/her individually). This allows us, in principle, to compute the system-wide optimal policy, where the objective is to maximize overall occupied time. For this purpose, we model the problem as a Markov decision process. In the second formulation, we assume that drivers are rational who seek to maximize their respective occupied time. Here, there is an implicit competition among drivers, simply because an increase in the number of cruising taxis in a zone decreases each driver's chance of finding passengers within a given time. This leads directly to a game theoretic formulation. We model the problem as a stochastic congestion game (a specialization of stochastic games) and seek to find a Nash equilibrium policy. Given an equilibrium policy, no driver has the incentive to singly deviate from it. Both problems are solved for finite horizon using value iteration coupled with a sampling technique.

There has been a surge of interest, in recent years, among AI and complexity theory communities in computational problems related to game theory. The central problem in the area is the computation of Nash equilibrium in different game settings. Classical algorithms to solve the standard simultaneous games have relied on homotopy methods, which solve fixpoint (one instance of which is the Nash equilibrium) problems. The most well-known of such methods is the Lemke-Howson algorithm. See (Herings and Peeters, 2009) for a recent survey, and (Goldberg et al., 2011) for a discussion on the complexity of such methods. Non-homotopy attempts in the literature include enumeration of strategy supports (Porter et al., 2004) and mixed-integer programming (Sandholm et al., 2005).

In the setting of dynamic games, specifically in stochastic games (Shapley, 1953), the problem of computing Nash equilibrium has been cast in the context of multiagent reinforcement learning, first introduced by (Littman, 1994), who shows the convergence of value iteration in 2-player zero-sum stochastic games. (Hu and Wellman, 2003) attempts to generalize the result to n-player general-sum games by extending Q-learning algorithm. Their algorithm converges to Nash equilibrium in a restrictive case. Recent attempt by (Kearns et al., 2000) proposes an algorithm that converges to an equilibrium-like joint policy but not Nash equilibrium. Finding an algorithm that converges to Nash equilibrium in n-player general-sum stochastic games remains an important open problem.

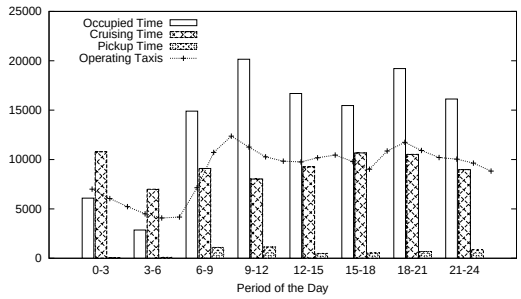
Despite the tremendous interest, many interesting real-world problems (such as the one presented here) are so large that even the best algorithms have no hope of computing an equilibrium directly. Furthermore, it has been shown that the problem is likely to be intractable even for the case of two-player simultaneous games (Chen and Deng, 2006), it being complete for the complexity class PPAD. The standard approach to overcome this problem is to construct a smaller game that is similar to the original game, and solve the smaller game. Then, the solution is mapped to a strategy profile in the original game (Ganzfried and Sandholm, 2011).

In this work, we tackle a moderate-size real-world problem, by solving for finite horizon approximate equilibrium. Our aim is to extend this solution approach to cover the full scale problem in the future. Our experimental results show that the optimal policy (derived from the cooperative model) manages to reduce the cruising time of the existing policy by approximately 30%. This result may be viewed as what can be achieved theoretically. In real-life implementation, however, the improvement will be closer to that of equilibrium policy, which is approximately 20%.

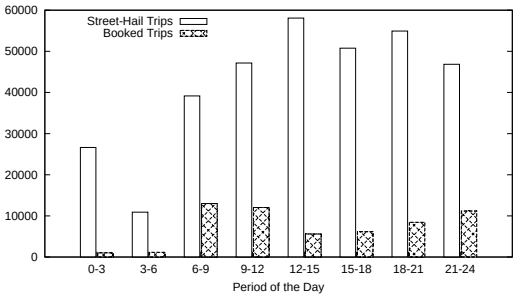
2 ANALYSIS OF CURRENT SYSTEM

Figure 1 and 2 summarize the taxi operation on weekdays (Mon-Thu) for the month of July 2009. In Figure 1a, we see the comparison of average daily time spent between delivering passengers, cruising, and picking up passengers (for booked trips) for different periods of the day. The average number of operating taxis is also shown in the figure. To book a taxi, passengers may send their request to the central operator and specify their current location. The central operator will then broadcast the request to cruising taxis around the specified location. Drivers who receive the request may bid for the job by specifying the time required to reach the pickup point. The job is given to the driver with the shortest pickup time. The proportion of street-hail vs. booked trips, for different periods of the day, is shown in Figure 1b. From Figure 1a, we observe that taxi cruising time is almost constant throughout the day, accounting for roughly half of the total operating hours. On the other hand, pickup time accounts for only a small percentage of operating hours. For this reason, in this work, we are focusing on reducing the cruising time for street-hail jobs.

Figure 2 describes the cruising behavior of drivers. In

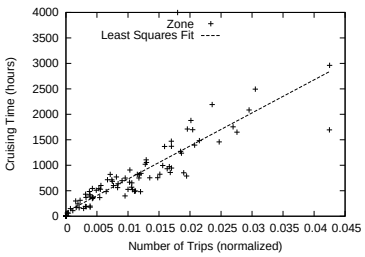


(a) The histogram shows the average total time spent daily, in hours, on: delivering passengers, cruising, and reaching pickup points (for booked trips) respectively, in different periods of the day. The curve shows the number of operating taxis.

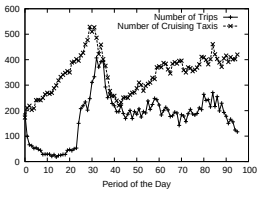


(b) The histogram shows the average daily number of street-hail and booked trips respectively in different periods.

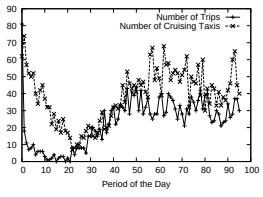
Figure 1: Summary of weekday data for July 2009



(a) The correlation between trip frequency and cruising time in a zone



(b) Number of trips vs. cruising taxis in a high trip-frequency zone with peaks



(c) Number of trips vs. cruising taxis in a low trip-frequency zone

Figure 2: Inefficiency of existing cruising policy

Figure 2a, we see that cruising time is high for zones with a high number of available trips. This indicates that drivers are spending time cruising in high trip-frequency zones. The same can be observed from Figure 2b and 2c. Figure 2b shows that taxis are entering high trip-frequency zones in anticipation for the surge of passengers. The number of cruising taxis will drop with the surge, but starts to build up again for the next surge, and the cycle continues. On the other hand, in low trip-frequency zones, except for early morning hours, the number of cruising taxis stays proportional to trip-frequency. We can conclude that drivers are employing a greedy cruising policy, spending a large amount of time cruising in high trip-frequency zone. This is one of the causes for the system's inefficiency, which is verified in the empirical study, when this policy is substituted for better cruising policies.

2.1 A MODEL FOR THE EXISTING SYSTEM

In this section, we model the aggregate behavior of a taxi service as a continuous time Markov chain. In our model, the taxi service operates on a road network which can be divided into logical cruising zones. We denote the network of zones by a directed graph $G = (N, E)$. At any point of time, a taxi is in one of the following states, which corresponds to the states in the Markov chain $\mathcal{S} = \{\mathcal{O}_{kl}, \mathcal{C}_k, \mathcal{W}_k | k, l \in N\}$: (1) the taxi is occupied and is delivering its passenger from zone k to l, denoted by the state $\mathcal{O}_{kl}$, or (2) the taxi is empty and cruising in a zone k, denoted by $\mathcal{C}_k$, or (3) the taxi is in zone k but not in operation, denoted by $\mathcal{W}_k$. Here, we assume that drivers have uniform cruising behavior that are independent of each other. As an example, Figure 3 shows a subset of Singapore's road network and the corresponding Markov chain, modeling the taxi service operating on the network.

In a continuous time Markov chain, the time spent in a state before moving to another state is a continuous random variable that is exponentially distributed. The rates of transition between the states constitute the generator matrix (or Q-matrix) of the Markov chain. In our model, the generator matrix consists of the following four components. The first component, $\{\lambda_{kl} | (k, l) \in E\}$, describes a driver's cruising behavior. Since a driver does not have visibility in regards to the state and location of other drivers, we can assume that they are approximately independent of each other. The second component, $\{\pi_{kl} | k, l \in N\}$, describes the likelihood of finding passengers in a zone, where π_{kl} is the rate of finding passengers in zone k with a destination point in zone l. Assuming independence for π_{kl}, the total rate of finding passengers in zone k is given by $\sum_l \pi_{kl}$ (a combination of Poisson

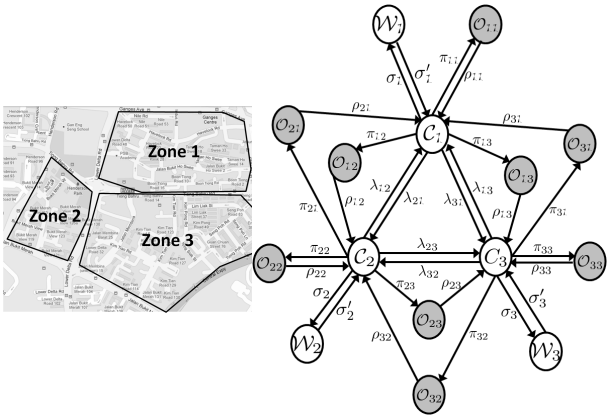


Figure 3: An example of a road network, divided into its cruising zones, and the corresponding Markov chain, modeling a taxi operating on the network. The shaded nodes indicate the states where the taxi is occupied. Here, we assume that taxis are uniform and independent of each other.

processes). The third component, $\{\rho_{kl}|k,l \in N\}$, describes the time needed to deliver passengers to their destination point. The nondeterminism of these variables is due to the variability of pickup and drop-off points within zones and the congestion on the road network. The forth component, $\{\sigma_k, \sigma'_k|k \in N\}$, describes the likelihood of a driver taking a break within a zone (σ_k) and the length of the break (σ'_k). Most taxis are operated by two or more drivers taking turns continuously. This accounts for the nondeterminism of the forth component.

We define the system efficiency as the steady state (stationary) probability of a taxi being in the occupied state. Let $\theta(s)$, for $s \in \mathcal{S}$, denote the steady state probability of being in the state s. This probability distribution can be obtained by solving the following system of equations:

$$\begin{aligned}
\forall k \in N, \quad & \sum_{l:(l,k)\in E} \lambda_{lk}\theta(\mathcal{C}_l) + \sum_{l:l\in N} \rho_{lk}\theta(\mathcal{O}_{lk}) + \sigma'_k\theta(\mathcal{W}_k) \\
& = \left(\sum_{l:(k,l)\in E} \lambda_{kl} + \sum_{l:l\in N} \pi_{kl} + \sigma_k\right)\theta(\mathcal{C}_k), \\
\forall k,l \in N, \quad & \pi_{kl}\theta(\mathcal{C}_k) = \rho_{kl}\theta(\mathcal{O}_{kl}), \\
\forall k \in N, \quad & \sigma_k\theta(\mathcal{C}_k) = \sigma'_k\theta(\mathcal{W}_k),
\end{aligned}$$

and normalizing the solution such that $\sum_{s\in\mathcal{S}} \theta(s) = 1$. The steady state probability of a taxi being in the occupied state is thus given by $\sum_{k,l\in N} \theta(\mathcal{O}_{kl})$.

We estimate the transition rates of the Markov chain using the dataset. The random variables cruising time (with rate λ_{kl}) and passenger find time (with rate π_k)

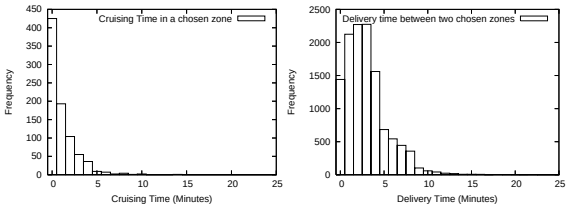

Figure 4: The frequency histograms (for one day) for cruising time in a randomly chosen zone, and delivery time between two randomly chosen zones, respectively.

can be estimated accurately with exponential distributions. The other variables, however, are closer to Erlang distributions than exponential distributions. Figure 4 shows, for example, two frequency histograms, one for each of these cases. In this work, we approximate both cases by exponential distributions using maximum likelihood estimate. These approximations are better when the zones are adequately close to each other, which is the case for Singapore.

One can derive the system efficiency once the parameters of the Markov chain are obtained. Since we also like to compute efficiency under different customer arrival rates and different numbers of operating taxis (for empirical study), we model the passenger-driver dynamics in a zone as an M/M/1 queue. Consider the subset of the Markov chain consisting only the states $\{\mathcal{C}_k|k \in N\}$ and the transitions rate between them $\{\lambda_{kl}|(k,l) \in E\}$. Each zone is modeled as a FIFO queue, where its arrival rate is the arrival rate of cruising taxis in the zone, and its service rate is the passengers arrival rate in the zone. Let μ_k denote the passengers arrival rate in zone k, then the waiting time in the queue (queueing time + service time) is exponentially distributed with the following rate, which we associate with π_k:

$$\pi_k = \mu_k - n\left(\sum_{l:(l,k)\in E} \phi(\mathcal{C}_l)\lambda_{lk}\right) \quad ,$$

where n is the number of taxis in operation and $\phi(\mathcal{C}_l)$ the steady state probability of being in the state $\mathcal{C}_l$. The steady state probabilities ϕ can be obtained, similar to θ, by solving the following system of equations:

$$\forall k \in N, \quad \sum_{l:(l,k)\in E} \lambda_{l,k}\phi(\mathcal{C}_l) = \phi(\mathcal{C}_k) \sum_{l:(k,l)\in E} \lambda_{kl} \quad ,$$

subject to $\sum_{k\in N} \phi(\mathcal{C}_k) = 1$. Now, given the drivers' cruising behaviors (in the form of smaller Markov chain parameterized by $\{\lambda_{kl}|(k,l) \in E\}$), travel time information $\{\rho_{kl}|k,l \in N\}$, and nonoperating profile $\{\sigma_k, \sigma'_k|k \in N\}$, we can derive the system efficiency as the function of passenger arrival rates $\{\mu_k|k \in N\}$ and

the total number of taxis n, by first constructing the full Markov chain, and then deriving its steady state probabilities.

3 A COOPERATIVE MODEL

The cooperative model is based on Markov decision process, which is a special case of stochastic games, where there is only one player. The player, in this case, is a central operator whose actions are all possible joint actions of the drivers, and whose objective is the overall occupied time of the service. The model is similar to the noncooperative case. The difference lies in the formulation of the utility function. In the noncooperative case, we have a set of utility functions to be optimized simultaneously, while in the cooperative case, we have a single aggregated utility function. We choose to present our models under the more general setting of stochastic games (next section). We will highlight the differences for the cooperative case.

4 A NONCOOPERATIVE MODEL

Stochastic games (Shapley, 1953; Littman, 1994) are a generalization of Markov decision processes to a multi-agent setting by allowing the state transitions to be influenced by their joint action. They are also a generalization of sequential games with perfect information, by introducing different states. The state (and thus the payoff matrix) changes as a result of both nature and the joint action of the agents. In congestion games, agents share a set of facilities (facilities can be viewed as resources, such as machines), and the utility an agent derives from using a facility reduces as the number of agents using the same facility increases. In the taxi context, the facilities correspond to the zones where taxi agents can cruise. Each zone has a fixed arrival rate of passengers, and therefore, an increase in the number of cruising taxis in the zone, decreases the likelihood that each would find passengers within a certain time period. Stochastic congestion games therefore are a generalization of congestion games, allowing the games to be played indefinitely. They are also a specialization of stochastic games, to the case where the underlying games are congestion games. A state in a stochastic congestion game defines an assignment of agents to facilities, and transitions to a new state are dependent on the old state and the agents' joint action. In this work, we consider only games with finite horizon.

4.1 STOCHASTIC CONGESTION GAMES

Formally, a finite stochastic congestion game (SCG) Γ is a tuple $(I, J, P, \mathcal{R})$, where

- $I = \{1, \ldots, n\}$ is the set of agents.
- $J = \{1, \ldots, m\}$ is the set of facilities. An action of an agent i, denoted by a^i where $a^i \in J$, is to choose a facility to which it would like to be assigned. We denote an agents' joint action by $a = (a^1, \ldots, a^n)$ and the set of possible joint actions by A, that is, $A = J^n$. Next, we denote by S, the set of possible states, where a state $s \in S$ is an assignment of agents to facilities, and we define s_j as the number of agents assigned to facility j in the state s.
- $P : S \times A \to \triangle(S)$ is the state transition function. For convenience, we will also write $P(s, a, s')$ for the probability that the next state is s' given that the current state is s and the players' joint action is $a = (a^1, \ldots, a^n) \in A$,
- $\mathcal{R} = \{r_j\}_{j \in J}$ is the reward function, where each $r_j : \{0, \ldots, n\} \to \mathbb{R}$ is a nonincreasing function that maps the number of agents assigned to facility j to the reward that each of the agents in j receives. We define $s(i, j)$ such that $s(i, j) = 1$ if agent i is assigned to facility j in the state s, and $s(i, j) = 0$ otherwise. The reward received by agent i in a state s, denoted by $R^i(s)$, is thus given by $\sum_{j \in J} s(i, j) r_j(s_j)$.

The game proceeds in steps, starting from some initial state s_T (the subscript indicates the number of remaining steps). In each step, the agents first observe the current state s_t, the number of remaining steps t, and simultaneously choose actions according to their respective policy. An agent i's policy is the function $\pi^i : S \times \{1, \ldots, T\} \to \triangle(J)$, where $\pi^i(s_t, t)$ computes agent i's mixed strategy, i.e., a probability distribution over the set of facilities, given the current state s_t and the number of remaining steps t. Each agent i's action in this step, denoted by a^i_t, is then drawn from the distribution given by $\pi^i(s_t, t)$, forming the joint action $a_t = (a^i_t, \ldots, a^n_t)$. Nature then selects the next state s_{t-1} according to the probabilities given by $P(s_t, a_t)$. In the new state s_{t-1}, each agent i receives $R^i(s_{t-1})$ as its reward, and the game proceeds to the next step.

Given a possible outcome of the game, agent i's utility, denoted by U^i, is defined such that

$$U^i_T(s_T, a_T, s_{T-1}, \ldots, s_1, a_1, s_0) = \sum_{t=0}^{T-1} R^i(s_t).$$

A Nash equilibrium of the game is a joint policy π, such that, for each agent i, π^i maximizes the expected utility of agent i given that the other players follow their respective policy specified by π. The expectation is taken over all possible outcomes of the game. For the cooperative case, there is only one utility formed

by summing up individual agent's utility. Here, we seek to find a joint policy that maximizes the expected value of this utility.

4.2 MODELING TAXI SYSTEM AS AN SCG

The drivers correspond to the set of agents I. The set of facilities J corresponds to the states of the Markov chain, $\mathcal{S} = \{\mathcal{C}_k, \mathcal{O}_{kl}, \mathcal{W}_k | k, l \in N\}$, defined previously. We will refer to them as facilities here. A state of the game is an assignment of agents to facilities. When an agent is assigned to facility $\mathcal{C}_k$, it means that the corresponding taxi is cruising in zone k. Similarly, when it is assigned to facility $\mathcal{O}_{kl}$ and $\mathcal{W}_k$, it means that the corresponding taxi is occupied and not in operation, respectively. One step in the SCG represents the period of one minute.

Next, we define available actions and the state transition function. The set of available actions for an agent depends on the state of the agent. When in facility $\mathcal{C}_k$, the agent may take one of the following actions: $(a1)$ continue cruising in the current zone, or $(a2)$ make an attempt to move to an adjacent zone. In this state, the agent has the chance of getting a passenger and be moved to one of the facilities $\mathcal{O}_{kl}$ in the next step. Given that an agent is in facility $\mathcal{C}_k$ and takes the action $a1$, the following may happen in a step: (1) The agent manages to find a passenger with l as the destination zone. In the next step, the agent will move to facility $\mathcal{O}_{kl}$. The probability of this event happening is given by:

$$\frac{\mu_k}{n(\mathcal{C}_k)}\gamma_{kl},$$

where γ_{kl} is the probability that a passenger's destination zone is l given that its starting zone is k, and $n(\mathcal{C}_k)$ is the number of agents in facility $\mathcal{C}_k$ in the current state. γ_{kl} can be estimated by the following:

$$\gamma_{kl} \approx \frac{\pi_{kl}}{\sum_{l \in N} \pi_{kl}}.$$

The expression $\mu_k / n(\mathcal{C}_k)$ also defines the reward of the agent in this state. (2) The agent doesn't find any passenger and stays in the same facility. The probability of this event is given by: $(1 - \mu_k / n(\mathcal{C}_k))e^{-\sigma_k}$, or (3) the agent doesn't find any passenger and moves to facility $\mathcal{W}_k$ with probability $(1 - \mu_k / n(\mathcal{C}_k))(1 - e^{-\sigma_k})$. On the other hand, if the agent chooses $a2$, one of the following may occur: (1) a passenger, with destination l, is found before the agent manages to move to a new zone. The agent moves to facility $\mathcal{O}_{kl}$ in the next step. The probability of this happening is given by $\mu_k \gamma_{kl} / n(\mathcal{C}_k)$. (2) Otherwise, no passenger is found, and the agent moves to a new zone.

Algorithm FINITENASHPOLICIES(Γ, T):
Initialization phase:
  For all $s \in S$, joint action $a \in A$:
    $\pi(s, 0)[a] \leftarrow \frac{1}{|A|}$;
    For all $i \in I$:
      $V_{s,0}(a, i) \leftarrow 0$;
Iteration phase:
  For $t = 1$ to T, all $s \in S$:
    For all pure strategy profile $a \in A$, $i \in I$:
      $V_{s,t}(a, i) \leftarrow \sum_{s'} P(s, a, s') \times$
      $\left\{R^i(s') + \sum_{a'} \pi(s', t-1)[a'] V_{s', t-1}(a', i)\right\}$;
    $\pi(s, t) \leftarrow$ FINDNASH($V_{s,t}$);
  Return π;

Figure 5: Value Iteration for Finite-horizon SCGs

When in facility $\mathcal{O}_{kl}$, the agent has only one available action. It will try to deliver its passengers to their destination point and move to facility C_l. The probability of this happening in the next step is given by $1 - e^{-\rho_{kl}}$, while the probability of staying in the same facility is $e^{-\rho_{kl}}$. The reward for the agent in this state is one. Similarly, when in facility $\mathcal{W}_k$, the agent may move to $\mathcal{C}_k$ with probability $1 - e^{-\sigma'_k}$, or otherwise stays in the same zone. The reward for being in this facility is zero. Note that in our model, the move to facility $\mathcal{W}_k$ is involuntary on the part of the agents. An agent will never choose to stop its operation because of the way the reward function is structured. Rather than being an available action, the move is treated as a requirement instead, for example, when the driver has to change shift or rest.

4.3 COMPUTING EQUILIBRIUM POLICY

In this section, we describe an algorithm to computing equilibrium policy in SCGs based on value iteration algorithm, shown in Figure 5. This algorithm takes an SCG Γ, and a time horizon T as input. It outputs a vector of policies $(\pi^i(s, t))_{i \in I}$, where each π^i maps any state s, and the number of remaining steps $t \leq T$ to a mixed strategy for player i, which is a probability distribution over the set of facilities. The algorithm outputs a vector of policies that is a Nash equilibrium for the T-step SCG Γ from any start state. This algorithm is a generalization of the classical finite-horizon value iteration for Markov decision processes (Kaelbling et al., 1998). Instead of backup values, the algorithm maintains backup matrices, denoted by $V_{s,t}$. Each $V_{s,t}(a, i)$ is a function that takes a joint action a, a player i, and returns the expected utility of player i in the t-step SCG Γ, if the game starts at the state s and the first joint action of the agents is a. We can view, therefore, each $V_{s,t}$ as defining a game in the usual sense, and associated with each $V_{s,t}$ is a Nash

equilibrium $\pi(s,t)$, where $\pi^i(s,t)$ denotes the mixed strategy of player i. We denote by $\pi(s,t)[a]$ the probability assigned by $\pi(s,t)$ to the joint strategy a. Both $V_{s,t}$ and $\pi(s,t)$ are constructed iteratively. The algorithm uses the function FINDNASH that returns a Nash equilibrium given the game $V_{s,t}$. For the cooperative case, the function FINDNASH is replaced by FINDOPT which computes social optimum policy instead of Nash equilibrium.

Computing Nash equilibrium in stochastic games is a very difficult problem. See, for example, (Bowling, 2000; Hu and Wellman, 2003; Ganzfried and Sandholm, 2009) for recent works in this area. And the value iteration algorithm (for finite horizon stochastic games) is computationally very expensive for large scale problem. In this work, we employ the sparse sampling technique proposed by (Kearns et al., 2000).

5 EMPIRICAL RESULT

We run a simulation (on a macro level) to evaluate the performance of our proposed solutions. We choose, as the case study, 15 connected zones that represent the congested central business district of Singapore and its surrounding areas. We consider only passengers with origins and destinations within these zones, and restrict the cruising area of drivers to these zones as well. The number of operating taxis is 500. From the dataset we estimate the the passenger arrival rates $\{\mu_k | k \in N\}$, delivery time rate $\{\rho_{kl} | k, l \in N\}$, and taxis nonoperating profile $\{\sigma_k, \sigma'_k | k \in N\}$ for these zones in different periods. Using this setting we compare existing cruising policy (also derived from the dataset), the optimal policy (computed from the cooperative model), and the equilibrium policy (computed from the noncooperative model). The measure of comparison is cruising time. For both cooperative and noncooperative model, joint actions are computed every minute with 2-step look ahead ($T = 2$).

We simulate one day of operation on a weekday. The driver-passenger dynamics in each zone is implemented as a FIFO queue. As a passenger appears in a zone, it joins the queue associated with the zone. If there are some taxis cruising in the zone, the passenger at the head of the queue is removed and assigned to a randomly chosen taxi. The average time spent in the queue models the average passengers waiting time.

The experimental results are shown in Figures 6, 7 and 8. Figure 6 compares the average cruising time (over multiple runs) of the three policies. On average, the optimal policy and the equilibrium policy reduce the cruising time of existing policy by approximately 30% and 20% respectively. Most of the savings are obtained during the peak periods. This matches our intuition,

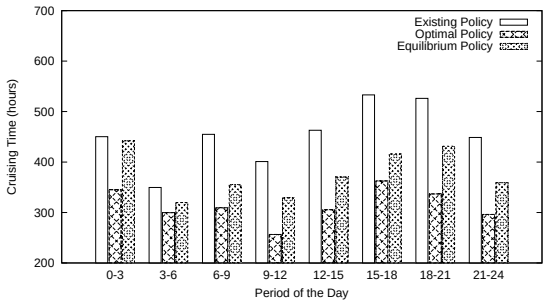

Figure 6: Comparison of cruising time between three policies. The optimal and equilibrium policies reduce the cruising time by approximately 30% and 20% respectively.

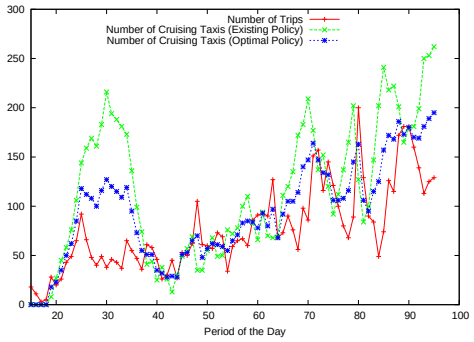

Figure 7: Number of trips vs. number of cruising taxi in a high trip-frequency zone. In general, the new policies send lower number of cruising taxis to high trip-frequency zones compared to existing policy.

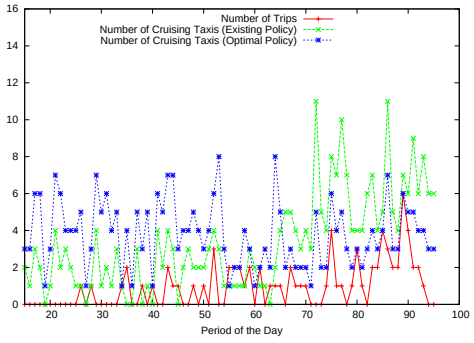

Figure 8: Number of trips vs. number of cruising taxi in a low trip-frequency zone. In general, the new policies send higher number of cruising taxis to low trip-frequency zones compared to existing policy.

that the new policies are able to better distribute cruising taxis among the zones, while the greedy policy sends too many cruising taxis to high trip-frequency zones. This is confirmed when we look at the number of trips vs. cruising taxis in both high and low trip-frequency zone (see Figure 7 and 8). The new policies are able to maintain balance between fulfilling trips requirement and managing cruising time.

6 Conclusion

We presented in this paper an interesting and useful application of Markov chains to manage an urban taxi service. The basic premise is the need to minimize cruising time (and therefore maximize utilization) of the taxis. There are several assumptions we made for this to work. We assume that each taxi has a device that guides the taxi driver. Using MDPs the system then generates a policy that optimizes cruising among all taxis. We showed, with the use of real data from a taxi operator in Singapore for the study, a cooperative model where taxis follow instructions and a noncooperative one where drivers compete with one another. Our study also assumes rational drivers that try to maximize the time their cars are occupied. For future works, we would need to incorporate real-world behavior of the passengers as well as relax the independence assumption of passengers and their destinations.

Uncertain Congestion Games with Assorted Human Agent Populations

Asrar Ahmed, Pradeep Varakantham, Shih-Fen Cheng
School of Information Systems, Singapore Management University, Singapore 178902
{masrara,pradeepv,sfcheng}@smu.edu.sg

Abstract

Congestion games model a wide variety of real-world resource congestion problems, such as selfish network routing, traffic route guidance in congested areas, taxi fleet optimization and crowd movement in busy areas. However, existing research in congestion games assumes: (a) deterministic movement of agents between resources; and (b) perfect rationality (i.e. maximizing their own expected value) of all agents. Such assumptions are not reasonable in dynamic domains where decision support has to be provided to humans. For instance, in optimizing the performance of a taxi fleet serving a city, movement of taxis can be involuntary or non-deterministic (decided by the specific customer who hires the taxi) and more importantly, taxi drivers may not follow advice provided by the decision support system (due to bounded rationality of humans).

To that end, we contribute: (a) a general framework for representing congestion games under uncertainty for populations with assorted notions of rationality. (b) a scalable approach for solving the decision problem for perfectly rational agents which are in the mix with boundedly rational agents; and (c) a detailed evaluation on a synthetic and real-world data set to illustrate the usefulness of our new approach with respect to key social welfare metrics in the context of an assorted human-agent population.

An interesting result from our experiments on a real-world taxi fleet optimization problem is that it is better (in terms of revenue and operational efficiency) for taxi drivers to follow perfectly rational strategies irrespective of the percentage of drivers not following the advice.

1 Introduction

Congestion games [5] and its variants have numerous applications in domains ranging from urban transportation [14] (e.g. movement of vehicles between different regions of an area) to capturing company dynamics in a congested industry [12] (e.g., strategizing on marketing investments by different companies selling the same product). There are many interesting challenges that exist in these problem domains: (a) Representing and accounting for implicit interactions between agents. For example, vehicles trying to get on the same road are implicitly competing (even though there may not be an actual intention to compete); (b) large-scale nature of problems; (c) involuntary movements of agents (in some decision epochs, agents might need to *follow* given instructions and cannot freely choose their own actions); and (d) accounting for humans in the loop, who may not follow perfectly rational policies.

While existing research in congestion games is extensive, we are unaware of research that addresses the issues mentioned in points (b), (c) and (d) mentioned above. To that end, we make three key contributions in this paper: (1) By extending on the cognitive hierarchy model [1] (introduced in behavioral game theory), we introduce a general model to represent the decision problem for perfectly rational agents in an agent population of assorted rationalities; (2) A scalable approach called Soft-max based Flow update for Assorted Populations (SoFA) for solving the decision problem of perfectly rational agents in an assorted population; and (3) Finally, we provide a detailed evaluation on both real-world and synthetic data sets for the taxi fleet optimization problem.

This paper is motivated by a real-world problem of improving the performance of a taxi fleet. The decision making problem faced by a typical taxi driver is interesting both practically and theoretically, since a driver needs to make both voluntary (driver's own decision) and involuntary (when customers board taxis) movements. In such a problem, customers are considered

as the resources, due to whom an implicit competition exists between taxis. Since demands are both zone-dependent and time-dependent, the problem becomes even more challenging. The goal here is to provide decision support to taxi drivers such that the operational efficiency of the fleet and the revenues obtained are improved. Similar problems exist in analyzing industry dynamics (where different companies strategize to maintain their competitive advantage) and labor mobility (where individuals reason about their movement to different geographical regions). Although the concept of *user equilibrium* [10] is well-adopted in modeling either static or dynamic traffic route selection, it cannot be applied in this class of problems due to the presence of involuntary movements.

Experimentally, we are able to show that SoFA converges on all our problems (both real-world and synthetic ones) with assorted human-agent populations (agents with different levels of rationality). It is an important result since we are able to show that if our algorithm converges, the solution for perfectly rational agents is an equilibrium strategy (i.e., no incentive w.r.t expected value). Another nice empirical result of our approach in the taxi fleet optimization problem is that perfectly rational drivers (i.e. ones who adopt policies suggested by SoFA) always outperform agents who do not follow the suggested policies.

2 Motivation: Taxi Fleet Optimization

Our research is motivated by the problem of optimizing a fleet of self-interested taxis[1]. For a fleet of taxi population $\mathcal{P}$, serving a city divided into a set of zones M, the goal is to provide decision support for taxi drivers to independently decide a sequence of zones to roam in.

The demand fulfillment is modeled at zone-level, assuming demands are common knowledge among all taxis. If the number of taxis in a particular zone during a time period is fewer than the number of customers, all taxis will be hired (the determination of their destinations is described in the following paragraph). Otherwise, only a fraction of the roaming taxis (up to the number of customers) will be hired.

The movements of taxis between zones depend on whether they are hired or not. If a taxi is hired, the movement is involuntary (decided by the customer onboard) and is governed by the probability distribution computed from the outgoing flows of customers to different zones. Therefore, if a taxi is hired by a customer in zone i, the probability of moving to zone j is computed based on the fraction of customers moving from zone i to j over all flows out of zone i. Furthermore, a hired taxi in such a case will receive a revenue of $Re^t(i,j)$ and incur a cost of $Co^t(i,j)$. On the other hand, if the taxi is not hired, the movement will be voluntary and deterministic, and the taxi will receive no revenue but incur the same cost of $Co^t(i,j)$.

The goal is to provide decision support (in terms of policies) for drivers who request for decision support on moving through the island, such that there is no incentive for them to deviate from their policies.

[1]In our definition, we assume that each taxi is driven by an independent driver (thus we use *taxi* and *taxi driver* interchangeably), who pays for all costs (e.g., monthly rent, fuel, maintenance) and keeps all earned revenue. We also assume that there will be no communication/collaboration among taxi drivers.

3 Model: DAAP

We now introduce a general framework for modeling problems such as taxi fleet optimization called the Distributed decision model for Assorted Agent Populations (DAAP). DAAP is an extension of the DDAP (Distributed Decision model for Agent Populations) model introduced by Varakantham *et al.* [7]. DAAP can be viewed as a framework for representing generalized congestion games with movement uncertainty. In particular, we generalize the notion of resources in congestion games to states and the movement uncertainty to transition functions (akin to the one in Markov Decision Problems, MDPs).

DAAP represents a subset of problems represented by the generic stochastic game model [2]. In DAAP, the transition and reward functions for an agent are dependent only on the aggregate distributions of other agent states, whereas in more general models like stochastic games the transition and reward function for an agent are dependent on specific state and action of every other agent. It should be noted that DAAP represents problems with selfish agents and hence is different to cooperative models such as DEC-POMDP.

DAAP is the tuple:

$$\left\langle \Gamma, \{\mathcal{P}_\tau\}_{\tau\in\Gamma}, \mathcal{S}, \mathcal{A}, \{\phi_\tau\}_{\tau\in\Gamma}, \{\mathcal{R}_\tau\}_{\tau\in\Gamma}, d^0, \{\mathcal{V}_\tau\}_{\tau\in\Gamma} \right\rangle,$$

where Γ represents the different agent types and $\mathcal{P}_\tau$ is the set of agents of type τ. Two agents belong to different types if they have (a) different transition (ϕ) or reward model ($\mathcal{R}$); or (b) different notion of rationality ($\mathcal{V}$). $\mathcal{S}$ corresponds to the set of states encountered by each agent. $\mathcal{A}$ is the set of actions executed by each agent. We define the set of state distributions, $D = \{d | d = \langle d_1, d_2, \cdots, d_{|\mathcal{S}|} \rangle, \sum_{s\in\mathcal{S}} d_s = |\mathcal{P}|\}$, where $\mathcal{P}$ is the set of all agents and d_s represents the number of agents in state s. d^0 represents the starting distribution of agent states. ϕ_τ models the involuntary movements of every agent of type τ and more specifically, $\phi^t_{\tau,d}(s,a,s')$ represents the probability that an agent of type τ in state $s(\in \mathcal{S})$ after taking action $a(\in \mathcal{A})$ would transition to state s', when the distribution is d

and time is t. $\mathcal{R}^t_{\tau,d}(s,a,s')$ is the reward obtained by an agent of type τ when in state s, taking action a and moving to state s' when the distribution of agents is d at time t.

$\mathcal{V}_\tau$ characterizes the rationality concept of interest to agents of type τ and represents the value function definition for agents of type τ. This is provided to capture the notion of bounded rationality (particularly for humans in the population). In this paper, we refer to the two extreme cases for bounded rationality, which are:
(a) Perfect rationality: agents compute exact best response to opponent policies;
(b) Local rationality: agents assume no other agent is present ($d^t = \mathbf{0}, \forall t$) in the system.
Further details on various rationality concepts are provided in Section 4.

The objective in solving a DAAP is to compute a policy,π_i for each agent i of type τ, such that there is no incentive for any agent to deviate from its policy, in terms of the value (i.e. $\mathcal{V}_\tau(\pi_i, \{\pi_k\}_{k\in\mathcal{P}_\tau, k\neq i})$).

3.1 Taxi Fleet Optimization as DAAP

The number of types in this problem is primarily due to varying degrees of human rationality. We will describe this in detail in Section 7.1. In representing the taxi fleet optimization as a DAAP, the key is using the transition function to represent the involuntary movement of taxis[2]. $\mathcal{P}$ is the set of taxis in the fleet, $\mathcal{S}$ is all the zones in which a taxi could be present. $\mathcal{A}$ is the set of zones to which a taxi driver wishes to move. The transition function, ϕ is computed based on the customer flow, fl between various zones. D^0 is the distribution of taxis at the starting time. Equation 1 provides the expression for computing the transition probability between states.

Intuitively, if there are fewer taxis than customers in a zone, then all taxis are hired and their transition probability to a specific zone is dependent on flows to different zones from the current zone (represented by condition **C1**). If there are more taxis in a zone than customers, then transition is dependent on whether the action (intended zone) is same as the destination zone (captured by conditions **C2** and **C3**).
C1: if $\sum_{\hat{s}} fl^t(s,\hat{s}) \geq d_s$
C2: if $a \neq s'$, $\sum_{\hat{s}} fl^t(s,\hat{s}) < d_s$
C3: if $a = s'$, $\sum_{\hat{s}} fl^t(s,\hat{s}) < d_s$

$$\phi^t_d(s,a,s') = \left\{ \begin{array}{ll} \frac{fl^t(s,s')}{\sum_{\hat{s}} fl^t(s,\hat{s})} & \mathbf{C1} \\ \frac{fl^t(s,s')}{d_s} & \mathbf{C2} \\ 1 - \frac{\sum_{\hat{s}\neq s'} fl^t(s,\hat{s})}{d_s} & \mathbf{C3} \end{array} \right\} \quad (1)$$

[2]Since the movement of taxis and their revenues (standardized meters) are identical, we do not index transition and reward model of DAAP with type.

Similar to the transition, $\mathcal{R}$ is the reward obtained based on the three conditions.

In solving the taxi optimization DAAP, our goal is to maximize expected revenue for the individual taxi drivers while reducing starvation. Since the transition function depends on the number of taxis in the zone, maximizing expected revenue implies minimizing starvation as well. In this problem domain, both the welfare metrics (revenue and starvation) are optimized at once, however, in other domains there could be multiple objectives that are not in alignment and multi-objective reasoning might be required.

4 Characterizing Rationality

A major contribution of the paper is the introduction of multiple levels of rationality to the uncertain congestion game that mimics bounded rationality of human decision makers. In the context of DAAP, this implies the computed policy will be followed differently: perfectly rational agents adopt the policy completely, while other agents only adopt the policy partially (or even not at all). To concretely represent bounded rationality, we extend on the cognitive hierarchy model developed by Camerer *et al.* [1]. Therefore, in DAAP, $\mathcal{V}_\tau$ will represent the rationality notion of an agent in terms of the cognitive hierarchy model.

Cognitive hierarchy model assumes there is a bound on the levels of reasoning agents can do and that agents differ in their levels of reasoning. *Level-0* agents are assumed to be non-strategic and either play randomly or use a heuristic. *Level-1* agents compute best response strategy by assuming all other agents in the population are *level-0*. In general, *level-L* agents compute best response strategy by assuming a distribution f across levels $\{0, 1, \ldots, L-1\}$. Camerer *et al* present a single-parameter model, called *Poisson cognitive hierarchy* model, where f is assumed to follow Poisson distribution.

We extend the cognitive hierarchy model in three ways. Firstly, the opponent distribution f is obtained from iterative Bayesian inference (details provided in Section 7.1). Secondly, the best response is computed using the *quantal best response* strategy. The quantal best response for player i to strategy s_{-i} is given by:

$$s_i(a_i) = \frac{e^{\lambda \cdot u_i(a_i, s_{-i})}}{\sum_{a'_i} e^{\lambda \cdot u_i(a'_i, s_{-i})}}.$$

For $\lambda = 0$, each action is assigned equal probability (which can be thought as completely irrational); as λ increases, quantal best response approaches standard best response (which is completely rational). Finally, we introduce the consideration of different decision horizons (referred to as T). With the above extensions, an agent's behavior can be quantified by a

three-tuple CH_QR(λ, L, T). To illustrate the flexibility of our model, we provide two examples below::

Example 1 *CH_QR*$(1, 0, 1)$ *corresponds to an algorithm that generates a quantal best response strategy with* $\lambda = 1$ *that maximizes one-step payoff without considering other agents.* *CH_QR*(∞, ∞, H) *corresponds to an algorithm that generates the exact best response considering full horizon, assuming all levels of reasoning from other agents.*

This parametric model enables us to evaluate the SoFA technique on various sets of assorted populations and demonstrate the utility of having perfectly rational agents within a human population. The Poisson cognitive hierarchy model has been shown to provide a good fit for empirical data involving human subjects. We demonstrate similar findings with the extended model.

5 Soft-max based Flow update for Assorted populations (SoFA)

In this section, we describe our algorithm for solving DAAPs. We provide an algorithm (Algorithm 1) that is general and is applicable to a problem where there are (a) multiple types of agents with each type having a different transition and reward model and (b) multiple notions of rationality. However, for expository purposes (and to focus on the theme of the paper), we consider the case where all agents have the same model (transition and reward functions) and the difference is only in their rationality concept.

Algorithm 1 SoFA($daap, \Gamma, \mathcal{P}$)

for all $\tau \in \Gamma$ **do**
  $\pi_\tau \leftarrow$ GetInitialPolicy(τ)
end for
$\tilde{\pi} \leftarrow \phi$
$iter \leftarrow 0$
while $\tilde{\pi} \neq \pi$ **do**
  $\tilde{\pi} \leftarrow \pi$
  for all $\tau \in \Gamma$ **do**
    $\langle d^1..d^H \rangle \leftarrow$ AgentDist(π_{-i}, d^0, ϕ), $i \in \mathcal{P}_\tau$
    $\{\tilde{x}^t_{s,a}\} \leftarrow$ BestRspnse($\tau, daap, \langle d^1 \cdots d^H \rangle$)
    $x^t_\tau(s,a) \leftarrow \frac{(iter \cdot x^t_\tau(s,a) + \tilde{x}^t_{s,a})}{iter+1}, \forall s, a, t$
    $\pi^t_\tau(s,a) \leftarrow \frac{x^t_\tau(s,a)}{\sum_a x^t_\tau(s,a)}, \forall s, a, t$
    $iter \leftarrow iter + 1$
  end for
end while

Our goal is to compute the policy for perfectly rational agents (policy computed using Algorithm 1) in a population that contains other types of agents. It should be noted that a round-robin best response algorithm does not converge even if we have just one type of perfectly rational agents. Therefore, we introduce our new algorithm, SoFA that is based on the well known Fictitious Play algorithm and has interesting theoretical properties.

Intuitively, the key idea is that at each iteration, an agent computes best response against aggregate policies (over iterations of policy computation) of other agents. Since, in DAAP, the interactions between agents are due to the implicit competition for resources, an agent only has to determine best response to distribution of agent states (and not individual agent states). This observation improves the scalability considerably due to two reasons:
(1) Agents have to plan for state distributions and not against individual states and actions of other agents;
(2) We can assume same policy for all agents of the same type (either due to having same model or same notion of rationality). This allows us to reduce best response computations. Intuitively, it is a reasonable assumption when there is a large number of agents, because such a mixed policy is equivalent to aggregating (differing) individual agent policies.

It should be noted that the best response computation varies from agent to agent depending on their rationality criterion as mentioned in Section 4. Furthermore, best response computation (as mentioned earlier) requires state distribution of other agents. State distributions of other agents can be computed given the starting distribution, type of agents and their policies. Formally, we let (a) $p^t_\tau(s)$ be the probability that an agent of type τ will be in s at time t; (b) d^t_s denote the number of agents in state s at time t; (c) $\mathcal{P}_\tau$ denotes the set of players of type τ.

$$p^0_\tau(s) = \frac{d^0_s}{|\mathcal{P}|},$$

$$d^t_s = \sum_{\tau \in \Gamma} p^t_\tau(s) \cdot |\mathcal{P}_\tau|, \ \forall t \tag{2}$$

$$p^{t+1}_\tau(s) = \sum_{a^t_\tau} \pi^t_\tau(s, a^t_\tau) \sum_{s' \in \mathcal{S}} p^t_\tau(s') \phi^t_{d^t}(s', a^t_\tau, s) \tag{3}$$

For a perfectly rational agent, the best response at each iteration is computed by solving an MDP where the ϕ and $\mathcal{R}$ are fixed for the state and action sets because the state distribution of other agents $(d^t, \forall t)$ can be computed for each decision epoch using Equation 3. Solving this best response MDP using traditional LP based methods or dynamic programming methods yields a deterministic policy (i.e. one action for each state). Due to this determinism, the aggregation of policies in fictitious play can take many iterations to converge. Therefore, we propose the use of Soft-Max operator for solving MDPs similar to the Soft-Max Value Iteration [15]. This implies that the "max" operator in standard value iteration is replaced by a "soft-max" operator. The soft-max operator makes the strategy equivalent to the quantal

response strategy indicated earlier.

We provide the intuition using the following example.

Example 2 *Consider an MDP with two actions, a_1 and a_2, each of which can be executed from a state s. $\mathcal{V}(s,a_1)$ and $\mathcal{V}(s,a_2)$ are the expected values for executing actions a_1 and a_2 respectively from state s. The policy at s with a standard MDP solver (policy iteration, value iteration etc.), π^1 and SoFA, π^2 would be:*

$$\pi^1(s,a_1) = \begin{cases} 1, & \text{if } a_1 = \arg\max_{\{a_i \in \{a1,a2\}\}} \mathcal{V}(s,a_i) \\ 0, & \text{otherwise} \end{cases}$$

$$\pi^2(s,a_1) = \frac{e^{\mathcal{V}(s,a_1)}}{e^{\mathcal{V}(s,a_1)} + e^{\mathcal{V}(s,a_2)}}$$

Algorithm 1 provides the pseudo code for the SoFA algorithm. Lines 6-13 provide the core of the algorithm. At each iteration of the algorithm, for each agent there are three key steps: (a) Firstly we compute the state distribution of all other agents (using Equation 3) on line 9; (b) Then, we compute the best response (depends on the agent's rationality criterion) corresponding to the aggregated policies (across iterations) of other agents on line 10; and (c) Finally, we calculate the aggregate state action flows and consequently the aggregate policy for the current agent on lines 11-12.

6 Theoretical Results

We provide key theoretical properties of our SoFA algorithm. Firstly, we will show that SoFA converges to equilibrium policies in cases where there are only locally rational agents ($L = 0$) in the mix. Secondly, we show that if SoFA converges on problems with multiple agent types (different transition/reward model or different notions of rationality), then perfectly rational agents will converge to equilibrium policies.

Proposition 1 *In an assorted population of perfectly rational agents and locally rational agents ($L = 0$), if there exists one type (w.r.t transition and reward model) of perfectly rational agents, then irrespective of the proportion of locally rational agents, SoFA algorithm converges to equilibrium policies for the perfectly rational agents. This is assuming Equation 3 can be used to compute update of probability.*

Proof. Let the population, $\mathcal{P}$ be divided into two sets $\mathcal{P}_r$ (perfectly rational agents) and $\mathcal{P}_l$ (locally rational agents), i.e. $\mathcal{P} = \mathcal{P}_l \cup \mathcal{P}_r$. If there exists a potential function for this DAAP, then SoFA would converge to Nash equilibrium. We now define a function $\phi^t()$ and then show that it is a potential function for the DAAP problem. (In the interest of space, we use Π_{ik} to represent the set of $\{\pi_i\}_{i\neq k, i\in\mathcal{P}}$ throughout the proof.)

$$\phi^t(\{\pi_i\}_{i\in\mathcal{P}}) = \sum_k \mathcal{V}_i^t(\pi_k, \Pi_{ik}) \tag{4}$$

To show that this is a potential function for a given DAAP, we need to show that for any arbitrary agent k and two of its policies, $\pi_{(k,1)}$ and $\pi_{(k,2)}$:

$$\begin{aligned} &\phi^t(\Pi_{ik} \cup \pi_{(k,1)}) - \phi^t(\Pi_{ik} \cup \pi_{(k,2)}) \\ &= \mathcal{V}_k^t(\pi_{(k,1)}, \Pi_{ik}) - \mathcal{V}_k^t(\pi_{(k,2)}, \Pi_{ik}) \end{aligned} \tag{5}$$

We prove this proposition using mathematical induction over the time horizon t.

Base case for t = 0
For $k \in \mathcal{P}_r$, the value function for an agent is given by:

$$\mathcal{V}_k^0(\pi_{(k,1)}, \Pi_{ik}) = \sum_{s,a} p_k^0(s) \cdot \pi_{(k,1)}(s,a) \cdot \mathcal{R}_k(s,a,d^0)$$

For $k \in \mathcal{P}_l$, the only difference in value function from above would be $d^0 = \mathbf{0}$. It is easy to see that for all agents except k (irrespective of whether $k \in \mathcal{P}_l$ or $k \in \mathcal{P}_r$), the value remains the same if policy does not change for t = 0. Due to this Equation 5 holds (the terms for all other agents will cancel out).

Therefore, let us assume that the ϕ is a potential function for horizon t = m, i.e.,

$$\begin{aligned} &\phi^m(\Pi_{ik} \cup \pi_{(k,1)}) - \phi^m(\Pi_{ik} \cup \pi_{(k,2)}) \\ &= \mathcal{V}_k^m(\pi_{(k,1)}, \Pi_{ik}) - \mathcal{V}_k^m(\pi_{(k,2)}, \Pi_{ik}) \end{aligned} \tag{6}$$

Now, we will prove that it holds for $t = m + 1$

Let us consider the case where $k \in \mathcal{P}_r$,

$$\begin{aligned} \mathcal{V}_k^{m+1}(\pi_{(k,1)}, \Pi_{ik}) &= \sum_{s,a} p_k^0(s) \cdot \pi_{(k,1)}(s,a) \cdot \mathcal{R}_k(s,a,d^0) \\ &+ \sum_{s,a,s'} p_k^0(s) \cdot \pi_{(k,1)}(s,a) \cdot \phi_k(s,a,s',d^0) \cdot \\ &\quad \mathcal{V}_k^m(s', \pi_{(k,1)}, \Pi_{ik}) \end{aligned}$$

From Equation 3

$$\begin{aligned} &= \sum_{s,a} p_k^0(s) \cdot \pi_{(k,1)}(s,a) \cdot \mathcal{R}_k(s,a,d^0) + \\ &\quad \sum_{s'} p_k^1(s') \cdot \mathcal{V}_k^m(s', \pi_{(k,1)}, \Pi_{ik}) \\ &= \sum_{s,a} p_k^0(s) \cdot \pi_{(k,1)}(s,a) \cdot \mathcal{R}_k(s,a,d^0) + \mathcal{V}_k^m(\pi_{(k,1)}, \Pi_{ik}) \end{aligned} \tag{7}$$

Using Equation 7 and from assumption of Equation 6, we have

$$\begin{aligned}
&\mathcal{V}_k^{m+1}(\pi_{(k,1)}, \Pi_{ik}) - \mathcal{V}_k^{m+1}(\pi_{(k,2)}, \Pi_{ik}) \\
&= \sum_{s,a} p_k^0(s) \cdot \pi_{(k,1)}(s,a) \cdot \mathcal{R}_k(s,a,d^0) \\
&\quad - \sum_{s,a} p_k^0(s) \cdot \pi_{(k,2)}(s,a) \cdot \mathcal{R}_k(s,a,d^0) \\
&\quad + \sum_{\{i \neq k, i \in \mathcal{P}\}, s, a} p_i^0(s) \cdot \pi_i(s,a) \cdot \mathcal{R}_i(s,a,d^0) \\
&\quad - \sum_{\{i \neq k, i \in \mathcal{P}\}, s, a} p_i^0(s) \cdot \pi_i(s,a) \cdot \mathcal{R}_i(s,a,d^0) \\
&\quad + \phi^m(\Pi_{ik} \cup \pi_{(k,1)}) - \phi^m(\Pi_{ik} \cup \pi_{(k,2)})
\end{aligned}$$

Combining terms using the definition of potential function (Equation 4), we have

$$= \phi^{m+1}(\Pi_{ik} \cup \pi_{(k,1)}) - \phi^{m+1}(\Pi_{ik} \cup \pi_{(k,2)})$$

Since $k \in \mathcal{P}_l$ is a sub-case of $k \in \mathcal{P}_r$, where $d^t = \mathbf{0}$, we can adopt the same steps and prove that Equation 5 holds. Hence the proof. ■

While the following proposition is straightforward, it is important because our algorithm converges on all the problems provided in the experimental results section.

Proposition 2 *For DAAP problems with multiple types of agents, if SoFA converges, then perfectly rational agents will not have any incentive (in terms of expected value) to deviate.*

Proof. If SoFA converges, it implies that the agent policy does not change (line 6) from the previous iteration after computing best response (corresponding to other agent policies). Therefore, perfectly rational agents will have converged to a policy where there is no incentive to deviate in terms of expected value. ■

7 Experimental Results

In this section, we evaluate policies generated by SoFA (perfectly rational if SoFA converges) within the context of the taxi fleet optimization problem, where only a proportion of the taxi drivers follow SoFA strategies and others follow strategies obtained from the cognitive hierarchy model described in Section 4. Firstly, we will perform the behavioral analysis of the real-world taxi data set to obtain the composition of the assorted human-agent population. Once the distributions for assorted human-agent populations are obtained, we will show the performance of SoFA on various synthetic and real-world problem sets.

7.1 Human Behavioral Analysis

We now introduce iterative Bayesian inference to compute the distribution over levels of reasoning for taxi drivers. Let $Pr_i^t(L)$ denote the probability of player i using *level-L* reasoning in iteration t. Let $f^t(L)$ be the mean probability of *level-L* reasoning in the population, and $f^t(L) = \frac{\sum_i Pr_i^t(L)}{N}$. The expected levels of reasoning after t iterations can be computed by: $mean^t = \sum_L L \cdot f^t(L)$. Let $g_L^t(h)$ denote the perceived proportion of $level-h$ agents by $level-L$ agents in iteration t, which can be computed by:

$$g_L^t(h) = \frac{f^t(L)}{\sum_{l=0}^{L-1} f^t(l)}, \ \forall h < L.$$

Given λ, T, and $\{g_L^t(h)\}$, we can compute the behavioral strategy of *level-L* agent in iteration t by considering actual distribution of taxis. The procedure is based on Bayesian update and its pseudo-code is listed in Algorithm 2. In Algorithm 2, the prior distribution is initialized to be uniform. The movements of free taxis provide necessary observations to continuously update the prior distribution.

The data set we use for computing average levels of reasoning consists of GPS traces from close to 8000 active taxis over 30 working days. Each record in the data set provides a timestamp, taxi coordinate, and the status of the taxi (hired or free). When the taxi is free and moves from one location to another, we consider it as a valid observation. We set the length of time period to be 5 minutes and only consider the morning peak hours from 6 to 9 AM. The data set is sliced into 10 3-day chunks, and the algorithm is executed one chunk at a time. On average, this gives us $90,000$ valid observations across all taxis for each run. We also set the look ahead $T = 1$ for behavioral analysis[3].

L^{max}	$\lambda = 1$	$\lambda = 3$
4	1.21 ± 0.04	1.50 ± 0.05
5	1.35 ± 0.04	1.58 ± 0.05

Table 1: Expected levels of reasoning.

Table 1 gives expected value of levels of reasoning for two different but uniform initial distributions and for $\lambda = \{1, 3\}$. $L^{max} = 4$ implies maximum levels of reasoning is set to 4 and each level $\{0 \cdots 4\}$ is assigned initial probability of 0.2. It should be pointed out that although the actual distribution we obtain is not Poisson, the mean values we obtained are well within the

[3]As a sanity check for the Bayesian inference, we compared the average revenue of taxis from the data set and using the cognitive hierarchy model. The values were within 1% of each other ($283 and $280 per day respectively).

Algorithm 2 Iterative Bayesian Inference(λ, T)

$Pr_i^0(L) = \text{UniformDistribution}(L^{\max})$

  for all DataSet **do**
    $\langle d^1 \cdots d^T \rangle \leftarrow \text{GetAgentDist}(\text{DataSet})$
    for all $L \leq L^{max}$ **do**
      $\pi^{it}(L) = \text{Behavior}(\lambda, T, g_L^{it}, \langle d^1 \cdots d^T \rangle)$
    end for
    $s_i = \text{ObservedStartZone}(\text{DataSet})$
    $a_i = \text{ObservedAction}(\text{DataSet})$
    $Pr_i^{it}(L|a) = \frac{\pi^{it}(L,s_i,a_i) \cdot Pr_i^{it}(L)}{\sum_l \pi^{it}(l,s_i,a_i) \cdot Pr_i^{it}(l)}, \forall L$
  end for
  $it \leftarrow it + 1$
end while

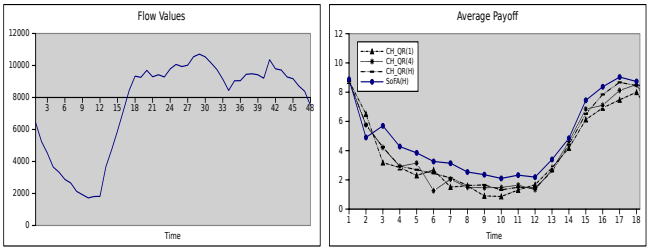
range of $[1, 2]$ which, as noted by Camerer *et al.*, can explain behavior in close to 100 games. The actual distribution we obtained are skewed towards lower levels of reasoning. A more rigorous study is needed to cross-validate this across larger data set and study the effect of look-ahead, T, on the final distribution.

7.2 Experimental Setup

To demonstrate that perfectly rational policies are useful in an assorted taxi driver population of different rationalities, we experiment on two different data sets. One is a synthetic data set that simulates random scenarios of demand distributions and another a real-world data set of a taxi company in Singapore. The synthetic data set was created with an inspiration from the real-world taxi data set and so we differentiate between peak hour and normal hours, multiple types of zones, time dependent flow-in and flow-out from a zone etc.

The main parameters of interest in the synthetic data set are (a) the map (defines how zones are connected); (b) total number of zones; (c) number of neighbors for each zone; (d) demand for all zones (represents people going into a zone) characterized by whether it is a residential zone, entertainment zone, office zone or a hospital; (e) total number of taxis; (f) total demand for taxis in a day; (f) length of peak hours. We generate problem instances considering a range of values for all these parameters.

Creating such a detailed simulation data set has helped us in evaluating our algorithm across multiple parameters and investigate the specific parameters affecting the final performance. For each map we compute policies by employing various algorithms and simulate them multiple times to obtain values for the comparison metrics.



(a) (b)

Figure 1: Customer flow at various points and the average payoff obtained by various approaches.

The real-world data set consists of flows of customers, revenues and costs for taxis between various zones across Singapore over a period of six months. We consider a time unit to be 30 minutes long and hence the time horizon for an entire day is $H = 48$. Figure 1 (a) depicts the aggregate demand for taxis throughout the day in this data set. The peak and non-peak hours are easily distinguishable. There are around 8000 taxis and 79 zones.

For all the graphs with aggregated results, we computed standard deviation as well. However, standard deviation is shown in the graphs only if it is greater than 0.1%. We evaluate the algorithms across the social welfare parameters highlighted in Section 2: (1) Average payoff of all taxis. (2) Minimum payoff across all taxis and (3) Starvation, which represents the lack of availability of taxis. The first two metrics provide an intuition for how the payoff distribution for taxi drivers changes. The third metric ensures an improvement from the system management (or taxi fleet owners) perspective.

We first present the results for the case when all agents adopt one type of rationality and then we will present the results for an assorted population. Although, we do not have theoretical guarantees on convergence when there are agents following behavioral strategies along with perfectly rational agents, empirically, we achieved convergence on all the problem instances. Our algorithm converged on all the problems in the synthetic and real-world data set within 2 hours[4].

7.3 Homogeneous Population

We compare the performance of SoFA algorithm against the strategies generated by the extended cognitive hierarchy model described in Section 7.1. While we experimented with a varied set of λ values, we only show results for $\lambda = \{1, 3\}$ because they yield the most

[4]The most amount of time was taken by the real-world problem set, where there are 8000 taxis and 79 zones.

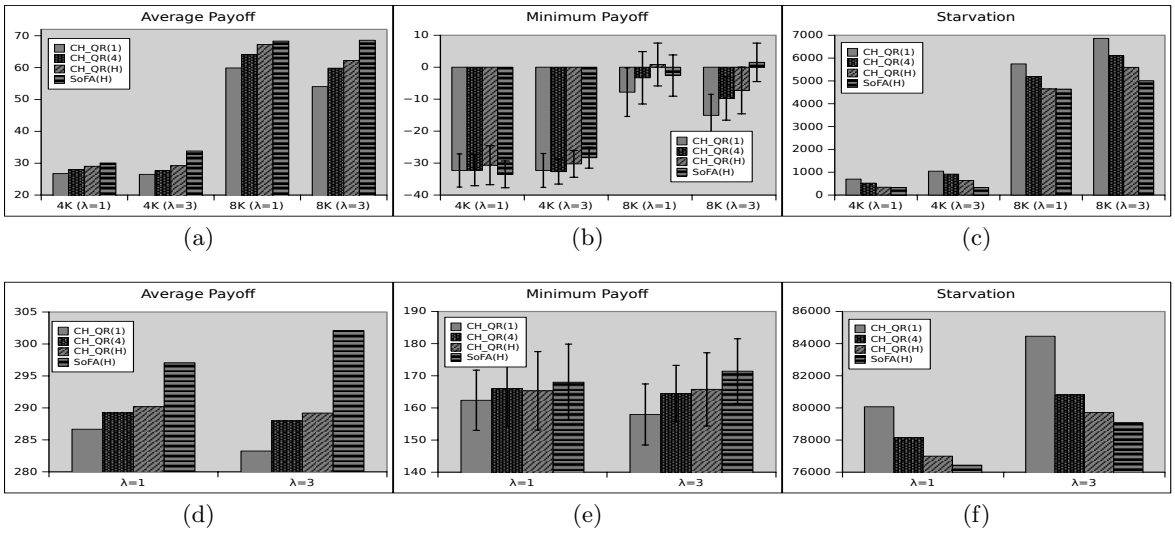


Figure 2: Performance of SoFA and behavioral strategies with $T = \{1, 4, H\}$ on synthetic and real-world datasets.

diverse set of observations. As for the time horizon, we considered $T = \{1, 4, H\}$. As for the levels of reasoning, L, we use the distributions obtained from iterative Bayesian inference corresponding to $\lambda = \{1, 3\}$. We also set $L^{max} = 4$. Thus, in our result graphs, $CH\_QR(5)$ with $\lambda = 3$ would imply the population consists of {17%, 39%, 26%, 13%, 5%} of levels $\{0 \cdots 4\}$ agents respectively with *look-ahead=5*. For $\lambda = 1$, it would be {20%, 52%, 17%, 5%, 6%}.

Figure 2 provides the results on the synthetic and real-world data sets. Graphs (a)-(c) are results for 40 zone problems and (d)-(f) are for the the taxi data set. Here are some of the key observations with respect to average and minimum payoff, starvation:

(i) For both synthetic and real-world problems, SoFA outperforms all the benchmark algorithms, due to the Nash equilibrium policies employed by SoFA agents.
(ii) Behavioral strategies with look ahead equal to horizon outperformed strategies with shorter look ahead.
(iii) We observe that for behavioral strategies, $\lambda = 1$ performs better than $\lambda = 3$. This could be because for $\lambda = 3$, the proportion of higher level reasoning agents increases and hence overall performance goes down. On the other hand, for SoFA, due to the randomized policies, performance increases from $\lambda = 1$ to $\lambda = 3$.
(iv) For the synthetic data set, when population size is $4k$, the behavioral strategy with $\lambda = 1$ and look ahead equals to *horizon* obtains marginally higher minimum payoff than all other algorithms. But when the population size is increased to $8k$ and with $\lambda = 3$, minimum payoff is guaranteed to be orders of magnitude higher under SoFA.
(v) For synthetic and real-world data sets, SoFA outperforms others for $\lambda = 3$ w.r.t. minimum payoff.
(vi) With respect to starvation (lower values are better), SoFA outperforms others on all data sets.

Figure 1(b) gives the average payoff for each algorithm at each time step on the real-world data set. We observe that SoFA performs better than other algorithms. Furthermore, it should be noted that there is high degree of similarity in the performance of SoFA over time and the flow values of Figure 1(a). This implies that SoFA is able to adapt quickly to the changes in demand over time.

7.4 Assorted Population

We now evaluate SoFA with an assorted population of agents. It should be noted that for a fixed λ and T, there are more than one type of agents in the population. We use X to denote the ratio of agents that are following SoFA policies. For instance, X = 20% (along X-axis in Figure 3) implies 20% agents are perfectly rational and the rest are following behavioral strategies for a particular λ.

Figure 3 provides the performance of SoFA within a varying population of agents: (a)-(c) and (d)-(f) are results for the synthetic and real-world data sets respectively. We make the following observations regarding average payoff, minimum payoff, and starvation:

(i) The performance of SoFA improves as the population of agents following behavioral strategies increases from 20% to 80%. The performance of boundedly rational agents at the same time goes down. It indicates that irrespective of the population of boundedly rational agents, it is always useful to employ a SoFA policy. SoFA outperforms behavioral strategies even when the proportion of agents following SoFA increases to 80%.
(ii) On the synthetic data set, SoFA outperforms other algorithms w.r.t. minimum revenue when the propor-

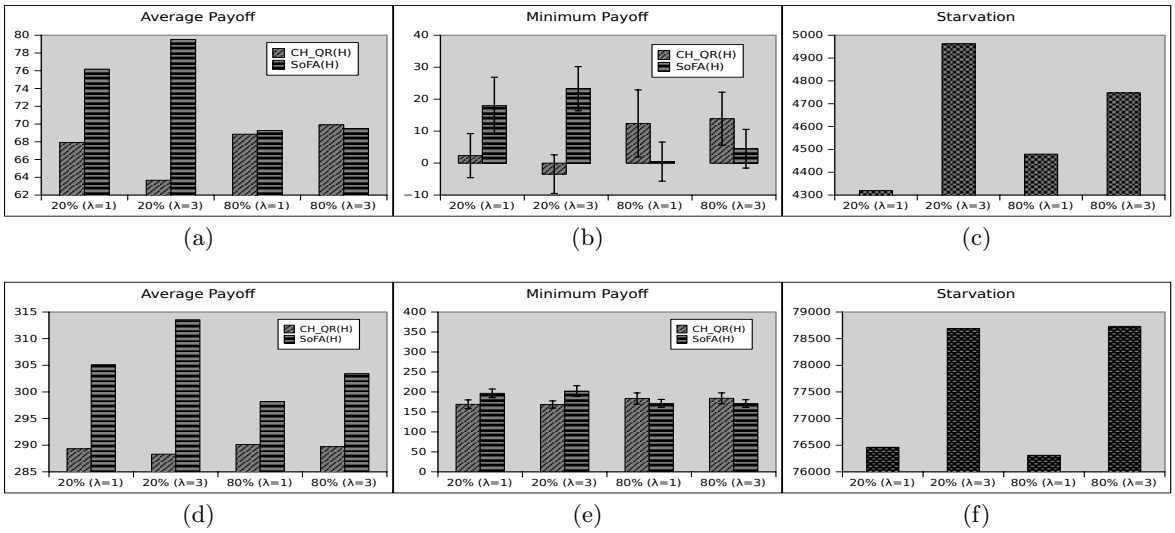

Figure 3: SoFA vs behavioral strategies in assorted population with $T = H$ on synthetic and real-world datasets.

tion of agents is 20%.
(iii) On real-world data set the minimum payoffs are almost equal across both strategy models.
(iv) Starvation values decrease with increase in the number of perfectly rational agents.

From all these experiments on both synthetic and real-world problem instances, we conclude that with respect to all welfare metrics (average revenue, minimum revenue and starvation), for any agent, it is useful to pursue the policy computed for perfectly rational agents in problems such as taxi fleet optimization.

8 Related Work and Conclusions

In this section, we briefly describe research related to the contributions made in this paper. The first thread of related research is in the field of transportation. User equilibrium (UE) is a classical and powerful equilibrium concept in transportation explaining individual route choices in face of competition for road usages from other users. Originally proposed in static setting [10], it was later expanded to dynamic cases (where temporal choices are also important) [3]. In either format, static or dynamic, the concept of UE provides a way to infer and to predict the behaviors of individual drivers; such ability helps not just individual drivers to identify better routes, but it can also help policy makers to properly design road network in anticipation of driver's responses. While the solution concept of UE is relevant, it does not account for the presence of involuntary movements for agents.

The second thread of related research is from *behavioral game theory* where different models have been proposed to accommodate experimental results (involving human subjects) and theoretical predictions. These include cognitive hierarchy model [1] and quantal response equilibrium [4]. More recently, variants of these models have been evaluated across different games [13]. As opposed to evaluation on traditional small benchmark problems, we have studied these models in the context of a very large scale real-world setting in this paper.

The next thread of relevant research is due to Weintraub *et al.* [12, 11]. This research introduces the concept of oblivious equilibrium for large scale dynamic games. They provide a mean field approximation to solve problems where there is stochasticity in state transitions. While, the problem is similar to DAAPs, the assumption of mean field (or a stationary distribution of taxis in our case) is not applicable in the context of taxi problems. In fact, there is a huge variance in the set of possible distributions at each decision epoch and hence oblivious equilibrium is not directly applicable in our context.

DAAP model represents a subset of problems represented by the generic Partially Observable Stochastic Games (POSG) model. However, all the approaches [6, 9, 8] provided in the literature are for solving identical payoff stochastic games (also referred to as Decentralized POMDPs or DEC-POMDPs) and not generic POSGs. Furthermore, they do not scale to problems with 8000 agents.

Abstract

We consider the budget optimization problem faced by an advertiser participating in repeated sponsored search auctions, seeking to maximize the number of clicks attained under that budget. We cast the budget optimization problem as a Markov Decision Process (MDP) with *censored observations*, and propose a learning algorithm based on the well-known *Kaplan-Meier* or *product-limit* estimator. We validate the performance of this algorithm by comparing it to several others on a large set of search auction data from Microsoft adCenter, demonstrating fast convergence to optimal performance.

1 Introduction

In this paper we study algorithms for optimized budget expenditure in sponsored search. Given an advertiser's budget, the goal of such algorithms is to maximize the number of clicks obtained during each budgeting period. We consider a single-slot model in which our algorithm's competing bid — representing the rest of the "market" for clicks — is drawn from a fixed and unknown probability distribution. While in reality, advertisers (or their proxies) may often bid strategically and not stochastically, we view this assumption as analogous to classical models in finance, where despite strategic behavior of traders at the individual level, models of macroscopic price evolution that are stochastic (such as Brownian motion models) have been quite effective in developing both models and algorithms. Our empirical results will demonstrate that algorithms designed for these stochastic assumptions also perform quite well on the non-stochastic sequence of bids actually occurring in real search auctions.

The assumption of stochastic bids by the competing market leads to a Markov Decision Process (MDP) formulation of the optimal policy, where the states of the MDP specify the remaining time in the period and the remaining budget. However, the second-price nature of sponsored search introduces the challenge of *censored* observations: only if we win the click do we observe the actual competing price; otherwise, we only know our bid was too low.

Our main contributions are the introduction of efficient algorithms that combine the MDP formulation with the classical Kaplan-Meier [5] or product-limit estimator for censored observations, and a large-scale empirical demonstration that these algorithms are extremely effective in practice — even when our underlying distributional assumptions are badly violated. Our source of data is auction-level observations on hundreds of high-volume key-phrases from Microsoft adCenter. We show that our algorithms rapidly learn to compete with the strongest possible benchmark — the performance of an offline-optimal algorithm that knows the future competing bids, and always selects the cheapest clicks in each period.

2 Related Work

There is some prior work directly concerning the problem of optimizing an advertiser's budget [6, 12], as well as work concerned with characterizing the dynamics or equilibria of a market in which advertisers play from a family of optimizing strategies [2, 3]. All these works attempt to model the strategic behavior of agents participating in a sponsored search auction. We will depart from this, modeling the auction market stochastically, as is more common in finance.

The sponsored search budget optimization problem has also been formulated as an instance of online knapsack [12]. For the online knapsack problem, it is known that no online algorithm can converge to the optimum in the worst case [8]. The stochastic knapsack problem has also been studied, and there is an algorithm with near-optimal average-case performance [7]. One of our

proposed algorithms is a censored learning version of such an algorithm. Our main proposed algorithm is closely modeled on an algorithm from a financial optimization problem [4], which similarly integrates a censored estimation step with greedy optimization.

Finally, we apply classical techniques from reinforcement learning in a finite state MDP, including Q-learning (c.f. [11]), as well as classical techniques from the study of censored observations [5, 9].

3 Preliminaries

The optimization problem we consider occurs over a series of *periods*. At the beginning of each period, the budget optimization algorithm is allocated a fresh budget B. This assumption is meant to reflect the manner in which advertisers actually specify their budgets in real sponsored search markets. Broadly speaking, the algorithm's goal is to maximize the number of clicks purchased, in each period, using the budget B.

Each period consists of a number of *auctions*, or an opportunity to earn a click. We consider the *single-slot* setting, wherein the search engine displays a single advertisement for each auction [1]. The algorithm places a *bid* in each auction. Before the bid is placed, a *price* is fixed by the auction mechanism. If the algorithm's bid exceeds this price, the algorithm wins an *impression*. For simplicity, we begin by assuming that winning an impression automatically guarantees that the algorithm also wins a click; we will describe later how to relax this assumption.

Once the algorithm wins a click, it is charged the price from its budget. Otherwise, the algorithm maintains its budget, and the next auction occurs. In actual sponsored search markets, the price is determined by the bids of arbitrary agents competing for the click in a modified second-price auction (see e.g. [10]).

The major assumption of this work is to instead model the prices as i.i.d. draws from an unknown distribution; we will refer to this price as the *market price*, since it represents the aggregate behavior of our algorithm's competitors. As in other financial applications, it is often analytically intractable to model the individual agents in a market strategically, so we instead consider the market stochastically as a whole. We will demonstrate that our algorithm outperforms other methods in practice on actual auction data from Microsoft adCenter, even when the i.i.d. assumption is badly violated.

We will consider some fixed, unknown, distribution $\mathcal{P}$ supported on $\mathbb{Z}^+$ with mass function $p(\cdot)$. On each auction, the market price is an independent random variable distributed as $\mathcal{P}$. We think of the budget B and market prices as being expressed in terms of the smallest unit of currency that can be bid by the algorithm. Modeling the problem in this manner motivates a natural algorithm.

It is important to note that the market prices are not observed directly by the algorithm. Rather, the algorithm is only privy to the consequences of its bid (whether a click or impression is received), and changes to its budget.

Succinctly, we consider the following protocol:

for period $u = 1, 2, ...$ **do**
  $B_{u,T} = B$
  for auctions remaining $t = T, T-1, ..., 1$ **do**
    Algorithm bids $b_{u,t} \leq B_{u,t}$.
    Nature draws price $x_{u,t} \sim \mathcal{P}$.
    if $b_{u,t} \geq x_{u,t}$ **then**
      $c_{u,t} \leftarrow 1$
      $B_{u,t-1} \leftarrow B_{u,t} - x_{u,t}$
    else
      $c_{u,t} \leftarrow 0$
      $B_{u,t-1} \leftarrow B_{u,t}$
    end if
    Algorithm observes $c_{u,t}$, $B_{u,t-1}$
  end for
end for

When an algorithm places a large enough a bid, winning the click, it also observes the true market price, since its budget it reduced by that amount. However, should the algorithm fail to win the click, it only knows that the market bid was higher than the bid placed. Thus, the algorithm receives what is known in the statistical literature as partially *right-censored observations* of the market prices $\{x_{u,t}\}$.

Informally, we always assume that an algorithm has available to it any information it would have in a real sponsored search auction (although not always at the same granularity), and no more. So it may be informed of whether it received a click or impression on an auction-by-auction basis, but not information regarding prices if it did not win the click.

Finally, we assume there is only a single keyword which the advertiser is bidding on. Our methods generalize to the setting where there are multiple keywords with multiple click-through rates and valuations for a click. However, for simplicity, we do not consider these extensions in this work.

[1] We suspect our methods can be adapted to the multi-slot case, but leave it to future work.

3.1 Notation

Given a distribution $\mathcal{P}$, supported on $\mathbb{Z}^+$, with mass function p, we let the tail function $T_p(b) = \sum_{b'=b+1}^{\infty} p(b')$ denote the mass to the right of b.

We use $[N]$ to mean the set $\{1, ..., N\}$, and $[N]_0 = [N] \cup \{0\}$.

4 MDP Formulation

An algorithm for the optimization problem introduced in the previous section can be described as an agent in a Markov Decision Process (MDP). An MDP $\mathcal{M}$ can be written as $\mathcal{M} = (\mathcal{S}, \{A_s\}_{s\in\mathcal{S}}, \mu, r)$ where $\mathcal{S}$ is a set of states, and A_s are the set of actions available to the agent in each state s, and $\mathcal{A} = \cup_{s\in\mathcal{S}} A_s$. For $a \in A_s$, $\mu(a, s, s')$ is the probability of transitioning from state s to state s' when taking action a in state s. $r(a, s, s')$ is the expected reward received after taking action a in state s and transitioning to state s'. The goal of the agent is to maximize the expected reward received while transitioning through the MDP.

In our case, the state space is given by $\mathcal{S} = [B]_0 \times [T]_0$. With t auctions remaining in period u, the algorithm is in state $(B_{u,t}, t) \in \mathcal{S}$. Furthermore, the actions available to any algorithm in such a state are the set of bids that are at most $B_{u,t}$. So for any $(b, t) \in \mathcal{S}$ we let $\mathcal{A}_{(b,t)} = [b]_0$.

When $t \geq 1$, two types of transitions are possible. The agent can transition from (b, t) to $(b, t-1)$ or from (b, t) to $(b', t-1)$ where $0 \leq b' < b$. In the former case, the agent must place a bid lower than the market price. Therefore, we have that $\mu(a, (b, t), (b, t-1)) = T_p(a)$. Furthermore, the agent does not win a click in this case, and $r(a, (b, t), (b, t-1)) = 0$. In the latter case, let $\delta = b - b'$. The agent must bid at least δ, and the market price must be exactly δ on auction t of the period in question. Therefore, we have that $\mu(a, (b, t), (b', t-1)) = p(\delta)$ and $r(a, (b, t), (b', t-1)) = 1$ so long as $a \geq \delta$.

When $t = 0$, for any action, the agent simply transitions to (B, T) with probability 1, with no reward. The agent's budget is refreshed, and the next period begins.

All other choices for $(a, s, s') \in \mathcal{A}_s \times \mathcal{S} \times \mathcal{S}$ represent invalid moves, and hence $\mu(a, s, s') = r(a, s, s') = 0$.

Finally, conditioned on an agent's choice of action a and current state s, its next state s is independent of all previous actions and states, since the market prices $\{x_{u,t}\}$ are independent. The Markov property is satisfied, and we indeed have an MDP.

We call this the *Sponsored Search MDP* (SS-MDP). If π is a fixed mapping from $\mathcal{S}$ to $\mathcal{A}$ satisfying $\pi(s) \in \mathcal{A}_s$, we say that π is a *policy* for the MDP.

Note that an agent in the SS-MDP, started in an arbitrary state (b, t), arrives at the state (B, T) after exactly $t + 1$ actions. Therefore, we can define the random variable $C_\pi(b, t)$ to be the total reward (i.e. number of clicks) attained by policy π before returning to (B, T). We say that π is *an optimal policy for the SS-MDP* if an agent started at (B, T), playing $\mu(s)$ in each state s encountered, maximizes the expected number of clicks rewarded before returning to (B, T). In other words:

Definition 1. *A policy π^* is an optimal policy for the SS-MDP if $\pi^* \in \arg\max_\pi E[C_\pi(B, T)]$.*

The SS-MDP is determined by the choice of budget B, time T and distribution p. We will want to make the optimal policy's dependence on p explicit, and consequently we will write it a π_p^*.

5 The Value Function

MDPs lend themselves to dynamic programming. Indeed, we can characterize exactly the optimal policy for the SS-MDP when the probability mass function p is known.

For a distribution p, let $V_p(b, t)$, the *value function for* p, denote the expected number of clicks received by an optimal policy started at state (b, t). That is, if π_p^* is an optimal policy, then $V_p(b, t) = E[C_{\pi^*}(b, t)]$.

First note that when $T = 0$, $V_p(B, T) \equiv 0$. Consider the policy $\pi^*_{a,b,t}$ that takes action a in state (b, t), and plays optimally thereafter. Let $V_p(a, b, t) = E[C_{\pi^*_{a,b,t}}(b, t)]$ be the clicks received by such a policy from state (b, t). Observe that $V_p(a, b, t)$ can be written in terms of $V_p(\cdot, t-1)$:

$$V_p(a, b, t) = \sum_{\delta=1}^{a} p(\delta)[1 + V_p(b - \delta, t-1)] + T_p(a)V_p(b, t-1).$$

In other words, if the market price is $\delta \leq a$, which occurs with probability $p(\delta)$, the agent will win a click at the price of δ and transition to state $(b - \delta, t - 1)$. At this point it behaves optimally, earning $V_p(b - \delta, t - 1)$ clicks in expectation. If the market price is greater than a, which occurs with probability $T_p(a)$, the agent will retain its budget, transitioning to the state $(b, t-1)$, earning $V_p(b, t-1)$ clicks in expectation. Furthermore, we know that:

$$V_p(b, t) = \arg\max_{a \leq b} V_p(a, b, t).$$

Therefore, if p and $V_p(\cdot, T-1)$ are known then we can compute $V_p(a, b, t)$ in $O(B)$ operations, and so

compute $V_p(b,t)$ in $O(B)$ operations. Recalling that $V_p(b,0) \equiv 0$, we can compute $V_p(b,t)$ for all $(b,t) \in [B]_0 \times [T]_0$ in $O(B^2T)$ operations.

6 Censored Data

In the previous sections, we described how to compute the optimal policy π_p^* when p is known. A natural algorithm for budget optimization is therefore to maintain an estimate $\hat{p}$ of p, and bid greedily according to $\pi_{\hat{p}}^*$. Before describing such an algorithm, we will discuss the problem of estimating p.

As introduced in Section 3, the observations received by a budget-optimization algorithm are partially right-censored data. We begin with a general discussion of censoring.

Suppose that $\mathcal{P}$ is a distribution with mass function p and $(z_1, ..., z_n)$ are i.i.d., $\mathcal{P}$-distributed random variables. Fix n integers $k_1, ..., k_n$, and define $o_i = \min(z_i, k_i)$. We say that the sample $\{o_i\}$ is partially right-censored data.

If $o_i < k_i$, we say that o_i is a direct observation. In other words, $o_i = z_i$ and we have observed the true value of z_i. Otherwise, $o_i = k_i$ and we say that o_i is a censored observation. We know only that $z_i \geq k_i$.

Given such partially right-censored data, the Product-Limit estimator [5] is the non-parametric maximum-likelihood estimator for p.

Definition 2. *Let $\mathcal{P}$ be a discrete distribution with mass function p, and let $\{z_i\}$ be i.i.d. $\mathcal{P}$-distributed random variables. Given integers $K = (k_1, ..., k_n)$ and observations $O = (o_1, ..., o_n)$ where $o_i = \min(z_i, k_i)$, let $PL(K, O)$ be the Product-Limit estimator for p.*

Specifically, given integers K, and a set of observations O generated by a distribution $\mathcal{P}$, let $D(s) = |\{o_i \in O \mid s = o_i < k_i\}|$ be the number of direct observations of value s, and $N(s) = |\{o_i \in O \mid s \leq o_i, s < k_i\}|$. Now let $S(t) = \prod_{s=1}^{t-1} 1 - \frac{D(s)}{N(s)}$. The CDF of $PL(K, O)$ is given by $1 - S(t)$.

In our setting, we are receiving censored observation of the random variables $\{x_{u,t}\}$ where the censoring set K is given by $\{b_{u,t}+1\}$, and $o_{u,t} = \min\{b_{u,t}+1, x_{u,t}\}$. When a click is received (i.e. $x_{u,t} < b_{u,t} + 1$), we observe $x_{u,t}$ directly since $x_{u,t} = B_{u,t} - B_{u,t-1}$, the amount which the algorithm is charged for winning the click. Otherwise, the algorithm is charged nothing, and we only know that $x_{u,t} \geq b_{u,t} + 1$.

Finally, we will eventually consider the setting in which winning an impression does not necessarily guarantee winning a click. In such a setting, we will have both left-censored and right-censored observations of $x_{u,t}$, what is known as *doubly-censored data*.

If the algorithm bids $b_{u,t}$ and does not win the impression, we know that $x_{u,t} \geq b_{u,t} + 1$. Similarly, if the algorithm wins both the impression and the click, it gets to observe $x_{u,t}$ directly. However, should the algorithm win the impression but not the click, it is only informed that it placed a large-enough bid (that it won the impression), or $x_{u,t} < b_{u,t} + 1$, without observing $x_{u,t}$ directly. We give a more detailed discussion of this setting in Section 9. For doubly-censored data, there is algorithm giving the non-parametric MLE [9].

7 Greedy Product-Limit Algorithm

The algorithm we propose maintains an estimate $\hat{p}$ of p. With budget b remaining, and t auctions remaining, the algorithm will greedily use its current estimate of p, and bid $\pi_{\hat{p}}(b,t)$. The pseudo-code for *Greedy Product-Limit* contains a detailed description.

Algorithm 1 Greedy Product-Limit

Input: Budget B

Initialize distribution $\hat{p}$ uniform on $[B]$
Initialize $K = []$; Initialize $O = []$
for period $u = 1, 2, ...$ **do**
  Set $B_{u,T} := B$
  for auctions remaining t=T,T-1,...,1 **do**
    Bid $\pi_{\hat{p}}^*(B_{u,t}, t)$
    Set $k_{u,t} \leftarrow \pi_{\hat{p}}^*(B_{u,t}, t) + 1$
    $K \leftarrow [K, k_{u,t}]$
    if Click won at price $x_{u,t}$ **then**
      $O \leftarrow [O, x_{u,t}]$
    else
      $O \leftarrow [O, k_{u,t}]$
    end if
    Update $\hat{p}$ to $PL(K, O)$
  end for
end for

8 Competing Algorithms

In this section we will describe a few alternative strategies against which we compare *Greedy Product-Limit*. The first relies on an observation that, given an *arbitrary* sequence of market prices, there is a simple bidding strategy that has a constant competitive ratio to the offline optimal.

8.1 Offline Optimality

So far we have focused our attention on the notion of optimality introduced in Section 4. Namely, an algorithm is optimal if it achieves $V_p(B,T)$ clicks,

in expectation, in every period. However, given an arbitrary (non-stochastic) vector of T market prices $\mathbf{x} = (x_1, ..., x_T)$, we can define $C^*(\mathbf{x}, B)$ to be the maximum number of clicks that could be attained by any sequence of bids, knowing $\mathbf{x}$ *a priori*. In other words, if $\mathbf{b} \in \{0,1\}^T$, and $\|\mathbf{b}\|_0 = |\{b_i \mid b_i = 1\}|$, then we define

Definition 3.

$$C^*(\mathbf{x}, B) \triangleq \max_{\mathbf{b} \in \{0,1\}^T} \|\mathbf{b}\|_0 \textit{ subject to } \mathbf{x} \cdot \mathbf{b} \leq B.$$

We call a sequence of bids for $\mathbf{x}$ that attains $C(\mathbf{x}, B)$ clicks an *optimal offline policy*. Notice that one attains the optimal offline policy by greedily selecting to win the clicks with the cheapest prices, until the budget B is saturated.

8.2 Fixed Price

Competing against the notion of optimality introduced in Section 8.1 may seem onerous in the online setting. Indeed, competing against an arbitrary sequence of prices is a special case of the online knapsack problem, which is known to be hard. However, we will now show that for any sequence of prices $\mathbf{x}$, there always exists a simplistic bidding policy which would have attained a constant factor of the bids of the optimal offline policy.

Let $Fixed(b)$ be the policy that bids b on every auction that it has budget to do so, and define $C(\mathbf{x}, b, B)$ to be the number of clicks attained by $Fixed(b)$ against $\mathbf{x}$ with budget B.

Theorem 1. *For any sequence of prices* $\mathbf{x}$*, and budget* B*, there exists a bid* b *such that* $C(\mathbf{x}, b, B) \geq \frac{1}{2} C^*(\mathbf{x}, B)$.

Proof. Let b^* be the value of the price for the most expensive click that the optimal offline policy selects to win. Suppose that the optimal offline policy wins $M+N$ clicks, where M clicks were won with a price of exactly b^* and the remaining N clicks were won with a price of $b^* - 1$ or less.

If $N \geq \frac{1}{2} C^*(\mathbf{x}, B)$, then $Fixed(b^* - 1)$ would win all N clicks, giving the desired result.

Otherwise, we know that $M \geq \frac{1}{2} C^*(\mathbf{x}, B)$. Consider the policy $Fixed(b^*)$. In the worst case, the policy will win only clicks with price b^* before saturating its budget. However, we know that $Mb^* \leq B$, and so $C(\mathbf{x}, b^*, B) \geq M \geq \frac{1}{2} C^*(\mathbf{x}, B)$, as desired.

□

8.3 Fixed-Price Search

This motivates a simple algorithm which attempts to find the best fixed-price, *Fixed-Price Search*.

Algorithm 2 Fixed-Price Search

```
Select b_1 arbitrarily.
for period u = 1, 2, ... do
    C_u := 0
    for auctions remaining t = T, T-1, ..., 1 do
        Bid b_u
        if Click won then
            C_u ← C_u + 1
        end if
    end for
    b_{u+1} ← UpdateBid({b_{u'}, C_{u'}}_{u'=1}^{u})
end for
```

The algorithm plays a fixed-price strategy each period. At the end of the period it uses a subroutine *UpdateBid* to select a new fixed-price according to how many clicks it has received. There are many reasonable ways to specify the *UpdateBid* subroutine, including using additive or multiplicative updates (e.g. treating each price as an expert and running a bandit algorithm such as Exp3 [1]). But general, the performance of any such approach cannot overcome the fixed-price "gap" of $E_{\mathbf{x}}[C^*(\mathbf{x}, B) - \max_b C(\mathbf{x}, b, B)]$.

8.4 Q-learning

Given the MDP formulation of the problem in Section 4, we may hope to solve the problem using techniques from reinforcement learning. Q-learning with exploration is one of the simplest algorithms for reinforcement learning, giving good results in a number of applications.

In Q-learning, the agent begins with an estimate $Q(a, b, t)$ of the function $V_p(a, b, t)$, called the Q-value, for each state (b, t) and action $a \in [b]$. In a state (b, t), the agent greedily performs the best action a^* for that state using the current Q-values receiving some reward $\hat{r}$ and arriving at a new state $(b', t-1)$. The Q-values for state $(b', t-1)$ and the observed reward $\hat{r}$ are then used to update $Q(a^*, b, t)$. This is often combined with forced exploration. Notice that Q-learning will necessarily ignore the special assumptions placed on the underlying MDP. In particular, from our discussion in Section 4, we have that $\pi(a, (b_1, t_1), (b'_1, t_1 - 1)) = \pi(a, (b_2, t_2), (b'_2, t_2 - 1))$ when $b_1 - b'_1 = b_2 - b'_2$.

8.5 Knapsack Approaches

As referenced in Section 2, the problem of budget optimization in sponsored search is very related to the

online knapsack problem. In the online knapsack problem, an optimizer is presented with a sequence of items with values and weights. At each time step, the optimizer makes an irrevocable decision to take the item (subtracting its weight from the optimizer's budget, and gaining its value). In the worst case, Marchetti-Spaccamela et al. demonstrate that a constant-factor competitive ratio with the offline is not possible [8]. Nevertheless, there are many results from the online knapsack literature that are applicable to our setting.

While in the worst case the online knapsack problem is hard, Lueker gives an average-case analysis for an algorithm for the *Stochastic Knapsack Problem*, which is related to our setting [7]. In the Stochastic Knapsack Problem, items $\{(r_i, x_i)\}$ are i.i.d. draws from some fixed, *known*, distribution. r_i is the profit or reward earned by taking the item, and x_i is the price of the item. In our setting, all clicks are considered indistinguishable for a fixed keyword, and so $r_i = 1$.

Note that the protocol differs from ours in a few ways. Firstly, there is no learning. The underlying distribution is assumed to be known. Secondly, there is no censoring of data, or any notion of an auction. The optimizer is presented with each item up-front, at which point it must make a decision before moving on to the next. Thirdly, in the language of our setting, there is only a single period.

Under these assumptions, the algorithm of Lueker gives a simple algorithm which differs from the true optimum by an average of $\Theta(T)$, where T is the length of the period, assuming that the budget available scales with T [7].

Nevertheless, the same ideas behind Greedy Product-Limit give us a natural adaptation of this algorithm to our setting. Suppose that the prices are presented up-front and that $\mathcal{P}$ is known. With budget B remaining and time T remaining in a period, the algorithm computes:

$$v(B/T) \triangleq \max_v \{v \mid \sum_{a=1}^{v} a \cdot p(a) \leq B/T\}$$

and takes the click iff its market price x satisfies $x \leq v(B/T)$. Thus, when the prices are not presented up-front, it is equivalent to simply bidding $v(B/T)$.

Note that bidding $v(B/T)$ is natural; it is the bid that, in expectation, costs B/T, or smooths the remaining budget over the time remaining. We can now combine this with an estimation step, using the product-limit estimator, as we did for *Greedy Product-Limit*, simply replacing line 7 with the assignment $k_{u,t} := v(B/T)$. We refer to this strategy as *LuekerLearn*.

Notice, however, that once $\hat{p}$ has converged to the true p, we should not expect this algorithm to outperform *Greedy Product-Limit*, which would bid optimally. For a fixed choice of distribution p, budget B, and number of auctions T, let $L_p(B,T)$ be the expected number of clicks earned by running the algorithm of Lueker, knowing p. $L_p(B,T) \leq V_p(B,T)$, by definition of $V_p(B,T)$. We will comment (as established by Lueker) that the gap $V_p(B,T) - L_p(B,T)$ is exacerbated by distributions with large variance relative to B and T, an issue we will return to in Section 9; see also Figure 1.

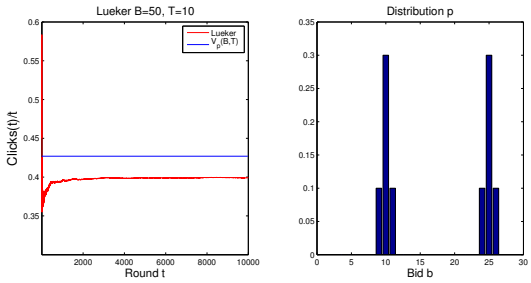

Figure 1: A distribution for which $L_p(B,T)$ is bounded away from $V_p(B,T)$. The red curve plots the performance (averaged over auctions) of the algorithm of Lueker's algorithm when the distribution p is known. The distribution is displayed on the right.

8.6 Budget Smoothing

There is also literature in which other budget-smoothing approaches are considered. Zhou et al. consider the budget optimization problem in sponsored search as a online knapsack problem directly [12]. In our setting, their algorithm guarantees a $\ln(B) + 1$ competitive ration with the offline optimum. Their algorithm smooths its budget over time, and operates by bidding: $1/(1+\exp(z(t)-1))$ where $z(t)$ is the fraction of budget remaining at time t.

9 Experimental Results

In this section we will describe experimental results for the previously described algorithms. We use bids placed through Microsoft's adCenter in two sets of experiments. In the first, we assume that our modeling assumptions from Section 3 are correct, and construct a distribution $\mathcal{P}$ from the empirical data for use in simulation. In the second set of experiments, we run the methods on the historical data directly, taken as an individual sequence and thus violating our stochastic assumptions. We will see that in both cases, our suggested algorithm outperforms the other methods discussed. First, however, we discuss an important generalization to the setting that we have considered

so far.

9.1 Impressions and Clicks

Until now we have assumed that all ad impressions result in a click (i.e. winning an auction results in an automatic click). We will now relax this assumption. Instead, when an advertiser wins an impression, we will suppose that whether a click occurs is an independent Bernoulli random variable with mean r. We call r the *click-through rate*. If a click does indeed occur, the advertiser is charged the market price. Otherwise, the advertiser is informed that an impression has occurred, but maintains its budget.

All the methods described generalize to this setting in a straightforward manner. Nevertheless, it is worth being explicit about how *Greedy Product-Limit* must be modified. First note that the MDP formulation for the problem differs in the definition of the transition probability μ. In particular, we now have $\mu(a,(b,t),(b-\delta,t-1)) = rp(\delta)$ (when $\delta \leq a$), and $\mu(a,(b,t),(b,t-1)) = (1 - r\sum_{\delta=1}^{a} p(\delta))$. π_p^* can still be computed using dynamic programming, where:

$V_p(a,B,T) = (1 - r\sum_{\delta=1}^{a} p(\delta))V_p(B,T-1) + \sum_{\delta=1}^{a} rp(\delta)[1 + V_p(B-\delta,T-1)]$

and $\pi_p^*(B,T) = \arg\max_{a \leq B} V_p(a,B,T)$

Furthermore, as discussed in Section 6, rather than using the Product-Limit estimator, this setting requires that the new algorithm treat doubly-censored data, for which techniques exist [9].

9.2 Data

The data used for these experiments were generated by collecting the auction history from advertisers placing bids through Microsoft's adCenter over a six month period. For a given keyword, we let the number of times that keyword generated an auction be its *search volume*, $\texttt{Vol}_k$, and take keyword k to be the keyword with the k-th largest volume.

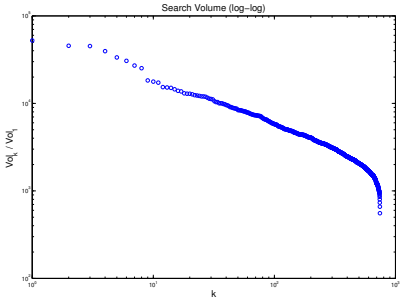

Figure 2: Log-log plot of $\texttt{Vol}_k/\texttt{Vol}_1$ for each k

The distribution of search volume is clearly heavy-tailed (see Figure 2) and is well approximated by a power law over several orders of magnitude.

We ran our experiments on the 100 keywords with largest search volume. As we will discuss further in the next section, the bidding behavior is quite varied among the different keywords in the data set.

In actual sponsored search-auctions, each bidder is given a *quality-score* for each keyword. Bidders' actual bids are multiplied by these quality scores to determine who wins the auction. For each keyword k, and auction t, let $x_{k,t}$ be the *quality-score-adjusted bid* for the advertiser that historically won the top slot for that auction, and $c_{k,t}$ indicate whether a click occurred.

We take the perspective of a new advertiser with unit quality score. $x_{k,t}$ is the amount that such an advertiser would have needed to bid to have instead taken the top slot (and the amount the advertiser would be charged should they also receive a click).

Finally, we make the single-slot assumption throughout, so even if multiple ads were indeed shown historically, we assume that an algorithm wins an impression if and only if it wins the top slot. In principle, *Greedy Product-Limit* can be modified to operate when multiple ad slots are available. However, we avoid this complication in this work.

9.3 Distributional Simulations

The first set of simulations use the historical data $\{x_{k,t}\}$, to construct an empirical distribution p_k on market prices for each keyword k. We also set a fixed click-through rate r_k, for each keyword using the background click-through rate for that keyword (the empirical average of $\{c_{k,t}\}$). While our main results in the next section eliminate the distribution p_k and use the sequence $\{x_{k,t}\}$ directly, we first simulate and investigate the case where our modeling assumptions hold.

Figure 3 demonstrates that the types of distributions generated in this manner are quite varied.

The budget B_k allocated to the advertiser for keyword k is selected so that, optimally, a constant fraction of clicks are available. In other words, the simulations were run with $B_k(T)$ satisfying $V_{p_k}(B_k(T),T) = fT$, where $f = 10\%$. Each experiment was run for 10 periods containing $T = 100$ auctions each, and 20 experiments were run for each keyword.

A major observation is that *Greedy Product-Limit* converges to the optimum policy on the time-scale of auctions, not periods. This is significant since certain methods considered are doomed to converge on the time-scale of periods instead. For example, each state

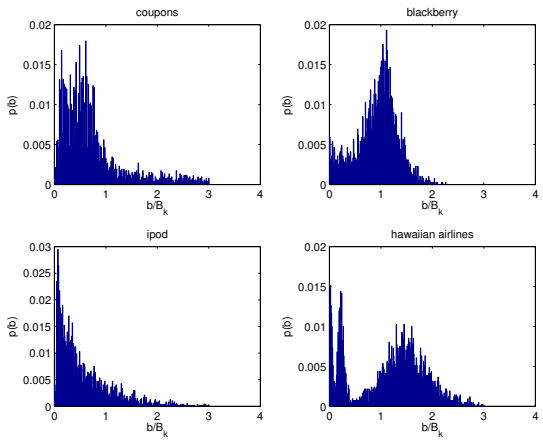

Figure 3: Each plot represents the empirical distribution p_k for a different keyword k. The x-axis represents the bid as a fraction of the total budget B_k allocated to the advertiser for keyword k.

can be visited at most once by Q-learning in a single period. Furthermore, for a particular time t, the only state corresponding to that t visited is $(B_{u,t}, t)$, (i.e. the state corresponding to the budget held by the algorithm at that time). Similarly, the Fixed-Price algorithm adjusts its bid at the end of every period. Table 1 shows that after just 2 periods, *Greedy Product-Limit* (GPL) has come within five percent of optimal across all keywords. For each algorithm, the results are the averages of 20 different simulations, and are statistically significant. An unpaired 2-sample t-test between the results for GPL and those of any other algorithm yields p-values that are less than 10^{-20}.

Table 1: Average Competitive Ratio with $V_{p_k}(B,T)$, across all keywords and experiments, after two periods.

Algorithm Name	Competitive Ratio	Std
Greedy Product-Limit	0.9573	0.1704
LuekerLearn	0.8448	0.1842
Fixed-Price Search	0.8352	0.1733
Q-learn	0.7484	0.1786
Budget Smoothing	0.1597	0.2418

9.4 Sequential Experiments

The main result of our work comes from experiments run on the real sequential data $\mathbf{d}_k = \{x_{k,t}, c_{k,t}\}_t$. Rather than taking $\{x_{k,t}, c_{k,t}\}$, and constructing the distribution p_k and a click-through rate, as in the previous section, we can use the sequence directly. Each of the previous methods are well-defined if the prices and clicks are generated in this manner, as opposed to being generated by the stochastic assumptions that motivated *Greedy Product-Limit*. We break the sequence into 10 periods of length $T = 100$. In reality, the number of auctions in a period might vary. However, this is minor, as an advertiser can attain good estimates of period-length. We allocate to each algorithm the same budget B_k used in the stochastic experiments.

Recall the notion of offline optimality defined in section 8.1. For each keyword k, we can compute the exact auctions that one should win knowing the sequence $\{x_{k,t}, c_{k,t}\}$ *a priori*. We will demonstrate that *Greedy Product-Limit* is competitive with even this strong notion.

We first look at the nature and time-scale of the convergence of *Greedy Product-Limit*.

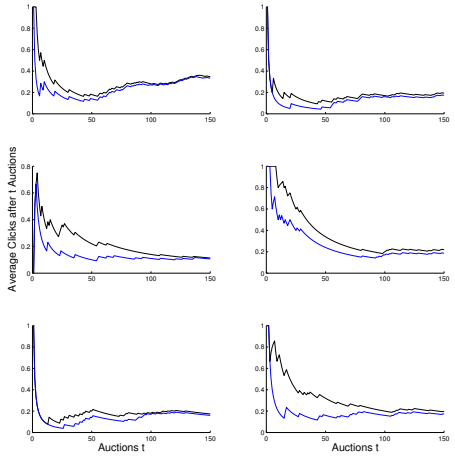

Figure 4: Convergence rates for 6 different keywords. The x-axis denotes auctions t, and the y-axis plots, in black, the number of clicks attained by the offline optimal after t auctions, normalized by t. The blue plot shows the same for *Greedy Product-Limit*. *Greedy Product-Limit* converges in the auction time-scale, not the period time-scale.

We will shortly see that *LuekerLearn*, the modification of *Greedy Product-Limit* attains similar performance. Like *Greedy Product-Limit*, it converges in the time-scale of auctions. However, recalling Figure 1, *LuekerLearn* will sometimes converge to something suboptimal, especially on keywords where there is a lot of variance in the bids. Figure 5 demonstrates this behavior on the sequential data. In fact, let A_k denote the cumulative number of clicks attained by *Greedy Product-Limit* and L_k denote the cumulative number of clicks attained by *LuekerLearn* after 10 periods for keyword k, defining $Z_k = A_k/L_k$ and $S_k = std(\{x_{k,t}\}_t)$. The observations $\{Z_k\}$ are positively correlated with $\{S_k\}$,

with a correlation coefficient of 0.2103 that is significant with a p-value of 0.0357.

Figure 6 demonstrates that, ignoring variance, *Greedy Product-Limit* has indeed converged to optimal across all keywords after just a single period. Let O_k be the offline optimal number of clicks that can be attained for keyword k after 10 periods (the entire data set). Let $A_{k,p}$ denote the cumulative number of clicks attained by an algorithm on keyword k after p periods. For an algorithm that is optimal after a single period, we should expect $A_{k,p}/O_k$ to be roughly $p/10$ for each period p. Indeed, while there are certain keywords for which this doesn't happen, we see that this is true on average.

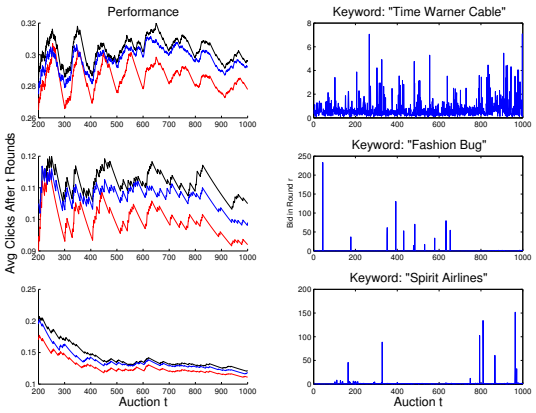

Figure 5: On the left the y-axis plots, in black, the number of clicks attained by the offline policy after t auctions, normalized by t. The blue plot shows the same for *Greedy Product-Limit* and the red for *LuekerLearn*. In all three, *LuekerLearn* is bounded away from the offline optimal. The right side displays $x_{k,t}/\bar{x}_k$ where $\bar{x}_k$ is the average over $x_{k,t}$ for the corresponding keyword. Note the "bursty" nature of the market price, with auctions occurring that set a market price hundreds of times greater than the average.

Figure 7 and Table 2 summarize the performance of the competing methods.

Table 2: Average Competitive Ratio with O_K, across all keywords.

Algorithm Name	Competitive Ratio	Std
Greedy Product-Limit	0.9062	0.1166
LuekerLearn	0.8962	0.1152
Fixed-Price Search	0.6253	0.1395
Q-learn	0.5879	0.1558
Budget Smoothing	0.3105	0.3252

Notice that besides *Greedy Product-Limit*, the only other algorithm that competes with the offline optimal is our modification to the stochastic knapsack algorithm, *LuekerLearn*. As previously discussed, the convergence of *Q-learn* and *Fixed-Price Search* happens on the time-scale or periods, not auctions. We suspect that with more data, both would converge (as they do in the stochastic setting), albeit *Fixed-Price Search* would converge only to the best fixed-price in hindsight. Finally, as demonstrated in Figure 5, when there is large variation in bidder behavior, *LuekerLearn* might stay bounded away from the offline optimal.

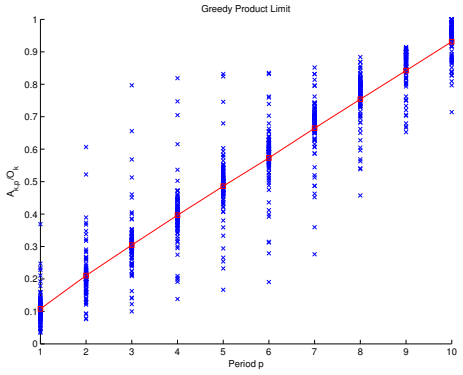

Figure 6: Each scatter point represents $A_{k,p}/O_k$ for a different keyword k, at the end of period p displayed on the x-axis. The line is the mean of $A_{k,p}/O_k$ across all k for a fixed period p.

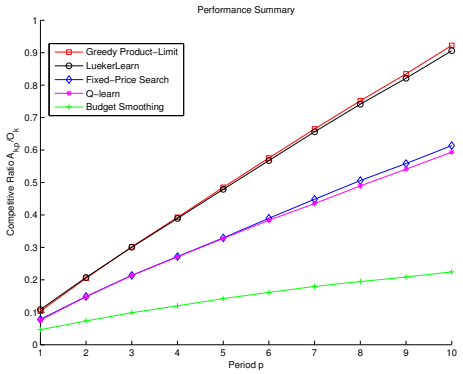

Figure 7: Average of $A_{k,p}/O_k$ across all k for each algorithm.

10 Future Work

We conjecture that *Greedy Product-Limit* always converges (rapidly) to the optimal policy in the stochastic setting, and hope to prove so in the future.

Abstract

In recent years, non-parametric methods utilizing random walks on graphs have been used to solve a wide range of machine learning problems, but in their simplest form they do not scale well due to the quadratic complexity. In this paper, a new dual-tree based variational approach for approximating the transition matrix and efficiently performing the random walk is proposed. The approach exploits a connection between kernel density estimation, mixture modeling, and random walk on graphs in an optimization of the transition matrix for the data graph that ties together edge transitions probabilities that are similar. Compared to the de facto standard approximation method based on k-nearest-neighbors, we demonstrate order of magnitudes speedup without sacrificing accuracy for Label Propagation tasks on benchmark data sets in semi-supervised learning.

1 Introduction

Non-parametric methods utilizing random-walks on graphs have become very popular in Machine Learning during the last decade. These methods have been applied to solve Machine Learning problems as diverse as clustering (von Luxburg, 2007), dimensionality reduction (Lafon and Lee, 2006), semi-supervised learning (SSL) (Zhu, 2005), supervised learning (Yu et al., 2005), link analysis (Ng et al., 2001), and others. Unfortunately, these methods suffer from one fundamental and recurring problem: the quadratic dependency on the number of examples, which subsequently affects their scalability and applicability to large-scale data sets. Many different approximation frameworks have been proposed in the literature to tackle the above problem. Typically, these methods work by *sparsifying* the underlying graph representation by either reducing the number of nodes representing data points or reducing the number of edges representing data points similarities.

The first class of techniques aims to reduce the number of nodes in the graph from N to M ($M \ll N$). The reduction is carried out in various ways: random sampling (Kumar et al., 2009; Amizadeh et al., 2011), mixture modeling (Zhu and Lafferty, 2005), non-negative matrix factorization (Yu et al., 2005), sparse griding (Garcke and Griebel, 2005), Latent Markov Analysis (Lin, 2003), etc. A common problem with these techniques is that it is not clear how fast one should increase M when N increases. Subsequently, although the memory and the matrix-vector multiplication complexities are reduced to $O(M^2)$, we go back to $O(N^2)$ in effect if M changes with the same rate as N does.

The second class of techniques tries to sparsify the edges in the graph. k-nearest-neighbor graphs (Zhu, 2005) and b-matching (Jebara et al., 2009) are among the most famous methods in this group. The main concern with these methods, however, is the computational complexity of building these sparse graphs. Even with the smart speed-up techniques, such as k-nearest-neighbor graphs (Liaw et al., 2010; Moore, 1991), the actual time for building the full sparse graph can vary in practice.

A third class of methods goes around the problem of finding a sparse graph representation by trying to approximate the quantity of interest in the problem directly. Manifold regularization techniques (Belkin et al., 2006; Tsang and Kwok, 2006) directly find a smooth function on the graph. Fergus et al. (2009); Nadler et al. (2006); Amizadeh et al. (2012) try to directly estimate the eigen decomposition of the underlying transition matrix in the limit assuming factorized underlying distribution. Although these methods can be very effective, they are also task specific and do not give us an explicit approximation of the graph similarity (transition) structure.

The framework proposed in this paper directly approximates the transition matrix of the data graph. Our

method is similar to the second group of approximation techniques in the sense that it does not reduce the graph nodes. However, instead of zeroing out the edges (like in the second group), our framework groups the edges together to *share* edge transition probabilities that are similar. To do so, we use a recent advancement from Thiesson and Kim (2012), which for a very different task (fast mode-seeking) developed a fast dual-tree based (Gray and Moore, 2000) variational framework that exploits a mixture modeling view on kernel density estimation. Mixture modeling and the random walk on graphs are also closely related (Yu et al., 2005). Based on this connection between kernel density estimation, mixture modeling, and random walk on graphs, we extend the framework in Thiesson and Kim (2012) to a fast and scalable framework for 1) transition matrix approximation and 2) inference by the random walk.

By further exploiting the connection between mixture modeling and random walk, we also propose a lower-bound log-likelihood optimization technique to find the optimal bandwidth for the Gaussian similarity kernel (which is a very popular kernel for constructing transition matrices on data graphs). Moreover, using our framework, one can adjust the trade-off between accuracy and efficiency by *refining* the model. As we show in the paper, at its coarsest level of refinement, our framework achieves complexity order of $O(N^{1.5}\log N)$ for construction, $O(N)$ inference via matrix-vector multiplication, and memory consumption of $O(N)$, which improves the performance of graph sparsification methods reviewed earlier. To demonstrate the speed-up in practice, we experimentally show that without compromising much in terms of accuracy, our framework can build, represent and operate on random-walk transition matrices orders of magnitude faster than the baseline methods.

2 Background

Kernel density estimation plays an important conceptual role in this paper. Let $\mathcal{M} = \{m_1, m_2, \ldots, m_N\}$ denote a set of kernel centers corresponding to observed data $\mathcal{D}$ in $\mathbb{R}^d$. The kernel density estimate for any data point $x \in \mathbb{R}^d$ is then defined by the following weighted sum or mixture model:

$$p(x) = \sum_j p(m_j)p(x|m_j) \tag{1}$$

where $p(m_j) = \frac{1}{N}$, $p(x|m_j) = \frac{1}{Z_\sigma}k(x, m_j; \sigma)$, and k is a kernel profile with bandwidth σ and normalization constant Z_σ. For the commonly used Gaussian kernel, $k(x, m_j; \sigma) = \exp(-\|x - m_j\|^2/2\sigma^2)$ and $Z_\sigma = (2\pi\sigma^2)^{\frac{d}{2}}$.

Now let us assume we want kernel density estimates for data points $\mathcal{D} = \{x_1, x_2, \ldots, x_N\}$ in $\mathbb{R}^d$ that also define the kernel centers. That is, $\mathcal{D} = \mathcal{M}$, and we use the $\mathcal{D}$ and $\mathcal{M}$ notation to emphasize the two different roles every example takes - one as a data point, the other as a kernel center. Let us exclude the kernel centered at $m_i = x_i$ from the kernel density estimate at that data point. In this case, the estimate at $x_i \in \mathcal{D}$ can be defined as the $N-1$ component mixture model:

$$p(x_i) = \sum_{j\neq i} p(m_j)p(x_i|m_j) = \sum_{j\neq i} \frac{1}{N-1}\frac{1}{Z_\sigma}k(x_i, m_j; \sigma), \tag{2}$$

where $p(m_j) = 1/(N-1)$.

In the mixture model interpretation for the kernel density estimate, the posterior kernel membership probability for a data point can be expressed as

$$p(m_j|x_i) = \frac{p(m_j)p(x_i|m_j)}{p(x_i)} = \frac{k(x_i, m_j; \sigma)}{\sum_{l=1}^{N} k(x_i, m_l; \sigma)} \tag{3}$$

These posteriors form a matrix $P = [p_{ij}]_{N\times N}$ where $p_{ij} = p(m_j|x_i)$ for $i \neq j$ are the true posteriors, and $p_{ij} = 0$ for $i = j$ are neutral elements added for later notational convenience. Note that in this representation, each row in P holds a posterior distribution $p_{i\cdot} \triangleq \{p_{ij}|j = 1, \ldots, N\}$.

The complexity of computing and representing P is $O(N^2)$, which is costly for large-scale data sets with large N. In this work, we seek ways of alleviating the problem by taking the advantage of the cluster structure in data (and kernels) that would let us *share* posteriors among groups of data points and kernels instead of computing them for each individual pair. More precisely, suppose that the data set $\mathcal{D}$ consists of two well-separated clusters in $\mathbb{R}^d$, denoted by C_1 and C_2. In this case, it is likely that the posteriors $p(m_j|x_i)$ are roughly similar for all $x_i \in C_1$ and $m_j \in C_2$ so that one can approximate all posteriors for the pairs in between these two clusters with one value. Notice how this approximation directly targets the posteriors and not the expensive intermediate kernel summation in the denominator of (3). This simple idea can be generalized recursively if we have nested cluster structure in the form of a *cluster hierarchy*. In this case, the computational savings can be dramatic.

3 Dual-tree Based Variational P

Whilst the approximation idea for P outlined above may appear simple, it needs careful handcrafting in order to yield a practical and computationally efficient framework. We start building our framework by borrowing the ideas from the dual-tree-based variational approach proposed by Thiesson and Kim (2012).

3.1 Dual-tree Block Partitioning

The dual-tree-based variational approach in Thiesson and Kim (2012) maintains two tree structures; the *data partition tree* and the *kernel partition tree*, that hierarchically partition data points (kernels) into disjoint subsets, such that an intermediate node in a tree represents a subset of data points (or kernels) and leaves correspond into singleton sets. In this work we assume the structure of the two trees is identical, leading to the exactly same subsets of data points and kernels represented by the tree.

The main reason for introducing the partition tree is to define relations and permit inferences for groups of related data points and kernels without the need to treat them individually. More specifically, we use the partition tree to induce a *block partition* of the matrix P, where all posteriors within the block are forced to be equal. We also refer to this partition as *block constraints* on P. Formally, a *valid* block partition $\mathcal{B}$ defines a mutually exclusive and exhaustive partition of P into blocks (or sub-matrices) $(A, B) \in \mathcal{B}$, where A and B are two *non-overlapping* subtrees in the partition tree. That is, $A \cap B = \emptyset$, in the sense that data-leaves in the subtree under A and kernel-leaves in the subtree under B do not overlap. (To maintain the convenient matrix representation of P, the singleton blocks representing the neutral diagonal elements in P are added to this partition.) Figure 1a) shows a small example with a valid block partition for a partition tree built for six data points (kernels). This block partition will, for example, enforce the block constraint $p_{13} = p_{14} = p_{23} = p_{24}$ for the block $(A, B) = (1\text{–}2, 3\text{–}4)$ (where $a-b$ denotes a through b).

To represent the block-constrained P matrix more compactly, we utilize the so-called *marked partition tree (MPT)* that annotates the partition tree by explicitly linking data groups to kernel groups in the block partition: for each block $(A, B) \in \mathcal{B}$, the data-node A is marked with the matching kernel-node B. Each node A in the MPT will therefore contain a, possibly empty, list of marked B nodes. We will denote this list of marks as $A_{mkd} \triangleq \{B|(A, B) \in \mathcal{B}\}$. Figure 1b) shows the MPT corresponding to the partition in Figure 1a). For example, the mark of kernels $B = 3{-}4$ at the node representing the data $A = 1{-}2$ corresponds to the same block constraint $(A, B) = (1-2, 3-4)$, as mentioned above. It is the only mark for this data node, and therefore $A_{mkd} = 1{-}2_{mkd} = \{3-4\}$. As another example, the list of marks for node $A = 5$ has two elements; $A_{mkd} = 5_{mkd} = \{5, 6\}$. An important technical observation, that we will use in the next section, is that each path from a leaf to the root in the MPT corresponds to the row indexed by that leaf in the block partition matrix for P. By storing the posterior probabilities at the marks in the MPT, we can therefore extract the entire posterior distribution $p_{i\cdot}$ by starting at the leaf that represents the data point x_i and follow the path to the root.

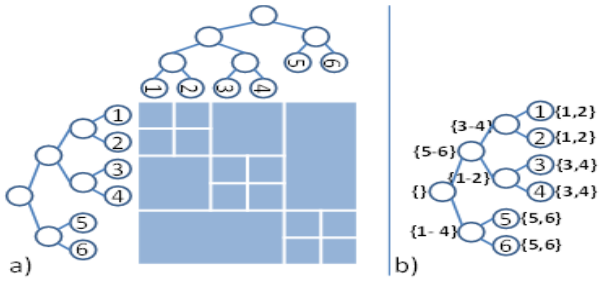

Figure 1: a) A block partition (table) for data partition tree (left) and identical kernel partition tree (top). b) MPT representation of the block partition.

Clearly, there are more than one valid partitions of P; in fact, any further *refinement* of a valid partition results in another valid partition with increased number of blocks. We postpone the discussion of how to choose an initial valid partition and how to refine it to Section 4.4. For now, let us assume that we are given a valid partition $\mathcal{B}$ of P with $|\mathcal{B}|$ number of blocks. By insisting on the block constraint of equality for all posteriors in a given block, the number of parameters in P is effectively reduced from N^2 to $|\mathcal{B}|$.

3.2 Optimization of Block Partitioning

In general, the block partition approach links groups of data points and kernels together such that any specific link is no longer able to distinguish its components. The key question now is whether we can cast the block partitioning problem into an optimization framework that can approximate well the true unconstrained P. We address the question by using a variational approximation approach. In this case, each block $(A, B) \in \mathcal{B}$ is assigned a single variational parameter q_{AB} that approximates the posteriors p_{ij} for all $x_i \in A$ and $m_j \in B$ in that block. That is, for $Q = [q_{ij}]_{N\times N}$

$$q_{ij} = q_{AB} \text{ s.t. } (A, B) \in \mathcal{B}, x_i \in A, m_j \in B \qquad (4)$$

Recall that in our setup, $q_{ij} = p_{ij} = 0$ for $i = j$.

The trick to solve the problem rests on expressing a variational lower bound for the log-likelihood of data:

$$\log p(\mathcal{D}) = \sum_i \log p(x_i) = \sum_i \log \sum_{j\neq i} p(m_j)p(x_i \mid m_j)$$
$$= \sum_i \log \sum_{j\neq i} \frac{q_{ij}}{q_{ij}} p(m_j)p(x_i \mid m_j)$$
$$\geq \sum_i \sum_{j\neq i} q_{ij} \log \frac{p(m_j)p(x_i \mid m_j)}{q_{ij}} \qquad (5)$$

$$= \log p(\mathcal{D}) - \sum_i D_{KL}\big(q_{i\cdot}\|p_{i\cdot}\big) \triangleq \ell(\mathcal{D}), \qquad (6)$$

where $D_{KL}(\cdot||\cdot)$ is the KL-divergence between two distributions. Notice that optimizing the lower bound $\ell(\mathcal{D})$ with respect to Q corresponds to minimizing the KL-divergence between the two distributions $q_{i\cdot}$ and $p_{i\cdot}$ for all i, since this is the only term in (6) that depends on Q. The block-constrained Q matrix is therefore a good approximation for the unconstrained P.

Let us now explicitly insert the block constraints from (4) into the expression for $\ell(\mathcal{D})$ in (5). With $p(m_i) = 1/(N-1)$ and the Gaussian (normalized) kernel for $p(x_i|m_j)$, the optimization reduces to finding the variational parameters q_{AB} that maximizes

$$\begin{aligned}\ell(\mathcal{D}) &= c - \frac{1}{2\sigma^2}\sum_{(A,B)\in\mathcal{B}} q_{AB}\cdot D^2_{AB} \\ &\quad - \sum_{(A,B)\in\mathcal{B}} |A||B|\cdot q_{AB}\log q_{AB}, \quad (7)\end{aligned}$$

where

$$\begin{aligned}c &= -N\log\big((2\pi)^{d/2}\sigma^d(N-1)\big) \\ D^2_{AB} &= \sum_{x_i\in A}\sum_{m_j\in B}\|x_i - m_j\|^2. \qquad (8)\end{aligned}$$

Thiesson and Kim (2012)[Algorithm 3] has developed a recursive algorithm that solves this optimization for all q_{AB}, $(A,B)\in\mathcal{B}$ in $O(|\mathcal{B}|)$ time. Specifically, their solution avoids the quadratic complexity that a direct computation of the Euclidean distances in (8) would demand by factorizing D^2_{AB} into data-specific and kernel-specific statistics as follows

$$D^2_{AB} = |A|S_2(B) + |B|S_2(A) - 2S_1(A)^T S_1(B), \quad (9)$$

where $S_1(A) = \sum_{x\in A} x$ and $S_2(A) = \sum_{x\in A} x^T x$ are the statistics of subtree A. These statistics can be incrementally computed and stored while the shared partition tree is being built; an $O(N)$ computation. Using these statistics, D^2_{AB} is computed in $O(1)$.

Now, the question is how to efficiently construct the shared partition tree from data. Well-known, efficient partition-tree construction methods include *anchor* tree (Moore, 2000), *kd*-tree (Moore, 1991) and *cover* tree (Ram et al., 2009; Beygelzimer et al., 2006) construction. We have used the anchor tree. With a relatively balanced tree, it takes $O(N^{1.5}\log N + |\mathcal{B}|)$ time and $O(|\mathcal{B}|)$ memory in total to build and store the variational approximation for the posterior matrix P from data. See the supplementary Appendix for more details on the anchor tree construction complexity.

4 Application to Random Walk

In this section, we show how the variational mixture modeling framework can be utilized to tackle large-scale random walk problems. The random walk here is defined on the graph $\mathcal{G}$ which is an undirected similarity graph whose nodes are the data points in $\mathcal{D}$ and the edge between nodes x_i and x_j is assigned the similarity weight $s_{ij} = \exp(-\|x_i - x_j\|^2/2\sigma^2)$.

4.1 Variational Random Walk

As we saw in Section 2, $p(m_j|x_i)$ models the posterior membership of data point x_i to the Gaussian kernel m_j. However, $p(m_j|x_i)$ can be interpreted from a completely different view as the probability of jumping from data point x_i to data point m_j in a random walk on $\mathcal{G}$. In fact, (3) is the same formula that is used to compute the transition probabilities on data graphs, when the Gaussian similarity is used (Lafon and Lee, 2006). As a result, the matrix P from the previous section can be seen as the transition probability matrix for a random walk on $\mathcal{G}$. Subsequently, the corresponding variational approximation of Q is in fact the approximation of the transition probability matrix using only $|\mathcal{B}|$ number of parameters (blocks); in other words, q_{AB} approximates the probability of jumping from a data point in A to a data point in B. This is, in particular, important because it enables us to compute and store the transition probability matrix in $O(N^{1.5}\log N + |\mathcal{B}|)$ time and $O(|\mathcal{B}|)$ memory for large-scale problems.

In the light of this random walk view on Q, the lower bound log-likelihood $\ell(\mathcal{D})$ in (7) will also have a new interpretation. More precisely, the second term in (7) can be reformulated as:

$$-\frac{1}{2\sigma^2}\sum_{(A,B)\in\mathcal{B}} q_{AB}\cdot D^2_{AB} = -\frac{1}{2\sigma^2}\sum_{i,j} q_{ij}\cdot\bar{d}_{ij} \quad (10)$$

where, q_{ij} is defined as in (4) and $\bar{d}_{ij} = D^2_{AB}/|A||B|$ is the *block-average distance* such that $(A,B)\in\mathcal{B}$, $x_i\in A$ and $m_j\in B$. This is, in fact, a common optimization term in similarity-graph learning from mutual distances (Jebara et al., 2009) and can be more compactly represented as $-\frac{1}{2\sigma}tr(Q\bar{D})$, where $Q = [q_{ij}]_{N\times N}$ and $\bar{D} = [\bar{d}_{ij}]_{N\times N}$ are the similarity and distance matrices, respectively. However, there is one problem with a maximization of this term: it will make each point connect to its closest neighbor with $q_{ij} = 1$ (and $q_{ij} = 0$ for the rest). In other words, the similarity graph will be highly disconnected. This is where the third term in (7) benefits the new interpretation. One can rewrite this term as:

$$\begin{aligned}-\sum_{(A,B)\in\mathcal{B}} |A||B|\cdot q_{AB}\log q_{AB} &= -\sum_{i,j} q_{ij}\log q_{ij} \\ &= \sum_{i=1}^{N} H(q_{i\cdot}) \qquad (11)\end{aligned}$$

where $H(q_{i\cdot})$ is the entropy of the transition probability distribution from data point x_i. As opposed to (10), the term in (11) is maximized by a uniform distribution over the outgoing probabilities at each data point x_i; that is, a fully connected graph with equal transition probabilities. The third term in (7) therefore acts as the *regularizer* in the learning of the similarity-graph, trying to keep it connected. The trade-off between the second and the third terms is adjusted by the coefficient $1/2\sigma^2$: increasing σ will leave the graph more connected.

4.2 Learning σ

Finding the transition probabilities for a random walk by the variational optimization of (7) has a side advantage too: (7) is a *quasi-concave* function of the bandwidth σ, which means that, given q_{AB}'s fixed, one can find the optimal bandwidth that maximizes the log-likelihood lower bound. By taking the derivative and solving for σ, the closed form solution is:

$$\sigma^* = \sqrt{\frac{\sum_{(A,B)\in\mathcal{B}} q_{AB} \cdot D_{AB}^2}{Nd}} \tag{12}$$

In the special case where each element of matrix P is a singleton block (i.e. the most refined case), one can find σ^* independent of q_{AB}'s values. To do so, we first form the following log-likelihood lower bound using the Jensen inequality:

$$\log p(\mathcal{D}) \geq \sum_i \sum_{j\neq i} p(m_j) \log p(x_i \mid m_j) \tag{13}$$

By maximizing the right-hand side w.r.t. σ, we get:

$$\sigma^* = \frac{1}{N}\sqrt{\frac{\sum_i \sum_{j\neq i} \|x_i - x_j\|^2}{d}} \tag{14}$$

In general, due to the dependence of σ^* to q_{AB}'s, we alternate the optimization of q_{AB}'s and σ in our framework. In practice, we have observed that the convergence of this alternate optimization is fast and not sensitive to the initial value of σ.

4.3 Fast Inference

In the previous subsections, we saw how the variational dual-tree based framework can be used to efficiently build and store a variational transition matrix Q of a random walk. We will now demonstrate that the block structure of this transition matrix can be very useful for further inference in similarity-graph based learning algorithms. In particular, using the MPT representation of Q, we can efficiently compute the multiplication with an arbitrary vector $Y = (y_1, y_2, \ldots, y_n)^T$ of observations to achieve $\hat{Y} = QY \simeq PY$ in $O(|\mathcal{B}|)$ rather than $O(N^2)$ computations.

Algorithm 1 Calculate $\hat{Y} = QY$

Input: MPT with $\{q_{AB} : B \in A_{mkd}\}$ on each node A, and (x_i, y_i) on each leaf.
Output: $\hat{y}_i$ on each leaf.

```
A = Root(MPT)
CollectUp(A)
DistributeDown(A, 0)

function CollectUp(A)
  if IsLeaf(A) then
    T_A = y_A                    //null-vector if y_A is not observed
  else
    CollectUp(A_l)
    CollectUp(A_r)
    T_A = T_{A_l} + T_{A_r}
  end if
end function

function DistributeDown(A, py)
  for all marks B ∈ A_mkd do
    py += |B| q_AB T_A
  end for
  if IsLeaf(A) then
    ŷ_A = py
  else
    DistributeDown(A_l, py)
    DistributeDown(A_r, py)
  end if
end function
```

Algorithm 1 describes the $O(|\mathcal{B}|)$ computation of $\hat{Y}$. The algorithm assumes that each y_i is stored at the corresponding leaf x_i in the MPT–e.g., by association prior to constructing the MPT. Alternatively, an index to the leaves can be constructed in $O(N)$ time. The algorithm starts with a CollectUp phase that traverses the MPT bottom-up and stores incrementally computed sum-statistics at each node A, as

$$T_A = \sum_{x_i \in A} y_i = T_{A_l} + T_{A_r},$$

where A_l, A_r are the left and right children of A. This is an $O(N)$ computation. Let $\mathcal{B}(x_i) \triangleq \{(A,B) \in \mathcal{B} \mid x_i \in A\}$ denote the set of marked blocks that can be experienced on the path in the MPT from leaf x_i to the root. For example, in Figure 1, $\mathcal{B}(3) = \{(3,3), (3,4), (3{-}4, 1{-}2), (1{-}4, 5{-}6)\}$. With each q_{AB} stored at the node A marked with B in the MPT, a DistributeDown phase now conceptually computes

$$\hat{y}_i = \sum_{(A,B)\in\mathcal{B}(x_i)} |B| q_{AB} T_A \simeq \sum_j p_{ij} y_j,$$

by following the path from each leaf to the root in the MPT. The more efficient implementation in Algorithm 1 traverses the MPT top-down, avoiding recalculations of the shared terms for the updates by propagating the value of the shared terms through the variable py. This traversal has complexity $O(|\mathcal{B}|)$. On completion of the algorithm the leaves in the MPT will contain $\hat{Y} = \{y_i\}_{i=1}^N$. The fast matrix-vector multiplication is a significant achievement because it allows us to significantly speed up any algorithm with this computational bottleneck. Two such algorithms

are Label Propagation (LP) (Zhou et al., 2003) used for Semi-supervised Learning and Link Analysis (see, e.g., Ng et al. (2001)), and Arnoldi Iteration (Saad, 1992) used for spectral decomposition. More specifically, given a similarity graph over the data points x_i, the LP algorithm iteratively updates the label matrix $Y = [y_{ij}]_{N\times C}$ (where C is the number of label classes) at time $t+1$ by propagating the labels at time t one step forward according to the transition matrix P:

$$Y^{(t+1)} \leftarrow \alpha P Y^{(t)} + (1-\alpha)Y^0 \tag{15}$$

Here, the matrix Y^0 encodes the initial labeling of data such that $y^0_{ij} = 1$ for label$(x_i) = y_i = j$, and $y^0_{ij} = 0$ otherwise. The coefficient $\alpha \in (0,1)$ determines how fast the label values are updated. The repeated matrix multiplication in (15) definitely poses a bottleneck for large-scale problems, and this is where our fast framework comes into play.

4.4 Partitioning and Refinement

So far, we have assumed that a valid partition $\mathcal{B}$ of P with $|\mathcal{B}|$ number of blocks is given. In this section, we illustrate how to construct an initial valid partition of P and how to further refine it to increase accuracy of the model. We should note that the methods for partitioning and refinement in this section are different from the ones in Thiesson and Kim (2012).

Let $\mathcal{B}_{diag}$ denote the N neutral singleton blocks that appear on the diagonal of P. The coarsest (with the smallest number of blocks) valid partition $\mathcal{B}_c$ for P is achieved when for every block $(A,B) \in \mathcal{B}_c = \mathcal{B}\setminus\mathcal{B}_{diag}$, we have that A and B are sibling subtrees in the partition tree. (Recall that data and kernels are partitioned by the same tree.) Any other partition will either not be a valid partition conforming with the partition tree, or it will have a larger number of blocks. The number of blocks in $\mathcal{B}_c$, therefore equals twice the number of inner nodes in the anchor tree; i.e. $|\mathcal{B}_c| = 2(N-1)$. Figure 1 is an example of a coarsest valid block partition. On the other hand, the most refined partition is achieved when $\mathcal{B}_r = \mathcal{B}\setminus\mathcal{B}_{diag}$ contains $N^2 - N$ singleton blocks. Hence, the number of blocks in a valid partition $|\mathcal{B}|$ can vary between $O(N)$ and $O(N^2)$. As we saw in the previous sections, $|\mathcal{B}|$ plays a crucial role in the computational performance of the whole framework and we therefore want to keep it as small as possible. On the other hand, keeping $|\mathcal{B}|$ too small may excessively compromise the accuracy of the model. Therefore, the rational approach would be to start with the coarsest partition $\mathcal{B}_c$ and split the blocks in $\mathcal{B}_c$ into smaller ones only if needed. This process is called *refinement*. As we refine more blocks, the accuracy of the model effectively increases while its computational performance degrades. Note that a block (A,B) can be refined in two ways: either *vertically* into $\{(A_l,B),(A_r,B)\}$ or *horizontally* into $\{(A,B_l),(A,B_r)\}$. Here the subscript r (l) denotes the right (left) child node.

After any refinement, we can re-optimize (7) to find the new variational approximation Q for P. Importantly, any refinement loosens the constraints imposed on Q, implying that the KL-divergence from P cannot increase. From (6) we can therefore easily see that a refinement is likely to increase the log-likelihood lower bound $\ell(\mathcal{D})$, and can never decrease it. Intuitively, we want to refine those blocks which increase $\ell(\mathcal{D})$ the most. To find such blocks, one need to refine each block in each direction (i.e. horizonal and vertical) one at a time, re-optimize Q, find the difference between the new $\ell(\mathcal{D})$ and the old one (aka *log-likelihood gain*), and finally pick the refinements with maximum difference. However, this is an expensive process since we need to perform re-optimization per each possible refinement. Now the question is, whether we can obtain an estimate of the log-likelihood gain for each possible refinement without performing re-optimization. The answer is positive for horizontal refinements, and rests on the fact that each row in Q defines a (posterior) probability distribution and therefore must sum to one. In particular, this sum-to-one constraint can for $\mathcal{B}(x_i) \triangleq \{(A,B) \in \mathcal{B} \mid x_i \in A\}$ be expressed as

$$\textstyle\sum_{(A,B)\in\mathcal{B}(x_i)} |B| \cdot q_{AB} = 1 \text{ for all } x_i \in \mathcal{D}. \tag{16}$$

Consider the horizontal refinement of (A,B) into $\{(A,B_l),(A,B_r)\}$. By this refinement, in essence, we allow a random walk, where the probability of jumping from points in A to the ones in B_l (i.e. q_{AB_l}) is different from that of jumping from A to B_r (i.e. q_{AB_r}). If we keep the q values for other blocks fixed, we can still *locally* change q_{AB_l} and q_{AB_r} to increase $\ell(\mathcal{D})$. Since the sum of the outgoing probabilities from each point is 1 (see (16)) and the other q's are unchanged, the sum of the outgoing probabilities from A to B_l and B_r must be equal to that of the old one from A to B:

$$|B_l| q_{AB_l} + |B_r| q_{AB_r} = |B| q_{AB}. \tag{17}$$

Under this local constraint, we can find q_{AB_l} and q_{AB_r} in closed form such that $\ell(\mathcal{D})$ is maximized:

$$q_{AB_c} = \frac{|B|\exp(G_{AB_c}) q_{AB}}{\sum_{t\in\{l,r\}} |B_t|\exp(G_{AB_t})},\ c \in \{l,r\} \tag{18}$$

where $G_{AB} = -D^2_{AB}/(2\sigma^2|A||B|)$. By inserting (18) in (7), we can compute the maximum log-likelihood gain for the horizontal refinement of (A,B) as

$$\begin{aligned}\Delta^h_{AB} &= \ell'(\mathcal{D}) - \ell(\mathcal{D}) \\ &= |A||B| q_{AB} \cdot \log\left(\frac{\sum_{t\in\{l,r\}} |B_t|\exp(G_{AB_t})}{|B|\exp(G_{AB})}\right),\end{aligned} \tag{19}$$

where $\ell'(\mathcal{D})$ denotes the log-likelihood lower bound after the refinement. Note that the actual gain can be

greater than Δ^h_{AB} because after a refinement, all q values are re-optimized. In other words, Δ^h_{AB} is a lower bound for the actual gain and is only used to pick blocks for refinements. Unfortunately, for vertical refinements such a bound is not easily obtainable. The reason is that the constraints in (16) will not allow $q_{A_l B}$ and $q_{A_r B}$ to change if we fix the remaining q values. The local optimization that we applied for the horizontal refinement can therefore not be applied to estimate a vertical refinement. Whenever we pick a block (A, B) for vertical refinement, we therefore incorporate vertical refinements by applying the horizontal refinement to its symmetric counterpart (B, A) if it also belongs to $\mathcal{B}$. We call this *symmetric refinement*.

Now by computing Δ^h_{AB} for all blocks, we greedily pick the block with the maximum gain and apply symmetric refinement. The newly created blocks are then added to the pool of blocks and the process is repeated until the number of blocks reaches the maximum allowable block number $|\mathcal{B}|_{max}$, which is an input argument to the algorithm. This greedy algorithm can be efficiently implemented using a priority queue.

5 Experiments

In this section, we present the experimental evaluation of our framework. In particular, we have evaluated how well our method performs for semi-supervised learning (SSL) using Label Propagation (LP) (Zhou et al., 2003). The LP algorithm starts with a partial vector of labels and iteratively *propagates* those labels over the underlying similarity graph to unlabeled nodes (see (15)). After T iterations of propagation, the inferred labels at unlabeled nodes are compared against the true labels (which were held out) to compute Correct Classification Rate (CCR). We also measure the time (in ms) taken to build each model, propagate labels and refine each model. In our experiments, we set $T = 500$ and $\alpha = 0.01$. It should be noted that, here the goal is not to achieve a state-of-the-art SSL algorithm, but to relatively compare our framework to baselines in terms of efficiency and accuracy under the *same* conditions. This means that we have not tuned the SSL parameters to improve SSL; however, we use the same parameters for all competitor methods.

5.1 The Baselines

We have compared our method, *VariationalDT*, with two other methods for building and representing P. The first method is the straightforward computation of P using (3). We refer to this representation as the *exact model*. In terms of computational complexity, it takes $O(N^2)$ to build, store, and multiply a vector to P using the exact method. The second method is the *k-nearest-neighbor (kNN)* algorithm where each data point is connected only to its k closest neighbors. In other words, the rows of matrix P will contain only k non-zero entries such that P can be represented as a sparse matrix for small k's. In that way, kNN zeros out many of these parameters to make P sparse, as opposed to our VariationalDT method that groups and shares parameters in P. Note that we still assign weights to the k edges for each data point using (3). This means that as we increase k toward N, the model converges to the exact model. Therefore, k acts as a tuning parameter to trade off between computational efficiency and accuracy (the same role that $|\mathcal{B}|$ plays in VariationalDT). We call k and $|\mathcal{B}|$ the trade-off parameters.

Using the kNN representation, P can be stored and multiplied by an arbitrary vector in $O(kN)$. For constructing a kNN graph directly, the computational complexity is $O(rN^2)$ where $r = \min\{k, \log N\}$. A smarter approach is to use a metric tree in order to avoid unnecessary distance computations. Moore (1991) proposed a speedup of the kNN graph construction that utilizes a *kd-tree*. In our implementation of kNN, we have used the same algorithm with the *kd*-tree replaced by the anchor tree, introduced in Section 3. We call this algorithm *fast kNN*. The computational analysis of fast kNN greatly depends on the distribution of data points in the space. In the best case, it takes $O\big(N(N^{0.5}\log N + k\log k)\big)$ to build the kNN graph using fast kNN. However, in the worst case, the computational order is $O\big(N(N^{0.5}\log N + N\log k)\big)$. Table 1 summarizes the computational complexity orders for the models compared in the experiments. Note that for $|\mathcal{B}| = kN$ for some integer k, the VariationalDT and kNN will have the same memory and multiplication complexity. To increase k (or equivalently $|\mathcal{B}|$), one needs to refine the respective model. The last column in Table 1 contains the complexity of refining k to $k+1$ (or equivalently $|\mathcal{B}|$ from kN to $(k+1)N$) for kNN (or VariationalDT).

5.2 Experimental Setup

We have performed three experiments to evaluate the computational efficiency and accuracy of the models described above. It should be noted that for all methods, we have used the log-likelihood lower-bound technique in Section 4.2 to tune the bandwidth σ.

In the first experiment, we have run the LP algorithm for semi-supervised learning on the SecStr data set, one of the benchmark data sets for SSL (Chapelle et al., 2006). The data set consists of 83,679 different amino acids each of which is represented by 315 binary features. The task is to predict the secondary structure of the amino acids (2 classes). The goal in this experiment, as we increase the problem size N, is to study (a) the time needed to build the exact model, the

Models	Construction	Memory	Multiplication	Refinement
Exact	$O(N^2)$	$O(N^2)$	$O(N^2)$	N/A
Fast kNN	$O\big(N(N^{0.5}\log N + h\log k)\big)^*$	$O(kN)$	$O(kN)$	$O\big(N(\log N + N\log k)\big)$
Variational DT	$O(N^{1.5}\log N + \lvert\mathcal{B}\rvert)$	$O(\lvert\mathcal{B}\rvert)$	$O(\lvert\mathcal{B}\rvert)$	$O(\lvert\mathcal{B}\rvert\log\lvert\mathcal{B}\rvert)$

Table 1: Theoretical complexity analysis results. (*) h is equal to k in the best case and N in the worst case.

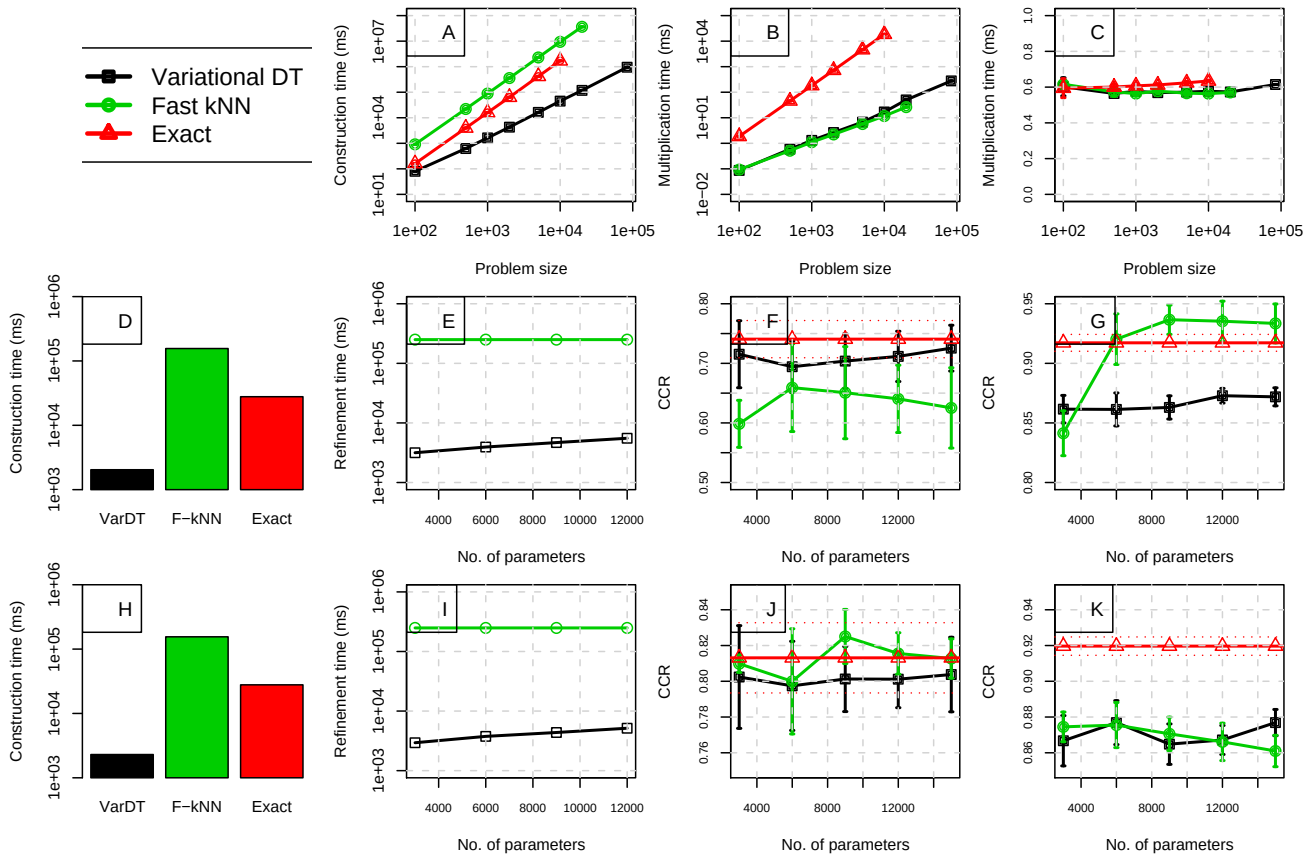

Figure 2: The experimental results for Variational DT, kNN and exact methods

coarsest Variational DT model (i.e. $|\mathcal{B}| = 2(N-1)$), and the coarsest kNN model (i.e. $k = 2$), (b) the time needed for multiplication in these models, and (c) CCR after label propagation given 10% labeled data. In particular, we draw samples of size s from the data set and use each sample to construct a model. Once a model is built, we choose 10% of the sample randomly to be fed to the LP algorithm as the labeled partition. We repeat this process 5 times for each problem size s and report the average result. Figure 2A) shows the construction time (in ms) for the three models as the problem size increases. As the plot shows, our method is orders of magnitude faster than the other two baselines (note that it is the log-log scale). In terms of the time needed for one multiplication, Figure 2B) shows that our method and kNN have similar complexity while both are order of magnitudes faster than the exact method. Note that Figure 2B) also shows the proportional memory usage for these methods because according to Table 1 multiplication and memory usage have the same complexity in all three methods. Finally, Figure 2C) depicts the CCR for the three models with different problem sizes. Although the exact model as expected is slightly more accurate than kNN and our method, the difference is not that big. In other words, by using VariationalDT we save orders of magnitudes in memory and CPU (i.e. both the construction and multiplication times) while compromising a little on accuracy.

In the second experiment, we study the efficiency and the effectiveness of the refinement process for the kNN and variationalDT models. To this end, first we build the coarsest kNN ($k = 2$) and VariationalDT ($|\mathcal{B}| = 2(N-1)$) models and then refine each model to

higher levels of refinement. At each refinement level, we make sure both methods have the same number of parameters; that is, $|\mathcal{B}| = kN$. We stop refining both models when the number of parameters reaches $O(N \log N)$. The data sets used for this experiment are Digit1 and USPS from the set of SLL benchmark data sets (Chapelle et al., 2006). Both data sets consist of digit images; while Digit1 is an artificially generated data set, USPS contains images of handwritten digits. Each data set has 1500 examples, 241 features and 2 classes. The second (third) row in Figure 2 shows the results for Digit1 (USPS) data set. Figures 2D,H) show the construction times for initial coarse models. Again our method is much faster than the baselines in terms of construction time. In Figures 2E,I), we have measured the time needed to refine each model to the next level of refinement. As the figure illustrates, VariationalDT needs an order of magnitude less time for refinement than kNN. Moreover, at each refinement level, we measure the CCR for LP when the size of the labeled set is 10 (Figure 2F,J) and 100 (Figure 2G,K). The red flat line in both plots depicts the CCR for the exact model. As the plots show, kNN and VariationalDT behave differently for different data sets and different sizes of labeled data. While refinement improves the kNN's performance significantly in Figure 2G, it degrades the kNN's performance in Figure 2F,K. We attribute this abrupt behavior to the *uniform* refinement of kNN graph. More precisely, when the kNN graph is refined, the degrees of all nodes are uniformly increased by 1 regardless of how much the log-likelihood lower bound is improved. Our method, on the other hand, explicitly aims to increase the log-likelihood lower bound resulting in a non-uniform refinement of P as well as more consistent behavior in terms of accuracy.

In the third experiment, we explore the applicability and the scalability of the proposed framework for very large data sets. The two data sets used in this experiment are taken from the Pascal Large-scale Learning Challenge.[1] The first data set, *alpha*, consists of 500,000 records with 500 dimensions. The second data set, *ocr*, is even larger with 3,500,000 records of 1156 features. Both data sets consist of 2 balanced classes. Table 2 shows the construction and propagations times as well as the number of model parameters when the Variational DT algorithm is applied. We could not apply other baseline methods for these data sets due to their infeasible construction times. Nevertheless, by extrapolating the graphs in Figure 2A, we guess the baselines would be roughly 3-4 orders of magnitude ($10^3 - 10^4$ times) slower. It should also be stressed that this experiment is specifically designed for showing the applicability of our framework for gigantic data sets and not necessarily showing its accuracy. However, even though we have not tuned the SSL parameters (like the labeling threshold), we still got $CCR = 0.56 \pm 0.01$ which is better than the random classifier. In conclusion, as a serial algorithm, our framework takes a reasonable time to construct and operate on these gigantic data sets. Furthermore, due to its tree-based structure, the Variational DT framework has the great potential to be parallelized which will make the algorithm even faster.

6 Conclusions

In this paper, we proposed a very efficient approximation framework based on a variational dual-tree method to estimate, store and perform inference with the transition matrix for random walk on large-scale data graphs. We also developed an unsupervised optimization technique to find the bandwidth for the Gaussian similarity kernel used in building the transition matrix. Algorithmically, we extended the variational dual-tree framework with a fast multiplication algorithm used for random walk inference with applications in large-scale label propagation and eigendecomposition. We also provided a complexity comparison between our framework and the popular k-nearest-neighbor method designed to tackle the same large-scale problems. In experiments, we demonstrated that while both the kNN based method and our method do not compromise much in terms of accuracy compared to the exact method, our method outperforms the kNN based method in terms of construction time with order of magnitudes difference. We also showed that our framework scales to gigantic data sets with millions of records.

Our future directions for this work include adding an inductive feature to our framework to deal with new examples as well as exploring the theoretical aspects of the approximation made by the algorithm.

Exploiting Uniform Assignments in First-Order MPE

Abstract

The *MPE* (Most Probable Explanation) query plays an important role in probabilistic inference. MPE solution algorithms for probabilistic relational models essentially adapt existing belief assessment method, replacing summation with maximization. But the rich structure and symmetries captured by relational models together with the properties of the maximization operator offer an opportunity for additional simplification with potentially significant computational ramifications. Specifically, these models often have groups of variables that define symmetric distributions over some population of formulas. The maximizing choice for different elements of this group is the *same*. If we can realize this ahead of time, we can significantly reduce the size of the model by eliminating a potentially significant portion of random variables. This paper defines the notion of *uniformly assigned* and *partially uniformly assigned* sets of variables, shows how one can recognize these sets efficiently, and how the model can be greatly simplified once we recognize them, with little computational effort. We demonstrate the effectiveness of these ideas empirically on a number of models.

1 Introduction

Probabilistic relational models (PRM) [5] such as the *Markov Logic Network* (MLN) [13] and the *Parfactor model* [11] encapsulate a large number of random variables and potential functions using first-order predicate logic. Using exact lifted inference methods [2; 9; 12; 6; 4], one can perform inference tasks directly on the relational model, solving many tasks which were previously considered intractable.

To date, the first-order MPE query is perceived as a derivative of these methods, since its computational structure is similar to computing the partition function of a first-order model, with the exception of maxing-out random variables instead of summing-out, as laid out by Braz et al. [3].

In this paper we introduce a method that simplifies many first-order MPE tasks by utilizing properties specific to the maximization operator, allowing us to solve models in which computing the partition function is complicated, or even intractable.

The MPE property which we capitalize on is called a *uniform assignment* (UA). Briefly, it is the existence of a group of random variables that are assigned identically in some MPE solution. In relational models, these groups correspond to sets of ground atoms derived from the same atomic formula. Once a group is recognized as uniformly assigned, it can be replaced by a single representative, substantially simplifying the model. In relational models, this replacement corresponds to an arity reduction – the removal of some logical variable(s) from the relevant atomic formula. With suitable care, the MPE probability in the new model is the same as that of the original model, and the MPE for the original model is easily derived from the MPE of the new model.

The key contribution of this paper is a computationally efficient procedure for finding a set of uniform assignments in a given model. For this purpose, we define a set of purely symbolic operators (*anchoring*, *model alignment*, and *symbolic fusion*), which are all based on standard lifted inference tools, *fusion* [2] and *propositionalization* [9]. When applied repeatedly, the three symbolic operators serve as a structure analysis tool, and result in a compact representation of the UA property, expressing which logical variables can be removed from which atomic formulas.

Once uniform assignments are detected, we proceed to simplify our model by applying a reduction procedure called *uniform assignment reduction* (UAR). The procedure reduces the arity of relevant atomic formulas, and suitably modifies table entries in the model, ensuring that the MPE probability of the modified model remains equal to that of the original.

Both steps, UA detection and UA reduction, are preprocessing steps that often result in a much smaller model. Both incur low computational overhead that is independent of domain sizes, and are totally agnostic to the MPE algorithm later applied. As we demonstrate, the effort of UAR reduction is small w.r.t. to the complexity of the underlying inference task, and incurs virtually no overhead even when no simplification is achieved. Finally, the smaller, simplified, model is passed to your favorite MPE engine, and from the computed MPE, the MPE of the original model is easily extracted.

Our UA detection method is general, and can be applied both on MLNs and parfactor models. However, UA detection is most naturally formulated on parfactors, since it utilizes the (symbolic) fusion operator, which is not commonly applied to MLNs. We therefore start with a background of the parfactor model, before introducing the concepts of our method in a Walk-through section. Formal definitions and complete algorithm formulation are presented next, followed by an extension of UA to recursive conditioning, a presentation of the experimental results, and a conclusion section.

2 Background

We review the properties of the parfactor model, as introduced by Poole [11], and later extended by Braz et al. [2] and Milch et al. [9]. Readers familiar with this model can safely skip to the following Walk-through section.

2.1 Model Representation

The parfactor model is a first-order representation of a factor network, such as a Bayesian [10] or a Markov [13] network. Random variables in the model correspond to ground atomic formulas (aka *ground atoms*) of the form $p(c_1, \ldots, c_n)$, where p is a predicate with an assignment range $range(p)$, and $c_1, \ldots, c_n$ are constant symbols. Under a set of assignments v to random variables, the notation $\alpha_{|v}$ is used to depict the values assigned to α, whether α is a ground atom or a set of ground atoms. A *factor* f is a pair (A, ϕ), consisting of a set of ground atoms $A = \bigcup_{i=1}^{m}\{\alpha_i\}$ and a potential function $\phi : \prod_{i=1}^{m} range(\alpha_i) \to \mathbb{R}_0^+$. Under the set of assignments v, the weight of factor f is $w_f(v) = \phi(\alpha_{1|v}, \ldots, \alpha_{m|v})$. The abbreviation $\phi : \alpha_i, \ldots, \alpha_m$ is used to denote a factor with a potential table ϕ and a respective set of ground atoms.

Example 2.1. Let factor f consist of the following, $\phi : smokes(Alice), drinks(Bob), friends(Alice, Bob)$. Hence, the table entries in ϕ represent the various chances of $Alice$ and Bob being friends, depending on whether $Alice$ and Bob are drinkers/smokers.

Whereas factor networks are modeled by a set of factors, the core representation unit of our model is the parameterized factor (aka *parfactor*), a first-order extension of a factor. Before reviewing its properties, we define the notions of *atoms*, *logical variables*, *substitutions* and *constraints*.

An atomic formula (aka *atom*) is a formula of the form $p(t_1, \ldots, t_n)$, where t_i is a constant or a *logical variable*. Each logical variable X has a domain $dom(X)$ with cardinality $|X|$. For instance, $smokes(X)$ denotes an atomic formula over logical variable X, where, in our running example, the domain of X contains $Alice$ and Bob. $LV(\alpha)$ is the set of logical variables referred by α, where α is a formula or a set of formulas.

A *substitution* θ over a set of logical variables L maps each variable in L to a constant symbol or some other logical variable, and $\alpha\theta$ is the result of applying θ to α. A *ground substitution* is the substitution of all logical variables in α with constants. For instance, a substitution Y/X applied to $friends(X, Y)$ results in $friends(X, X)$, and a ground substitution $X/Alice$ applied to atom $smokes(X)$ results in the ground atom $smokes(Alice)$. The range of atom α, denoted by $range(\alpha)$, is defined as the range of any ground atom $\alpha\theta$ obtained by the ground substitution θ.

A *constraint* C is a set of formulas over a set of logical variables L, defining the set of legal substitutions applicable to L. For instance, the constraint $X \neq Y$ defines any substitution under which the substitutions of X and Y are identical, as illegal. We use $rv(\alpha : C)$ to depict the set of random variables that can be obtained by any legal substitution on α, as defined by C.

$gr(L : C)$ is the set of legal ground substitutions which can be applied on L under constraint C, where $|L : C|$ is used to depict the size of the set. We use $C_L^{\downarrow}$ to depict the projection of a set of logical variables L on a constraint C. Similarly to [9], we require the constraints in our model to be in some normal form, where for each logical variable X, $|X : C|$ has a fixed value regardless of the binding of other logical variables in C.

Lastly, a *parfactor* is a tuple (L, C, A, ϕ), comprised of a set of logical variables L, a constraint C on L, a set of atoms A and a potential function $\phi : \prod_{\alpha \in A} range(\alpha) \to \mathbb{R}_0^+$. Applying substitution θ on parfactor $g = (L, C, A, \phi)$ results in $g\theta = (L', C\theta, A\theta, \phi)$, where L' is obtained by applying a substitution on its logical variables, and dropping those who are mapped to constants. Parfactors compactly model a set of factors upon their *grounding*, namely – upon applying all legal ground substitutions, as defined by C. The operator $gr(g)$ depicts the set of all legal ground substitutions . The abbreviation $\phi : \alpha_1, \ldots, \alpha_m \mid C_\psi$ is used to describe a parfactor with the set of atoms $\bigcup_i\{\alpha_i\}$, a constraint with formula ψ, and an explicit set of logical variables.

Example 2.2. Let parfactor g consist of the following, $\phi : smokes(X), drinks(Y), friends(X, Y) \mid C_{X \neq Y}$. In a world where the domain of X and Y equals

$\{Alice, Bob\}$, the grounding of g entails two factors: $\phi: \ smokes(Alice), drinks(Bob), friends(Alice, Bob)$ $\phi: \ smokes(Bob), drinks(Alice), friends(Bob, Alice)$

The weight of g is defined as $w_g(v) = \prod_{f \in gr(g)} w_f(v)$, where v is an assignment to all the ground atoms (random variables) entailed by the the grounding of g. This set of random variables is conveniently denoted by $rv(g)$.

2.2 Shattering, Fusion and Propositionalization

Let model G be a set of parfactors, let α_i denote an atom, and C_i denote its parfactor constraint. We say that G is *completely shattered*, if for any i, j, the sets of random variables denoted by $rv(\alpha_i : C_i)$ and $rv(\alpha_j : C_j)$ are either disjoint or equal. Hence, *shattering* [2] is a procedure which takes model G, and produces a completely shattered model G', s.t. the set of all ground factors entailed by G and G' is equal. To eliminate some possible ambiguity, we refer to all atoms in a completely shattered model as each having a unique predicate symbol.

Example 2.3. Let model G consist of two parfactors, $\phi_1: \ p(X, Y), q(Y)$ and $\phi_2: \ p(X, X)$.
The shattering of G replaces the first parfactor with two new parfactors, consisting of the same potential, as follows $\phi_1: \ p(X, X), q(X)$ and $\phi_1: \ p(X, Y), q(Y) \mid C_{X \neq Y}$.

Fusion [2] is the procedure of merging two or more parfactors by unifying logical variables, while maintaining the same model weight under any given assignment. Since there are several ways to unify logical variables, inference engines apply fusion according to some strategy. For instance, consider the fusion of $\phi_1: \ p(X, Y), q(Z)$ and $\phi_2: \ p(X, Y), q(Y)$. Two possible fusions (out of many) are $\phi_{f_1}: \ p(X, Y), q(Z), q(Y)$ and $\phi_{f_2}: \ p(X, Y), p(X, Z), q(Y)$, and so the inference engine must choose which one to apply. In this paper, fusion is used only symbolically (aka *symbolic fusion*), as a means of structure analysis. As a result, table entries are never examined, and the fusion procedure never "blows up".

Propositionalization [9] is the operation of partially grounding a parfactor over a set of logical variables, thereby eliminating these variables from the resulting set. For example, the propositionalization of Z in parfactor $\phi: \ p(Y, Z), q(X, Y)$, where $dom(Z) = \{z_1, z_2\}$, results in the two parfactors, $\phi: \ p(Y, z_1), q(X, Y)$ and $\phi: \ p(Y, z_2), q(X, Y)$.

2.3 First-Order MPE

We now define the MPE task. Given a set of parfactors G, the combined weight of an assignment v is

$$w_G(v) = \prod_{g \in G} w_g(v) = \prod_{g \in G} \prod_{f \in gr(g)} w_f(v) \qquad (1)$$

The Most Probable Explanation of a first-order model is the pair $(v, \frac{1}{Z} w_G(v))$, s.t. $v = \text{argmax}_{v'} \, w_G(v')$, and Z is a normalization factor. In this paper, as in [3], we address the task of obtaining the unnormalized MPE.

3 Walk-through: Simplifying the MPE Task

3.1 Motivation

Consider the following single-parfactor model:

$$\phi: \ friends(Y, X), friends(Z, X), knows(Y, Z)$$

In this model, the chance of two people knowing each other depends on having mutual friends. Although a simple model, all existing methods fail to lift the task of computing its partition function. More specifically, inversion elimination [2] fails since no atom contains all the logical variables. Counting conversion [2] and partial inversion [3] fail since all logical variables are occupied by at least two atoms, but never by all three. Recursive conditioning (splitting on atoms) [6] fails, since all atoms contain more than a single logical variable. Finally, additional elimination and model restructuring rules [7; 1] fail to assist as well.

However, obtaining the MPE of this same model, as we will demonstrate, is polynomial in the population size. This, of course, cannot be achieved by a simple modification of the lifted methods, but rather – by exploiting a property which is unique to MPE: *uniform assignments*. To understand this property and the derived framework, we shall study three model prototypes: *single-parfactor with no recurring formulas* (namely, each atomic formula appears only once), *single-parfactor with recurring formulas* and *multiple-parfactors*.

3.1.1 Single Parfactor, No Recurring Formulas

Consider model $\boldsymbol{\phi: \ a(X), b(Y), c(Z)}$. Computing the partition function of this model is polynomial in the domain size, but finding the MPE is even easier: let entry $\phi(\rho_a, \rho_b, \rho_c)$ be the maximum entry in table ϕ. An assignment with maximal potential is obtained by assigning all grounds of atoms of $a(X), b(Y)$ and $c(Z)$ uniformly, with ρ_a, ρ_b and ρ_c, respectively. We refer to $a(X), b(Y)$ and $c(Z)$ as *uniformly assigned formulas*.

We wish to exploit the UA property in a way that may seem redundant at the moment, by applying a procedure called *uniform assignment reduction* (UAR). UAR modifies the model while preserving the MPE probability, producing a simpler MPE task. In our example $\phi: \ a(X), b(Y), c(Z)$ is modified to $\phi': \ a', b', c'$, where the arity-reduced atoms a', b', c' have the same assignment range as their original counterparts, and $\phi' = \phi^{|\{X,Y,Z\}|}$. This exponentiation compensates for the reduced number of ground factors post

modification. Once the MPE of the modified model is obtained (by a simple table lookup), the MPE assignments for $a(X), b(Y)$ and $c(Z)$ are immediately derived.

3.1.2 Single Parfactor, Recurring Formulas

We return to the friends/knows example discussed earlier, $\boldsymbol{\phi : fr(Y,X), fr(Z,X), k(Y,Z)}$ (where $fr \equiv friends$, $k \equiv knows$). Unlike the previous case, a simple table lookup cannot resolve this model's MPE, since any assignment to one ground of fr inevitably affects table entries in two table positions: $fr(Y,X)$ and $fr(Z,X)$. As a first step, we identify $\{Y,Z\}$ as the *overlap set* of the model, as Y and Z are different logical variables occupying the same position in predicate fr. Intuitively, the overlap set is the "obstruction" under which the MPE task cannot be solved by a simple table lookup. Hence, the next logical step would be to eliminate this obstacle.

Assume now that we propositionalize both Y and Z, where the domain of both is $\bigcup_i\{o_i\}$. The result of this operation is a set of parfactors, residing over the set of atoms $A = \bigcup_{i,j}\{fr(o_i,X), k(o_i,o_j)\}$. If we fuse all these parfactors together without applying a "name change" to any of the logical variables, we obtain a single parfactor over A with no recurring formulas. Thus, the previous case applies and each of $fr(o_1,X),\ldots,fr(o_n,X)$ is detected as uniformly assigned. That is, for o_1 and for *every* possible value of X, $fr(o_1,X)$ will have the same value assigned in an MPE. Similarly, for o_2 and for *every* possible value of X, $fr(o_2,X)$ will have the same value assigned in an MPE, etc. Of course, this maximizing value for $fr(o_i,X)$ and $fr(o_j,X)$ may be different, if $i \neq j$. Interestingly, we did not refer to any of the table entries in our procedure. In other words, the UA property can be detected by a set of purely symbolic operations.

We encapsulate the above sequence of operations within a new operator called *anchoring*, denoted by $\circledast$, which applies a set of symbolic propositionalizations and fusions. In our example, $\phi : fr(Y,X), fr(Z,X), k(Y,Z) \circledast \{Y,Z\} = \phi_f : fr(*,X), k(*,*)$, where $fr(*,X)$ and $k(*,*)$ are called *anchored formulas*: $fr(*,X) \equiv \bigcup_i\{fr(o_i,X)\}$ and $k(*,*) \equiv \bigcup_{i,j}\{k(o_i,o_j)\}$. We emphasize that anchoring is a symbolic operation that does not require actually carrying out explicit propositionalization and fusion but is equivalent semantically. Thus, anchoring allows us to analyze the model's structure regardless of domain size, and to simplify the depiction of uniform assignments. Namely, the anchored formula $fr(*,X)$ carries the information that $fr(o_1,X),\ldots,fr(o_n,X)$ are uniformly assigned. Essentially, this says that in the MPE, for every o_j, $fr(o_j,X)$ will have the same value for every possible substitution of X. Thus, it depends on o_j alone, and we can use $fr'(o_j)$ to denote it, instead of $fr(o_j,X)$.

To sum up thus far, we identified an overlap set, applied anchoring and obtained a set of anchored formulas. As a last step, we wish to exploit the UA property implied by the anchored formulas. We return to the UAR procedure which was introduced previously. However, now arity reductions are applied discriminately, as only non-anchored logical variables (those remaining in the anchored formulas) can be removed from the model. Hence, only X is eliminated by the UAR procedure, producing $\phi' : fr'(Y), fr'(Z), k(Y,Z)$, where $\phi' = \phi^{|X|}$. From here, the MPE is resolved by any existing inference engine.

3.1.3 Multiple Parfactors

Here, we study a model consisting of two parfactors $\boldsymbol{\phi_1 : p(X), p(Y), q(Z)}$ and $\boldsymbol{\phi_2 : p(X), r(X), q(Z)}$. As before, we wish to detect UAs and apply a UAR procedure. However, the UA detection in this case is somewhat more complicated, and involves a sequence of operations: anchoring, *alignment* and symbolic fusion. We start by identifying $\{X,Y\}$ as an overlap set in the first parfactor, followed by its anchoring to $\phi_{f_1} : p(*), q(Z)$. At this stage, the form of p is not consistent among different parfactors in the model, since the second parfactor contains a non-anchored $p(X)$. To address this inconsistent form, we must *align* the model by anchoring the X logical variable in the second parfactor. Once completed, the second parfactor is replaced with $\phi_{f_2} : p(*), r(*), q(Z)$.

The next step invokes a (symbolic) fusion of the two anchored parfactors (those consisting of ϕ_{f_1} and ϕ_{f_2}), producing $\phi_f : p(*), r(*), q(Z)$. In general, symbolic fusions may produce additional overlaps, but in this simple case no overlaps are introduced. Hence, the anchored formulas now carry the UA property. Finally, UAR is applied independently on each of the original parfactors, producing ${\phi_1}^{|Z|} : p(X), p(Y), q'$ and ${\phi_2}^{|Z|} : p(X), r(X), q'$. Having introduced the core concepts of our algorithm, we move to a formal representation.

4 Formal Definitions

4.1 Overlap Set, Anchoring and Alignment

A *position* of logical variable X in formula α is the location of X in the formula's predicate under argument list ordering. In $p(X,Y)$, the positions of X and Y are 1 and 2 respectively.

An *overlap set* L_o in parfactor g is the set of all logical variables in g which do not occupy the same positions under all instances of the same formulas.

Example 4.1. : In parfactor
$\phi : p(X,Z,Y), p(Z,U,Y), q(S,W), q(S,T), r(S)$,
the overlap set is $L_o = \{X,Z,U,W,T\}$.

The *effect scope* of a set of logical variables L_o in parfactor $g = (L,C,A,\phi)$, denoted by L_{eff}, is the set of logical

variables in g whose set of substitutions is dependent on any binding of L_o. Formally, L_{eff} is defined as the minimal set of logical variables in g under which $L_o \subseteq L_{eff}$, and $\forall \theta_1, \theta_2 \in gr(L_{eff} : C) : gr(L \setminus L_{eff} : C\theta_1) = gr(L \setminus L_{eff} : C\theta_2)$. **In constraint-less parfactors, it is always the case that** $L_{eff} = L_o$.

Example 4.2. The effect scope of $\{X, W\}$ in parfactor $\phi : p(X), q(Y, Z), r(W)$ is $\{X, W\}$.

Example 4.3. The effect scope of $\{X\}$ in parfactor $\phi : p(X), q(Y), r(Z), s(W) | C_{X \neq Y \wedge Y \neq Z}$ is $\{X, Y, Z\}$.

Anchoring of parfactor $g = (L, C, A, \phi)$ over the set of logical variables L_o, denoted by $g \circledast L_o$, is a two step procedure: propositionalization of L_{eff}, which is the effect scope of L_o, followed by a symbolic fusion of the result set of parfactors. The final result, parfactor $g' = (L', C', A', \phi')$, contains the following properties:

- $L' = L \setminus L_{eff}$
- $C' = C^{\downarrow}_{L'}$
- $A' = \{\alpha\theta \mid \alpha \in A, \theta \in gr(L_{eff} : C)\}$

And some ϕ', which we refrain from actually computing in this context. The positions of the propositionalized logical variables under anchoring are called *anchored positions*. We use the substitution $\theta = \bigcup_{X \in L_{eff}} \{X/*\}$ on the set of logical variables in g to depict the result of anchoring.

Alignment of parfactor g according to parfactor g_*, denoted by $align(g, g_*)$, is the anchoring of g over L, where L consists of all logical variables in g that occupy positions which are anchored in g_*, under predicates which are mutual to g and g_*. For instance, aligning $\phi : p(X, Y), q(Z)$ according to $\phi_* : r(*), p(W, *)$, yields $\phi' : p(X, *), q(Z)$. We define $align(G, g_*)$ as applying $align(g, g_*)$ to all $g \in G$, and then repeatedly re-aligning the new content, until all instances of each predicate are anchored consistently.

4.2 Uniform Assignments and Arity Reduction

A *uniform assignment* over formula α is the assignment of a constant ρ to every ground of α, where $\rho \in range(\alpha)$. A *partially uniform assignment* over formula α with relation to a set of logical variables L is a uniform assignment over each ground substitution of L. Namely, a partially uniform assignment over $t(X, Y, Z)$ w.r.t. $\{Y, Z\}$ implies that $\forall y \in dom(Y), \forall z \in dom(Z) : t(X, y, z)$ is uniformly assigned.

To enable the application of uniform assignments on our model, we define the *arity reduction* operator $\alpha \downarrow \alpha_*$ on atomic formulas. If α and α_* have the same predicate symbol, $\alpha \downarrow \alpha_*$ is a new predicate obtained by removing all positions in α not anchored in α_*. For instance, $p(X, Y, Z) \downarrow p(W, *, T) = p'(Y)$. If both formulas differ in the predicate symbol, $\alpha \downarrow \alpha_* = \alpha$.

4.3 Uniform Assignment Reduction

A *Uniform Assignment Reduction* (*UAR*) applied to parfactor $g = (L, C, A, \phi)$ by formula α_*, denoted by $g \downarrow \alpha_*$, is the operation of applying $\alpha \downarrow \alpha_*$ to each $\alpha \in A$, followed by exponentiating the potential by the combined domain size of the removed logical variables. More formally, the operation $g \downarrow \alpha_*$ yields $g' = (L', C', A', \phi')$ with the following properties:

- $A' = \{\alpha \downarrow \alpha_* \mid \alpha \in A\}$
- $C' = C^{\downarrow}_{L'}$
- $L' = LV(A')$
- $\phi' = \phi^{|(L \setminus L') : C\theta'|}$

Where θ' is some ground substitution over L' under constraint C.

Example 4.4. Let $g = \phi : p(X), q(Y, Z)$.
Let $\alpha_* = q(W, *)$. Hence, $g \downarrow \alpha_* = \phi^{|Y|} : p(X), q'(Z)$.

Example 4.5. Let $g = \phi : p(X), q(Y) \mid C_{X \neq Y}$.
Let $\alpha_* = p(Z)$. Hence, $g \downarrow \alpha_* = \phi^{|X|-1} : p', q(Y)$,
since $|X : C_{X \neq Y}| = |X| - 1$ under any binding of Y.

Example 4.6. When the set of the logical variables remains the same, as in $\phi : p(Y), q(Y, Z) \downarrow q(W, *) = \phi : p(Y), q'(Z)$, no exponentiation is required.

5 Simplified First-Order MPE

The model simplification algorithm is comprised of two phases – detecting uniform assignments, and applying a uniform assignment reduction, as follows.

Algorithm 1: DETECT-UNIFORM-ASSIGNMENTS

input : G_{input} – a completely shattered model
output: A set of anchored formulas

$G \leftarrow G_{input}$
while $\exists g \in G, \exists L_o \neq \emptyset$ *s.t.* L_o *is an overlap set in* g **do**
  $g_* \leftarrow g \circledast L_o$ `// anchoring`
  $G \leftarrow align(G, g_*)$ `// alignment`

if $\exists g_1 \neq g_2 \in G$ *s.t.* $rv(g_1) \cap rv(g_2) \neq \emptyset$ **then**
  $G \leftarrow G \cup$ `SymbolicFusion(`g_1, g_2`)` $\setminus \{g_1, g_2\}$
  return `DETECT-UNIFORM-ASSIGNMENTS(`G`)`
else
  return all formulas in G

5.1 Detecting Uniform Assignments

The detection procedure (Algorithm 1) is purely symbolic, hence only the set of formulas is examined, whereas table entries are completely ignored. The detection starts by identifying all overlap sets in the model, accommodated by anchoring. The result is a set of parfactors with no recurring formulas. The entire model is then aligned accord-

Algorithm 2: SIMPLIFY-FOMPE

input : G – a completely shattered model
output: Simplified Model

$A_* \leftarrow$ DETECT-UNIFORM-ASSIGNMENTS(G)
foreach $\alpha_* \in A_*$ **do**
  foreach $g \in G$ **do** $G \leftarrow G \cup \{g \downarrow \alpha_*\} \setminus \{g\}$
return G

ingly, making sure that following manipulations operate on a completely shattered model. Next, two parfactors are chosen for a symbolic fusion. This, in turn, may generate a new overlap set. The cycle of overlap set detection, anchoring, and symbolic fusion is repeated until no two parfactors which share a formula are left. The procedure returns a set of anchored formulas, depicting the set of detected UAs.

One issue which remains unsolved is how to reapply the symbolic fusion procedure in order to produce as many arity reductions as possible. We use a greedy fusion scheme, where the logical variables of formulas with maximum arity are matched first. This, of course, does not guarantee an optimal sequence of fusions, and we leave the study of better fusion selection strategies for future work.

Proposition 1. *Given a completely shattered model G, Algorithm 1 produces a set of anchored formulas A_*, where there exists an MPE solution under which all formulas $\alpha_* \in A_*$ are partially uniformly assigned w.r.t. the logical variables in the anchored positions.*

Proof outline. The algorithm applies (symbolically) standard lifted inference tools, where each fusion is followed by anchoring, namely – the elimination of overlapping logical variables. Once all parfactors are merged into a single parfactor with no overlap sets, an MPE solution can be trivially obtained by assigning the atomic formulas uniformly, according to remaining logical variables. □

5.2 UAR Algorithm

After invoking DETECT-UNIFORM-ASSIGNMENTS, which detects uniform assignments in model G, a uniform assignment reduction is applied to each parfactor in G, producing a simplified model G'.

Proposition 2. *Algorithm 2 produces a simplified model G' with the same MPE probability as G.*

Proof outline. The formal proof is found in the Appendix. The idea is to pair each original parfactor $g \in G$ with its UAR result $g' \in G'$, and show the following: (i) for each assignment v' in model G' there exists an assignment v in model G, where the probabilistic weights of all pairs g and g' are equal; and (ii) for each optimal assignment v in G, under which formulas are uniformly assigned according to A_*, there exists an assignment v' s.t. the probabilistic weights of all pairs g and g' are equal. A_* here denotes the set of anchored formulas which yielded G'. □

Original model	$\phi_1 : p(X,Y), q(Y,Z), r(Z,X), s(X,Z)$ $\phi_2 : s(X, \underbrace{V}_{overlap}), s(X, \underbrace{W}_{overlap}), p(X,Y)$
Anchoring	$\phi_1 : p(X,Y), q(Y,Z), r(Z,X), s(X,Z)$ $\phi_2' : s(X,*), p(X,Y)$
Model alignment	$\phi_1' : p(X,Y), q(Y,*), r(*,X), s(X,*)$ $\phi_2' : s(X,*), p(X,Y)$
Symbolic fusion	$\phi_f : p(X,Y), q(Y,*), r(*,X), s(X,*)$
UA reduction	${\phi_1}^{\lvert X\rvert\cdot\lvert Y\rvert} : p', q'(Z), r'(Z), s'(Z)$ ${\phi_2}^{\lvert X\rvert\cdot\lvert Y\rvert} : s'(V), s'(W), p'$

Figure 1: Example – model simplification

5.2.1 UAR Example

We now cover the example in Figure 1. Let model G consist of $\phi_1 : p(X,Y), q(Y,Z), r(Z,X), s(X,Z)$ and $\phi_2 : s(X,V), s(X,W), p(X,Y)$. We start by detecting the overlap set {V,W} in ϕ_2, followed by a subsequent anchoring of ϕ_2 to $\phi_2' : s(X,*), p(X,Y)$, and the alignment of ϕ_1 to $\phi_1' : p(X,Y), q(Y,*), r(*,X), s(X,*)$. Next, a symbolic fusion is applied to ϕ_1' and ϕ_2', resulting in $\phi_f : p(X,Y), q(Y,*), r(*,X), s(X,*)$. The remaining formulas in ϕ_f are then passed to the SIMPLIFY-FOMPE procedure, where consecutive uniform assignment reductions yield ${\phi_1}^{\lvert X\rvert\cdot\lvert Y\rvert} : p', q'(Z), r'(Z), s'(Z)$ and ${\phi_2}^{\lvert X\rvert\cdot\lvert Y\rvert} : s'(V), s'(W), p'$.

5.3 Complexity Analysis

Let t, n, a and p denote the properties of the original model G, where t is the number of table entries, n is the number of atoms, a is the maximum arity of any predicate and p is the number of parfactors. The complexity of SIMPLIFY-FOMPE is simply $O(t)$. As for DETECT-UNIFORM-ASSIGNMENTS, each position in any atom of G is aligned no more than once, thus $O(n \cdot a)$ is the upper bound for the number of anchored positions. $p - 1$ is the maximal number of symbolic fusions. Combined, the total complexity is $O(t) + O(n \cdot a) + O(p \cdot O_f)$, where O_f is the upper bound of a symbolic fusion and depends on the fusion strategy. For example, a greedy fusion strategy takes $O(n \cdot a)$ time. Other polynomial time strategies are possible. In typical models, n and t are the dominating elements, and so we get a complexity that is linear in t and polynomial in n. All in all, the complexity is independent of domain sizes.

6 UA under Recursive Conditioning

As demonstrated, the UA property is heavily dependent on the structure of the model. One interesting aspect of recur-

sive conditioning is the structure modification induced by the conditioning operator (splitting on a singleton atom). This allows non UA formulas to be split into uniformly assigned groups, a property which is referred to as a *conditional UA*. Consequently, the scope of uniform assignments is extended beyond the role of preprocessing, as presented so far, since various conditioning contexts introduce further opportunities for exploiting the UA property.

Consider model $\phi_1 : p(X), q(X)$ and $\phi_2 : p(X), q(Y)$, where p and q are boolean, and the domain size of X and Y is n. Since all possible fusions of ϕ_1 and ϕ_2 result in an overlap (e.g. $\phi_f : p(X), q(X), q(Y)$), this model contains no uniform assignments. However, when conditioning on atom $p(X)$, the ground atoms of $q(X)$ split into two uniformly assigned groups. We demonstrate this as follows: let $k \in \{0, ..., n\}$ depict the number of $p(X)$ ground atoms assigned 0. Hence, under each binding of k, the domain is split into two parts, and a set of four logical variables is introduced: X_0^k, X_1^k, Y_0^k and Y_1^k, where $|X_0^k| = k$, $|X_1^k| = n - k$ and $dom(X_i^k) = dom(Y_i^k)$. By definition, each ground of $p(X_i^k)$ is assigned i, thus all random variables of predicate p are eliminated from the expression.

Formally:

$$\max_{rv(p(X),q(X))} \prod_X \phi_1(p(X), q(X)) \cdot \prod_{X,Y} \phi_2(p(X), q(Y)) =$$

$$\max_k \max_{rv(q(X))} \prod_i \prod_{X_i^k} \underbrace{\phi_1(i, q(X_i^k))}_{\equiv \phi_i^X(q(X_i^k))} \cdot$$

$$\prod_i \prod_{Y_i^k} \underbrace{\phi_2(0, q(Y_i^k))^k \phi_2(1, q(Y_i^k))^{n-k}}_{\equiv \phi_i^Y(q(Y_i^k))}$$

The result is a set of four parfactors, as follows:
(i) $\phi_0^X : q(X_0^k)$ (ii) $\phi_1^X : q(X_1^k)$
(iii) $\phi_0^Y : q(Y_0^k)$ (iv) $\phi_1^Y : q(Y_1^k)$

In this formation, it is easy to detect that both $q(X_0^k)$ and $q(X_1^k)$ are uniformly assigned. Namely, the set of parfactors can be simplified into
(i) $(\phi_0^X)^k : q_0'$ (ii) $(\phi_1^X)^{n-k} : q_1'$
(iii) $(\phi_0^Y)^k : q_0'$ (iv) $(\phi_1^Y)^{n-k} : q_1'$

We note that in this basic example, MPE can be efficiently solved without resorting to UAR. However, the same conditional UA principle applies to any model, thus the symbolic simplification becomes quite efficient when considering that the same computation is repeated for each k. Embedding UAR in a recursive conditioning inference engine, may indeed accelerate many of the lifted MPE tasks.

7 Experimental Evaluation

We present six sets of experiments. To highlight the fact that the method is independent of the inference engine used, and effective with different engines, we used two lifted inference engines, C-FOVE [9] and WFOMC [4], with and without the uniform assignment reduction. The engines were obtained from `http://people.csail.mit.edu/milch/blog/index.html` and `dtai.cs.kuleuven.be/ml/systems/wfomc` respectively, and were both modified to support max-product queries, by replacing Sum operators with Max, and ignoring the number of counting permutations. In WFOMC, specifically, the modification corresponds to changing the code in each of the NNF node subclasses. Times are shown in log scale, and the computation time of UAR was added to the overall time results.

Since WFOMC accepts weighted first-order formulas as input, each parfactor $\phi : p_1(X_1), \ldots, p_n(X_n)$ was passed to WFOMC as a weighted first-order formula of the form $p_1(X_1) \wedge \ldots \wedge p_{n-1}(X_{n-1}) \implies p_n(X_n)$. Unlike variants of belief propagation [14; 8], where table entries affect the runtime of the algorithm, the runtime of both WFOMC and C-FOVE in models which exclusively consist of non-zero and non-one entries is agnostic to the actual numerical values. Hence, all table entries in the models presented here were arbitrarily set to non-zero, non-one.

Figures 2 & 3 show the results of two models that were previously discussed in this paper, demonstrating how UAR extends the scope of known tractable models. In these two figures, we see that both C-FOVE and WFOMC quickly fail to lift the inference task, as they resort to propositional inference. Once UAR is applied, both solve the MPE query efficiently. Figure 4 introduces a model which is solvable in polynomial time, and again, becomes much easier to solve with UAR. The $\downarrow$ symbol denotes a logical variable which was eliminated by the UAR.

In all three figures, UAR computation never exceeds 40 milliseconds. This result is, of course, consistent with the complexity analysis, demonstrating that UA detection has a negligible effect on the overall performance. Given that MPE is computationally demanding, and exponential in the worst-case, one could hardly lose from attempting to run UAR in every MPE task.

Figure 5 presents the results of running WFOMC with and without UAR, on random models with varying number of parfactors. Each parfactor, in an n-parfactor randomized model, consists of 3 atoms. Each atom is obtained randomly from a uniformly distributed pool of $2n$ unary predicates, and a set of (maximum) 3 logical variables per parfactor. This randomization guarantees a (polynomially) tractable model, that can evaluate the effectiveness of UAR. However, even with small domain sizes, solving MPE is still computationally demanding. We tested these random models under three domain sizes: 5, 10 and 50. The results are an average over 10 randomized sets.

Figure 6 shows an unsuccessful attempt by UAR to simplify the Friends & Smokers model [14]. Since UAR com-

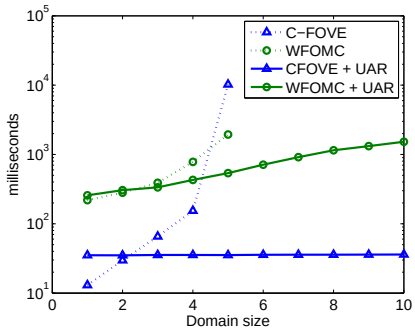

Figure 2: $\phi: friends(X_\downarrow, Y), friends(X_\downarrow, Z), knows(Y, Z)$

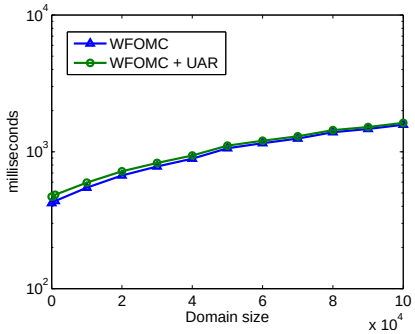

Figure 6: Friends & Smokers [14]

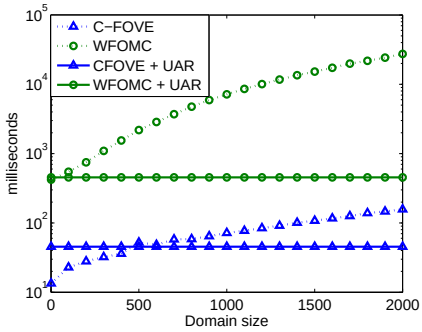

Figure 7: Students & Professors [6]

putation incurs very little overhead (48 milliseconds in this case), its effect on the result is negligible. In Figure 7, however, UAR is able to simplify the Students & Professors link prediction model [6], s.t. the computation becomes domain-size independent.

8 Conclusion

We introduced a model simplification method which narrows the assignment space of first-order MPE queries by batching together sets of random variables, while refraining from table lookups. The suggested method can be integrated into existing lifted inference engines or serve as a preprocessing algorithm, adding a low computational overhead compared to non-simplified queries. And thus, even in cases where UAR fails, the penalty for running this procedure is negligible.

We note that the UA property is not restricted to the specific detection method presented in this paper. For example, although we refrained from analyzing the content of the potential tables when detecting uniform assignments, one can leverage specific maximizing assignments to obtain farther reductions. Consider, for example, an atom p contained exclusively by parfactor $\phi : p(Y), p(Z)$. The overlap set of the two instances of p is not empty, and in general requires anchoring and alignment. However, if maximal entries in ϕ assign both instances of p the same value (e.g., they are $(0, 0)$ or $(1, 1)$, etc.) then p can be treated as uniformly assigned. Namely, the parfactor is simplified into $\phi^{|Y|\cdot|Z|} : p'$, by applying UAR. This idea can be further adapted by approximation algorithms, which may force uniform assignments in cases where they are not guaranteed. Finally, third parties may also wish to assert uniform assignments as part of user constraints. For all these purposes, the UAR serves as a valid reduction.

Appendix – UAR Proof

Let G be a completely shattered model, and let $G' = \bigcup_{g \in G} \{g \downarrow \alpha_*\}$ be the set of post-UAR parfactors, for some anchored formula α_*. WLOG, properties of each parfactor g in G are (L, C, A, ϕ), where $A = \{\alpha_1, \ldots, \alpha_n, \beta\}$, and $\forall i : rv(\alpha_i) = rv(\alpha_*) \wedge rv(\alpha_i) \cap rv(\beta) = \emptyset$.

Properties of each $g' = g \downarrow \alpha_* = (L', C', A', \phi')$ are

- $A' = \{\alpha'_1, \ldots, \alpha'_n, \beta\}$, where $\forall i : \alpha'_i = \alpha_i \downarrow \alpha_*$
- $L' = LV(A')$
- $C' = C^{\downarrow}_{L'}$
- $\phi' = \phi^{|(L \setminus L'):C\theta'|}$

Where θ' is some ground substitution over L' under constraint C.

In the context of parfactor g, let L^*_i denote the set of logical variables in α_i that occupy positions which are anchored in α_*, and let L_β depict the set of logical variables in β. We define $L^+ = L' = L^*_1 \cup \ldots \cup L^*_n \cup L_\beta$, followed by $L^- = L \setminus L^+$ which is the set of logical variables which occupy positions that are unanchored in α_* and contained exclusively by some α_i instances. Note that $gr(L^+ : C) = gr(L' : C')$, since $L^+ = L'$ and $C' = C^{\downarrow}_{L'}$.

Weights of each g and g', under assignments v and v', are:

$$w_g(v) = \prod_{\theta^+} \prod_{\theta^-} \phi(\alpha_1\theta^+\theta^-{}_{|v}, \ \ldots\ , \alpha_n\theta^+\theta^-{}_{|v}, \beta\theta^+\theta^-{}_{|v})$$

$$w_{g'}(v') = \prod_{\theta'} \phi(\alpha'_1\theta'{}_{|v'}, \ \ldots\ , \alpha'_n\theta'{}_{|v'}, \beta\theta'{}_{|v'})^{|L \setminus L':C\theta'|}$$

Where $\prod_{\theta^+}$, $\prod_{\theta^-}$ and $\prod_{\theta'}$ are abbreviations for $\prod_{\theta^+ \in gr(L^+:C)}$, $\prod_{\theta^- \in gr(L^-:C\theta^+)}$ and $\prod_{\theta' \in gr(L':C')}$.

Proposition 3. *For each v' there exists v such that $w_G(v) = w_{G'}(v')$*

Proof. We pick one of the α_i instances in some parfactor g, and construct v out of v' as follows:

1. $\forall \theta^* \in gr(L^*_i : C),\ \forall \theta \in gr(LV(\alpha_i) \setminus L^*_i : C\theta^*) : \alpha_i\theta^*\theta_{|v} = \alpha'_i\theta^*{}_{|v'}$
2. $\psi \in rv(G) \wedge \psi \in rv(G') \implies \psi_{|v} = \psi_{|v'}$
   Meaning, the assignment to variables which are mutual to G' and G is copied from v' to v.

The weights of each g and counterpart g' are then expressed as follows

$$\begin{aligned}
w_g(v) &= \prod_{\theta^+} \prod_{\theta^-} \phi(\alpha_1\theta^+\theta^-{}_{|v}, \ \ldots\ , \alpha_n\theta^+\theta^-{}_{|v}, \beta\theta^+\theta^-{}_{|v}) \\
&= \prod_{\theta^+} \prod_{\theta^-} \phi(\alpha_1\theta^+\theta^-{}_{|v'}, \ \ldots\ , \alpha_n\theta^+\theta^-{}_{|v'}, \beta\theta^+\theta^-{}_{|v'}) \\
&= \prod_{\theta^+} \prod_{\theta^-} \phi(\alpha'_1\theta^+{}_{|v'}, \ \ldots\ , \alpha'_n\theta^+{}_{|v'}, \beta\theta^+{}_{|v'}) \\
&= \prod_{\theta'} \phi(\alpha'_1\theta'{}_{|v'}, \ \ldots\ , \alpha'_n\theta'{}_{|v'}, \beta\theta'{}_{|v'})^{|L \setminus L':C\theta'|} \\
&= w_{g'}(v')
\end{aligned}$$

Since the full weights are a product over all parfactor weights, it follows that $w_G(v) = w_{G'}(v')$. □

Proposition 4. *Given optimal assignment $v = \text{argmax}_v\, w_G(v)$, under which α_* is uniformly assigned, there exists v' for which $w_{G'}(v') = w_G(v)$.*

Proof. First, we pick one of the α'_i instances in some parfactor g'. From the uniform assignment property depicted by α_*, it follows that $\forall \theta^* \in gr(L^*_i : C),\ \forall \theta_1, \theta_2 \in gr(LV(\alpha_i) \setminus L^*_i : C\theta^*) : \alpha_i\theta^*\theta_1(v) = \alpha_i\theta^*\theta_2(v)$. Next, we construct v' out of v as follows:

1. $\forall \theta^* \in gr(L^*_i : C),\ \forall \theta \in gr(LV(\alpha_i) \setminus L^*_i : C\theta^*) : \alpha'_i\theta^*{}_{|v'} = \alpha_i\theta^*\theta_{|v}$
   Enabled by the uniform assignment property.
2. $\psi \in rv(G) \wedge \psi \in rv(G') \implies \psi_{|v'} = \psi_{|v}$

As previously, weights of each g' and g are expressed as a function of ground substitutions, where $w_{g'}(v') = w_{g'}(v)$, and consequently $w_{G'}(v') = w_G(v) = \max_v w_G(v)$. □

From propositions 3 & 4 it follows that $max_{v'} w_{G'}(v') = max_v w_G(v)$, hence the correctness of UAR.

Abstract

Multinomial logistic regression is one of the most popular models for modelling the effect of explanatory variables on a subject choice between a set of specified options. This model has found numerous applications in machine learning, psychology or economy. Bayesian inference in this model is non trivial and requires, either to resort to a Metropolis-Hastings algorithm, or rejection sampling within a Gibbs sampler. In this paper, we propose an alternative model to multinomial logistic regression. The model builds on the Plackett-Luce model, a popular model for multiple comparisons. We show that the introduction of a suitable set of auxiliary variables leads to an Expectation-Maximization algorithm to find Maximum A Posteriori estimates of the parameters. We further provide a full Bayesian treatment by deriving a Gibbs sampler, which only requires to sample from highly standard distributions. We also propose a variational approximate inference scheme. All are very simple to implement. One property of our Plackett-Luce regression model is that it learns a sparse set of feature weights. We compare our method to sparse Bayesian multinomial logistic regression and show that it is competitive, especially in presence of polychotomous data.

1 Introduction

The multinomial logistic regression (or multinomial logit) model is one of the most popular models for modelling the effect of explanatory variables $X_i = (X_{i1}, \ldots, X_{id}) \in \mathcal{X}$ on a subject choice Y_i between a set of prespecified options $\{1, \ldots, K\}$. The model, which belongs to the class of generalized linear models (McCullagh & Nelder, 1989), takes the following form:

$$\Pr(Y_i = k | X_i, \beta) = \frac{e^{X_i^\top \beta_k}}{1 + \sum_{\ell=1}^{K-1} e^{X_i^\top \beta_\ell}} \qquad (1)$$

for $k = 1, \ldots, K-1$ and $\Pr(Y_i = K | X_i) = \frac{1}{1+\sum_{\ell=1}^{K-1} \exp(X_i^\top \beta_\ell)}$. The monograph of Agresti (1990) gives details on the foundations of this model and related ones such as conditional logit (McFadden, 1973). The parameters $\beta_k = (\beta_{k1}, \ldots, \beta_{kd})$, $k = 1, \ldots, K-1$ are unknown and have to be estimated from the data. Bayesian inference in multinomial logit is complicated by the fact that no conjugate prior exists for the regression parameters. Various algorithms have been proposed in the literature, see e.g. (Dey et al., 2000). In particular, similarly to Bayesian inference in probit models (Albert & Chib, 1993; Talhouk et al., 2012; Holmes & Held, 2006) proposed an auxiliary variable model for block Gibbs sampling. Alternative Markov Chain Monte Carlo (MCMC) algorithms have been compared by Girolami & Calderhead (2011). However, although some algorithms show excellent mixing properties, they lack simplicity of implementation.

When only some of the predictors are assumed to be relevant, sparse multinomial logistic regression has been proposed using Laplace priors.Krishnapuram et al. (2005) obtained Maximum A Posteriori (MAP) estimates via Minorization-Maximization-based algorithms, while fully Bayesian inference is conducted in (Cawley et al., 2007) and (Genkin et al., 2007).

In this article, we propose an alternative model to multinomial logit for multi-class classification and discrete choice modelling. We show that the use of a carefully chosen set of latent variables leads to an Expectation Maximization (EM) algorithm to find MAP estimates, a Gibbs sampler or a variational EM algorithm to approximate the full posterior. Importantly, the Gibbs sampler only requires to sample from standard distributions, which makes it computationally highly amenable. Moreover, for some values of the hyperpa-

rameter, we show that the model induces sparsity over the parameters. In particular, the MAP estimates are exactly sparse. We also provide detailed comparaisons with Bayesian sparse multinomial logit in terms of computational efficiency and prediction performances. The Bayesian treatment of sparse multinomial logistic regression is discussed in Appendix A. The model builds on the data augmentation model proposed by Holmes & Held (2006) and the Bayesian lasso of Park & Casella (2008). To the best of our knowledge is has not been proposed before.

2 Statistical model

We propose an alternative model for categorical data analysis. The model is defined as follows:

$$\Pr(Y_i = k|X_i, \lambda) = \frac{W_i^\top \lambda_k}{\sum_{\ell=1}^K W_i^\top \lambda_\ell} \tag{2}$$

for $k = 1, \ldots, K$, where $W_i = (W_{i1}, \ldots, W_{ip})$ and $W_{ij} = \mathcal{K}_j(X)$. $\mathcal{K}_j$ is a known function from $\mathcal{X}$ to $[0, +\infty[$. In practice, there is a lot of flexibility on the choice of the transformations $\mathcal{K}_j$ of the explanatory variables. In the remaining of this paper, we will consider $\mathcal{K}_j(X) = \exp(X_{ij})$, $\mathcal{K}_{d+j}(X) = \exp(-X_{ij})$ to account for negative effects and $\mathcal{K}_{2d+1}(X) = \exp(0)$ for the offset. The non-negative parameters λ_{kj}, $k = 1, \ldots, K$, $j = 1, \ldots, p$ are unknown and have to be estimated from the data.

The model shares strong similarities with the Plackett-Luce model for multiple comparisons (Luce, 1959; Plackett, 1975), for which efficient Bayesian inference can be carried out (Guiver & Snelson, 2009; Caron & Doucet, 2012). Similarly to this model, it also admits a Thurstonian interpretation (Diaconis, 1988) that we describe now. For $k = 1, \ldots, K$ and $j = 1, \ldots, p$, let

$$V_{ikj} \sim \text{Exp}(W_{ij}\lambda_{kj}) \ ,$$

where $\text{Exp}(b)$ denotes the exponential distribution with rate parameter b. As an analogy, let consider a race between K different teams, each team having p competitors. Each individual j in a team k has an arrival time V_{ikj} for competition i. Then Y_i denotes the winning team, i.e. the team k which has the individual with the lowest arrival time. Following properties of the exponential distribution, it is straightforward to show that

$$\Pr(\arg\min_\kappa(\min_j V_{i\kappa j}) = k|X_i, \lambda) = \frac{W_i^\top \lambda_k}{\sum_{\ell=1}^K W_i^\top \lambda_\ell} \ .$$

The decision boundaries between two classes k and ℓ are given by

$$W^\top(\lambda_k - \lambda_\ell) = 0 \ ,$$

i.e. they are linear in the transformed domain W. As the multinomial logit model, the model (2) satisfies Luce's axiom of choice (Luce, 1977) a.k.a. *independence from irrelevant alternatives*.

3 MAP estimation and Bayesian Inference

3.1 Data Augmentation

The likelihood defined by (2) does not admit a conjugate prior. We can nonetheless consider a data augmentation scheme as indicated by Caron & Doucet (2012). Assume that we have observed data $\mathcal{Y} = \{Y_i\}_{i=1}^n$. We introduce auxiliary latent variables $\mathcal{C} = \{C_i\}_{i=1}^n$ and $\mathcal{Z} = \{Z_i\}_{i=1}^n$ such that, for $i = 1, \ldots, n$

$$Y_i|C_i, \lambda \sim \text{Disc}\left(\frac{\lambda_{1C_i}}{\sum_\ell \lambda_{\ell C_i}}, \ldots, \frac{\lambda_{KC_i}}{\sum_\ell \lambda_{\ell C_i}}\right), \tag{3}$$

$$C_i|\lambda \sim \text{Disc}\left(\frac{W_{i1}\sum_k \lambda_{k1}}{W_i^\top \sum_\ell \lambda_\ell}, \ldots, \frac{W_{ip}\sum_k \lambda_{kp}}{W_i^\top \sum_\ell \lambda_\ell}\right), \tag{4}$$

$$Z_i|\lambda \sim \text{Exp}\left(W_i^\top \sum_\ell \lambda_\ell\right), \tag{5}$$

where $\text{Disc}(\pi_1, \ldots, \pi_p)$ denotes the discrete distribution of parameters $(\pi_1, \ldots, \pi_p)$ where $\pi_i \geq 0$ and $\sum_i \pi_i = 1$. Pursuing the analogy with team competition introduced in the previous section, the latent variables Z_i and C_i have the following interpretation. $Z_i = \min_{k,j}(V_{ijk})$ corresponds to the arrival time of the winner of the competition. As the variables V_{ijk} are exponentially distributed and the minimum of two exponential variable of rates w_1 and w_2 is an exponential variables of rate $w_1 + w_2$, we recover (5). $C_i \in \{1, \ldots, p\}$ corresponds to the index of the individual in the winning team who arrives first.

The model (3–4) corresponds to an ad-mixture of Discrete distributions. Indeed, the class probabilities defined by the Plackett-Luce model (2) can be rewritten in the form of a mixture model by integrating out the latent indicator variables $\{C_i\}_{i=1}^n$:

$$\Pr(Y_i = k|X_i, \lambda) = \sum_j \pi_{ij} \text{ Disc}\left(\frac{\lambda_{1j}}{\sum_\ell \lambda_{\ell j}}, \ldots, \frac{\lambda_{Kj}}{\sum_\ell \lambda_{\ell j}}\right),$$

where the mixture weight $\pi_{ij} = \frac{W_{ij}\sum_k \lambda_{kj}}{W_i^\top \sum_\ell \lambda_\ell}$ depends on the data through $\{W_{ij}\}_{j=1}^p$. Note that there is one mixture component per feature. Hence, each component characterises the classes by assigning a different importance weight to their associated feature.

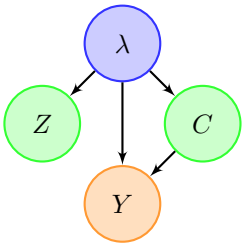

Figure 1: Graphical Model. Parameter of interest λ is in blue, latent variables Z and C in green and measurements Y in orange.

The resulting log-complete likelihood is given by

$$\ln p(\mathcal{Y}, \mathcal{C}, \mathcal{Z}|\lambda) = \sum_{k=1}^{K}\sum_{j=1}^{p}\left\{ n_{kj} \ln \lambda_{kj} - \lambda_{kj} \sum_{i=1}^{n} Z_i W_{ij} \right\} + \sum_{i=1}^{n}\sum_{j=1}^{p} \delta_{C_i j} \ln W_{ij} \ , \tag{6}$$

where $n_{kj} = \sum_i \delta_{Y_i k}\delta_{C_i j}$ and δ_{ij} is the Kronecker delta. We further assign a conjugate Gamma prior to the parameters λ:

$$\lambda \sim \prod_{k=1}^{K}\prod_{j=1}^{p} \mathrm{Gam}(\lambda_{kj}; a, b) \ . \tag{7}$$

where $a > 0$ is the shape parameter and $b > 0$ is the rate parameter. The graphical model is shown in Figure 1.

3.2 EM algorithm

The log-posterior can be maximized using the EM algorithm by iteratively maximizing a lower bound, called the negative *variational free energy* (Neal & Hinton, 1998), or a penalized version as below:

$$\begin{aligned} \ln p(\lambda|\mathcal{Y}) &\geq \langle \ln p(\mathcal{Y}, \mathcal{C}, \mathcal{Z}|\lambda) \rangle_q + \mathrm{H}\left(q(\mathcal{C}, \mathcal{Z})\right) + \ln p(\lambda) \\ &\equiv -\mathcal{F}(q, \lambda) + \ln p(\lambda) \ , \end{aligned} \tag{8}$$

where $\langle \cdot \rangle_q$ denotes the expectation with respect to $q(\mathcal{C}, \mathcal{Z})$ and $\mathrm{H}(\cdot)$ is the (differential) entropy. When the posterior $p(\mathcal{C}, \mathcal{Z}|\mathcal{Y}, \lambda)$ is analytically tractable, then we set $q(\mathcal{C}, \mathcal{Z}) = p(\mathcal{C}, \mathcal{Z}|\mathcal{Y}, \lambda)$ so that the bound is exact and we recover the EM algorithm.

Given the augmented model (3-5), the posterior factorizes: $p(\mathcal{C}, \mathcal{Z}|\mathcal{Y}, \lambda) = \prod_i p(C_i|Y_i, \lambda) p(Z_i|\mathcal{Y}, \lambda)$. The E-step consists in computing the posterior of the latent indicator variables for fixed λ.[1] This leads to

$$C_i|Y_i, \lambda \sim \mathrm{Disc}\left(\frac{W_{i1}\lambda_{Y_i 1}}{W_i^\top \lambda_{Y_i}}, \ldots, \frac{W_{ip}\lambda_{Y_i p}}{W_i^\top \lambda_{Y_i}} \right). \tag{9}$$

[1] Note that $p(Z_i|\mathcal{Y}, \lambda)$ is given by (5)

The M-step updates the parameter set λ for fixed posteriors:

$$\lambda \leftarrow \arg\max_{\lambda} \langle \ln p(\mathcal{Y}, \mathcal{C}|\lambda) \rangle_{p(\mathcal{C}|\mathcal{Y}, \lambda)} + \ln p(\lambda) \ .$$

It follows that

$$\lambda_{kj} = \begin{cases} \frac{a - 1 + \langle n_{kj} \rangle}{b + \sum_i \langle z_i \rangle W_{ij}} & \text{if } a > 1 - \langle n_{kj} \rangle \ , \\ 0 & \text{otherwise.} \end{cases} \tag{10}$$

where $\langle n_{kj} \rangle = \sum_i \frac{W_{ij}\lambda_{kj}}{W_i^\top \lambda_k}$ and $\langle z_i \rangle = \left(W_i^\top \sum_l \lambda_l \right)^{-1}$. For $a = 1$ and $b = 0$, the maximum a posteriori estimate coincides with the maximum likelihood estimate. If $a < 1$, one may obtain sparse estimates of the weights, as the numerator of (10) may become negative. By changing the value of the hyperparameter a, one may obtain different levels of sparsity. It could for example be set by cross-validation. Next, we propose a Bayesian treatment of λ. We first show that it is straightforward to derive a Gibbs sampler for (2) given our data augmentation. Subsequently, we derive a deterministic approximate Bayesian inference scheme, closely related to the Gibbs sampler.

3.3 Gibbs sampler

Using the same data augmentation, we can define a Gibbs sampler for sampling from the posterior distribution $p(\mathcal{C}, \mathcal{Z}, \lambda|\mathcal{Y})$. The conditional distribution $p(\mathcal{C}|\mathcal{Y}, \lambda)$ factorizes, such that each C_i can be updated conditioned on (Y_i, λ) using (9). Likewise, the conditional $p(\mathcal{Z}|\mathcal{Y}, \lambda)$ factorizes, such that each Z_i can be updated conditioned on λ as the posterior reverts to the prior (5). Finally, the conditional for each λ_{kj} is of the form $p(\lambda_{kj}|\mathcal{Y}, \mathcal{C}, \mathcal{Z}) \propto p(\lambda_{kj}) e^{\ln p(\mathcal{Y}, \mathcal{C}, \mathcal{Z}|\lambda)}$. Since the Gamma prior is conjugate to the complete likelihood, the conditional for λ_{kj} still follows a Gamma distribution.

To summarize, the Gibbs sampler is given by

$$C_i|Y_i, \lambda \sim \mathrm{Disc}\left(\frac{W_{i1}\lambda_{Y_i 1}}{W_i^\top \lambda_{Y_i}}, \ldots, \frac{W_{ip}\lambda_{Y_i p}}{W_i^\top \lambda_{Y_i}} \right), \tag{11}$$

$$Z_i|\lambda \sim \mathrm{Exp}\left(W_i^\top \sum_{\ell=1}^{K} \lambda_\ell \right), \tag{12}$$

$$\lambda_{kj}|\mathcal{Y}, \mathcal{C}, \mathcal{Z} \sim \mathrm{Gam}\left(a + n_{kj}, b + \sum_{i=1}^{n} Z_i W_{ij} \right). \tag{13}$$

3.4 Variational approximation

Next, we turn our attention to a deterministic approximation instead of sampling. Variational EM maximizes the variational lower bound (Neal & Hinton,

1998), which can be re-written in the form

$$\ln p(\mathcal{Y}) \geq -\mathcal{F}(q) = \langle \ln p(\mathcal{Y}, \mathcal{C}, \mathcal{Z}, \lambda) \rangle_{q(\mathcal{C})q(\mathcal{Z})q(\lambda)} + \mathrm{KL}\left[q(\mathcal{C})q(\mathcal{Z})q(\lambda) \| p(\mathcal{C}, \mathcal{Z}, \lambda|\mathcal{Y}))\right]. \quad (14)$$

The approximation assumes that the latent variables and the parameters are independent a posteriori given the data. The approximate posteriors are given by

$$q(\mathcal{C}) \propto p(\mathcal{C}) e^{\langle \ln p(\mathcal{Y}, \mathcal{Z}, \lambda|\mathcal{C}) \rangle_{q(\mathcal{Z})q(\lambda)}}, \quad (15)$$

$$q(\mathcal{Z}) \propto e^{\langle \ln p(\mathcal{Y}, \mathcal{C}, \mathcal{Z}, \lambda) \rangle_{q(\mathcal{C})q(\lambda)}}, \quad (16)$$

$$q(\lambda) \propto p(\lambda) e^{\langle \ln p(\mathcal{Y}, \mathcal{C}, \mathcal{Z}|\lambda) \rangle_{q(\mathcal{C})q(\mathcal{Z})}}, \quad (17)$$

In practice, this boils down to cycling through the following updates

$$\rho_{kji} \propto \delta_{Y_i k} W_{ij} e^{\langle \ln \lambda_{kj} \rangle}, \quad \langle z_i \rangle = \frac{1}{W_i^\top \sum_\ell \langle \lambda_\ell \rangle} , \quad (18)$$

$$a_{kj} = a + \langle n_{kj} \rangle , \qquad b_{kj} = b + \sum_i \langle z_i \rangle W_{ij} , \quad (19)$$

where $\langle \lambda_{kj} \rangle = \frac{a_{kj}}{b_{kj}}$, $\langle \ln \lambda_{kj} \rangle = \psi(a_{kj}) - \ln b_{kj}$, and $\langle n_{kj} \rangle = \sum_i \rho_{kji}$.

The similarity between the variational posteriors and the Gibbs sampler is striking. For example, $p(\lambda|\mathcal{Y}, \mathcal{C}, \mathcal{Z})$ and $q(\lambda)$ have the same form, except that the counts n_{kj} and the latent auxiliary variables Z_i are respectively replaced by their expected values, namely $\langle n_{kj} \rangle$ and $\langle Z_i \rangle$. However, unlike Gibbs sampling, the convergence of variational inference and the correctness of the algorithm are easy to check by monitoring the variational lower bound, which monotonically increases at each iteration. Hence, considering both approaches in parallel is convenient when debugging the Gibbs sampling code.

3.5 Identifiability and hyperparameters estimation

The likelihood (2) is invariant to a rescaling of the λ_{kj}'s. As a consequence, the scaling hyperparameter b does not have any effect on the prediction, It can be set to an arbitrary value, e.g. $b = 1$. Let

$$\Lambda = \sum_k \sum_j \lambda_{kj} , \qquad \overline{\lambda_{kj}} = \frac{\lambda_{kj}}{\Lambda} .$$

Because of the invariance w.r.t. rescaling, Λ is not likelihood identifiable and

$$p(\Lambda, \overline{\lambda}|\mathcal{Y}) = p(\Lambda) p(\overline{\lambda}|\mathcal{Y}) ,$$

with $p(\Lambda) = \mathrm{Gam}(\Lambda; Kp, b)$. It follows that

$$\Lambda^{\mathrm{MAP}} = \frac{Kp - 1}{b} .$$

To improve the mixing of the Markov chain, an additional sampling step can be added by sampling the total mass Λ from the prior then rescale the parameters λ adequately. While it would improve the mixing of the Markov chain, this is useless here as we are typically interested in the prediction with the normalized weights.

The parameter a can be estimated by cross-validation in the EM algorithm. For full Bayesian inference, we assume the following flat improper prior:

$$p(a) \propto \frac{1}{a}$$

and we add a Metropolis-Hastings sampling step in the Gibbs sampler. In the variational EM algorithm, a is estimated by type II Maximum Likelihood:

$$a \leftarrow \arg\max_a \left\{ -\mathcal{F}(q, \lambda) + \ln p(a) \right\}.$$

While this does not lead to a closed form update for a, the maximization can be performed by a line search.

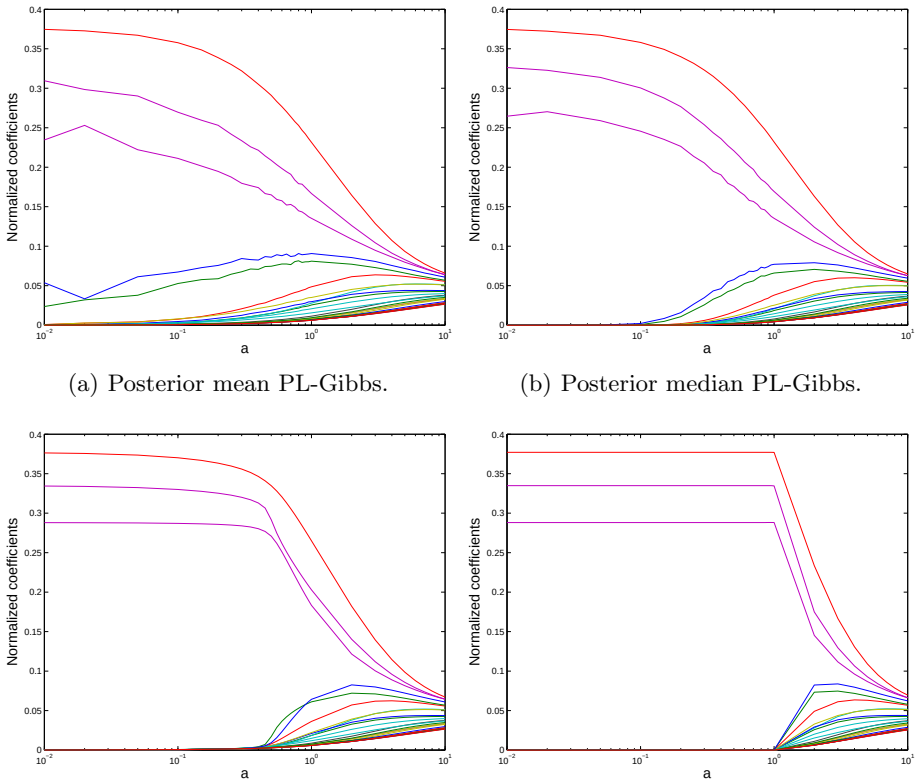
4 Experiments

In this section we investigate the performances of the Plackett-Luce regression model, which we will denote PL-EM, PL-Gibbs or PL-Var depending on the training algorithm we used (see Section 3).

4.1 Sparsity and regularization paths

First, we compare the sparsity properties of PL-EM, PL-Gibbs and PL-Var. We consider the iris dataset, which is available from the UCI repository. As with ℓ_1-penalization in generalized linear regression models, varying the value of the regularization coefficient a will enforce the amount of sparsity over the estimated λ of our model.

Figure 2 shows the regularization path for the coefficients as a function of a, using the MAP estimate obtained with EM, the posterior mean and median obtained with Gibbs sampling, and the posterior mean obtained with the variational approximation. Regularization paths report the values of the weights obtained when training the models with decreasing values of the hyperparameter a. When considering MAP, we obtain exactly sparse estimates for sufficiently small values of a. Similarly to what is observed with the Bayesian lasso (Park & Casella, 2008) the posterior mean estimates obtained by Gibbs sampling are not sparse but more concentrated around zero as the value of a decreases. The posterior median leads to sparser estimates, similarly to what is observed with the Bayesian lasso. Interestingly, the variational approximation shows similar sparsity as the posterior median, but converges faster.



(a) Posterior mean PL-Gibbs.

(b) Posterior median PL-Gibbs.

(c) Posterior mean PL-Var.

(d) MAP PL-EM.

Figure 2: Regularization paths for the iris dataset. The paths are the values of the weight parameters as a function of a. They are obtained by training the models for decreasing values of a. Each colour corresponds to a different λ_{kj}. The coefficient values are normalized to make the scales comparable.

4.2 Toy datasets

Next, we investigate the predictive and computational performances of the proposed PL models. We compare to Bayesian multinomial logistic regression (or logit). More specifically, we consider the Gibbs sampler described by Holmes & Held (2006), as the authors provide detailed pseudo-code on the algorithm, and the algorithm has no tuning parameter as in the case of our Gibbs sampler (as opposed to hybrid Monte Carlo, for example).[2] However, we will consider a sparse extension inspired by the Bayesian lasso of Park & Casella (2008). The Gibbs sampler is detailed in the Appendix.

We compare both models/algorithms in terms of computational efficiency and predictive performance on five datasets from the UCI repository: three polychotomous (Lenses, Wine and Iris) and three binary (Heart, German and Pima). Summaries of the different datasets are given in Table 1.

[2]To be precise we used the corrected version by van der Lans (2011); Holmes & Held (2011).

Name	d	K	n
Lenses	4	3	24
Wine	13	3	178
Iris	4	3	150
Heart	13	2	270
German	24	2	1000
Pima	8	2	768

Table 1: Dataset characteristics: covariates (d), categories (K), and data points (n).

As Holmes & Held (2006), we first conduct 5000 burn in iterations then the next 5000 iterations are used to collect posterior samples. Each method was implemented in Matlab on a standard computer. We compare the predictive performance by computing the average number of misclassifications over 20 replications (i.e. random splits of the data in training and test set). Predictions are based on Bayesian averaging over 5000 samples. The results are reported in Table 2. It can be observed that the proposed Plackett-Luce models are competitive with sparse Bayesian multinomial logit.

This is confirmed when computing the area under the receiver operating curve (Figure 3). Gibbs sampling is in general beneficial compared to the variational approximation. This can be explained by the fact the PL-Var tends to provide sparser solutions, hence loosing predictive power.

We used the same experimental setup to investigate the relative efficiency of PL-Gibbs and sparse Bayesian multinomial logit. The two methods are compared by calculating the effective sample size using the posterior samples for each covariate

$$ESS = \frac{N}{1 + 2\sum_k \gamma(k)} \ ,$$

where $N = 5000$ and $\sum_k \gamma(k)$ is the sum of the K monotone sample auto-correlations as estimated by the initial monotone sequence estimator(Geyer, 1992; Girolami & Calderhead, 2011). We report the minimum ESS over the set of whole set of covariates. Table 3 shows the results for the different datasets, based on 20 replications. It can be observed that ESS is better (higher) for sparse multinomial logit in the binary cases. However, the running time is also higher, leading to a relative speed (ratio of time to ESS) of 2 to 3 in favour of sparse logit. However, when the number of classes increases this trend is drastically changed with a relative speed of approximately 30 in favour of PL-Gibbs. As discussed in Section 5, we attribute this to the fact that, in multinomial logit, the coefficients of one class are sampled conditioned on the coefficients of the other classes. Unfortunately, these coefficients are strongly correlated, resulting in a poor mixing. By contrast, the PL regression models jointly sample (or update) the coefficients associated to all the classes.

4.3 Real data examples

First, we consider the colon cancer data[3]. This is a binary classification problem consisting of 62 data points and 2001 features. In general, 50 data points are used for training and 12 for testing. The average number of misclassifications is 0.36 ± 0.11 for PL-Gibbs and 0.33 ± 0.15 for sparse binary logit. Hence, both model perform similarly. However, sparse binary logit based on the sampler of Holmes & Held (2006) runs about 500 times slower.

Second, we consider the sushi data (Kamishima, 2003). Individuals were asked which out of 10 sushis they preferred. The number of training data points is 4000 and the number of test data points is 1000. The number of features is 11. We repeated the experiment 5 times. Here, the average number of misclassifications for Plackett-Luce and sparse multinomial logit were respectively 656 and 672. While the performances are poor in both cases, PL-Gibbs performs slightly better and is much faster to run. Generating 5000 samples with PL-Gibbs takes a couple of minutes on a standard quad-core laptop, while it takes approximately 6 hours with the sampler of Holmes & Held (2006).

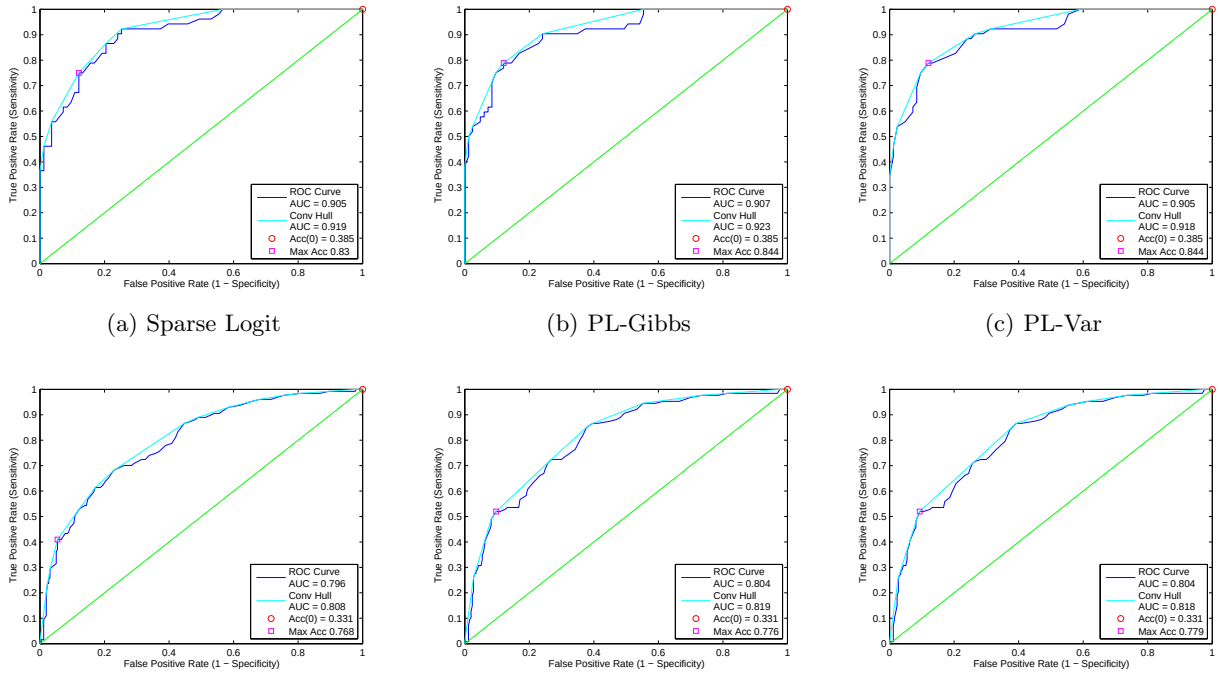
5 Discussion and extensions

The Gibbs sampler of the Plackett-Luce regression model only requires to sample from highly standard distributions (Exponential, Gamma and Discrete) for which very efficient generators exist. This is to be compared to Bayesian (multinomial) logistic regression, where it is required to sample from the truncated logistic and from other distributions without standard form, like for example the Kolmogorov-Smirnov, with rejection sampling (Holmes & Held, 2006). An important drawback of recent treatments of multinomial logistic regression like the one of Holmes & Held (2006) is that the multinomial outcomes are expressed as a sequence of binary outcomes. In other words, each vector of coefficient β_k is sampled conditional on the others.This explains why we observed experimentally



(a) Sparse Logit (b) PL-Gibbs (c) PL-Var

(d) Sparse Logit (e) PL-Gibbs (f) PL-Var

Figure 3: ROC for heart (first row) and pima (second row) datasets.

the relatively poor mixing properties of multinomial logit when the number of classes is more than 2. Inference in multinomial probit models often suffer from the same weakness (e.g., Albert & Chib, 1993). In the Gibbs sampler associated to the model we propose, the parameters λ_{kj} are updated jointly and independently given the latent variables.

Throughout the paper, we arbitrarily used an exponential transformation of the covariates. Additional flexibility could be introduced into the model by allowing other transformations, which would better characterize the classes. Indeed, one of the limitations of the proposed generative model is that for each observation X_i, it is assumed first a feature C_i is selected, and then its class Y_i is drawn given C_i. When features do not uniquely characterize the classes, it becomes difficult to distinguish them. Figure 4 shows the decision boundaries for the iris data set (when only considering the petal length and width). It could be argued that these decision boundaries are counter-intuitive, especially in contrast to the decision boundaries of the sparse multinomial logit. This is confirmed by the poor performance of PL regression on the iris data set (see Table 2). However, by introducing additional transformation, more natural boundaries can be obtained. For example, to obtain Figure 4) we considered the additional features $\exp(X_{i1} + X_{i2})$ and $\exp(-X_{i1} - X_{i2})$.

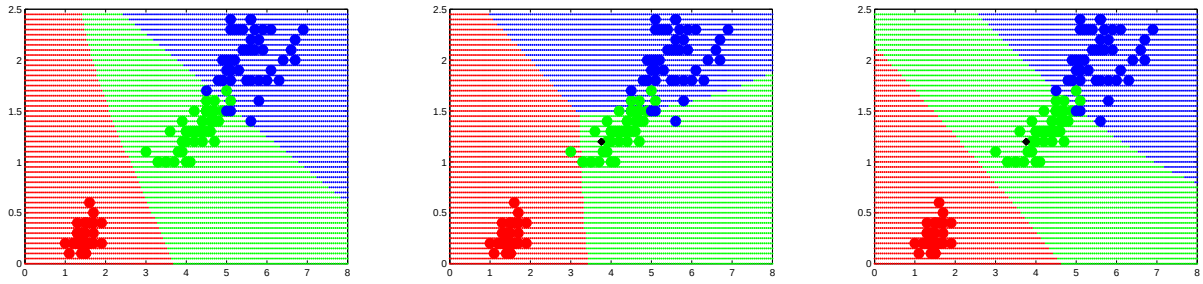
In general, devicing features of this kind would require prior knowledge of the problem at hand, which is rarely the case.

In this paper, we have focused on a Gamma prior for the weights parameters λ_{kj}. Now assume that $a = \alpha/p$. When the number of covariates p and hence $p^\star$ becomes very large, we have

$$\Lambda = \sum_{j=1}^{\infty} \lambda_{kj} \sim \text{Gam}(\alpha, b) \ .$$

Hence, the sequence of normalized ordered weights $\frac{\lambda_{k\sigma(1)}}{\Lambda} > \frac{\lambda_{k\sigma(2)}}{\Lambda} > \dots$ is drawn from the Poisson Dirichlet distribution of parameter α(Pitman, 1996), which is the distribution of the ordered weights in a draw from a Dirichlet process (Teh, 2010). The limit may give useful hints on the behavior of the model with a large number of covariates.

The model could also be directly extended by replacing the Gamma prior by the larger family of generalized inverse Gaussian distributions, which admits the Gamma distribution as a special case, and is also a conjugate prior for the complete-likelihood. Hence, the full conditional distribution of λ_{kj} follows a generalized inverse Gaussian distribution. The use of this distribution may offer more flexibility in the modelling of the tails of the prior for the parameters λ_{kj}.



(a) Sparse Logit. (b) PL-Gibbs. (c) PL-Gibbs with additional features.

Figure 4: Decision boundaries for iris dataset (feature 3 and 4).

Finally, it should be noted that the model studied in this paper has been suggested by Caron & Doucet (2012). However, no discussion of the algorithms, nor any study on the fit of this model to data were discussed there.

A Bayesian sparse multinomial logistic regression

In this Appendix, we provide a Gibbs sampler for sparse multinomial logistic regression. The likelihood is given by (1) and a sparsity-promoting prior is imposed on the regression weights β_{kj}, $k = 1, \ldots, K-1$ and $j = 1, \ldots, p$. More specifically, we consider the following hierarchical prior:

$$\beta_{kj}|\tau_{kj} \sim \mathcal{N}(0, \tau_{kj}) \ , \qquad \tau_{kj} \sim \text{Exp}\left(\frac{\theta}{2}\right).$$

This model ensures that marginally β_{kj} follows a double-exponential (a.k.a. Laplace) distribution of parameter θ. It is routinely used in Bayesian generalized linear mode to induce sparsity Genkin et al. (2007); Park & Casella (2008); Griffin & Brown (2010).We further assume a Gamma prior for the hyperparameter θ for conjugacy reasons (see below (20)):

$$\theta \sim \text{Gam}(c, d) \ .$$

As noted by Park & Casella (2008), the improper prior $p(\theta) \propto \frac{1}{\theta}$ should be avoided in this model as it leads to an improper posterior for θ.

We can define a Gibbs sampler for the above model by using auxiliary variables u_k, $k = 1, \ldots, K-1$ as defined in (Holmes & Held, 2006). We therefore can define a Gibbs sampler to sample from the full posterior distribution $p(\beta, u, \tau, \theta|y)$. The sampler is defined as follows at each iteration:

- For $k = 1, \ldots, K-1$:
  - Sample $u_k, \beta_k|\beta_{-k}, u_{-k}, \{\tau_{kj}\}$ as described in (Holmes & Held, 2006; van der Lans, 2011; Holmes & Held, 2011)
  - For $j = 1, \ldots, J$, sample

$$\frac{1}{\tau_{kj}} \sim \text{iGauss}\left(\sqrt{\frac{\theta^2}{\beta_{kj}^2}}, \theta^2\right).$$

- Sample θ as follows:

$$\theta|\{\tau_{kj}\} \sim \text{Gam}\left(Kp + c, \sum_k \sum_j \frac{\tau_{kj}}{2} + d\right). \quad (20)$$

The notation $\text{iGauss}\,(a, b)$ denotes the inverse-Gaussian distribution with density given by

$$p(x) = \sqrt{\frac{b}{2\pi}} x^{-3/2} \exp\left(-\frac{b(x-a)^2}{2a^2 x}\right).$$

Abstract

We consider a Markov decision process with deterministic state transition dynamics, adversarially generated rewards that change arbitrarily from round to round, and a bandit feedback model in which the decision maker only observes the rewards it receives. In this setting, we present a novel and efficient online decision making algorithm named *MarcoPolo*. Under mild assumptions on the structure of the transition dynamics, we prove that MarcoPolo enjoys a regret of $O(T^{3/4}\sqrt{\log T})$ against the best deterministic policy in hindsight. Specifically, our analysis does not rely on the stringent unichain assumption, which dominates much of the previous work on this topic.

1 INTRODUCTION

Sequential decision making problems come in a variety of different flavors. In some cases it is natural to model the environment as a stochastic process, while in other cases we require the more robust assumption that the environment behaves adversarially. In both cases, we can either assume that the environment is stationary or that it evolves over time. For some problems it suffices to assume that the decision-making agent is stateless, while for other problems we may need to assume that the agent has a state that depends on its past actions. We must also specify what level of feedback the agent observes after making each decision. Finally, if we assume that the agent indeed has a state, we must decide whether the state transition dynamics are deterministic or stochastic, and whether they are known or unknown to the agent.

In this paper, we consider sequential decision making in an adversarial and nonstationary environment where the agent has a state. That is, on each round of the sequential decision-making problem, the agent is in one of finitely many states $\mathcal{S}$ and performs an action from a finite action set $\mathcal{A}$. The rewards received by the agent depend both on its action and its state, and the mapping from state-action pairs to rewards is controlled by an adversary and changes arbitrarily over time. We assume that the only feedback that the agent observes is the value of the rewards that it receives, and specifically, that it does not get to see the rewards that it could have received if it had acted differently or if it were in a different state. This limited type of feedback is commonly known as *bandit feedback*. In fact, this feedback model is so natural that a typical researcher in reinforcement learning may not even add the qualifier "bandit" to it. However, we prefer to explicitly mention it to distinguish our setting from early work (Even-Dar et al., 2009) on adversarial MDPs that assumed more extensive feedback.

We also assume that the state transition dynamics are deterministic and fully known to the agent. However, we note that, in the case of deterministic dynamics, it is easy to relax the assumption that the dynamics are known. Following ideas of Ortner (2010), the agent can spend $\text{poly}(|\mathcal{S}|, |\mathcal{A}|)$ time figuring out the dynamics. Therefore, we assume that the agent knows its current state and knows which state it will transition to as a result of each action. This type of state transition model is often called a *deterministic Markov decision process* (DMDP).

Our adversarial reward setting makes sense when the agent faces other agents with conflicting interests. This happens, for instance, when robots interact with other robots, when bidding agents compete against each other in auctions, when trading agents compete to make money, or when the agent is a character in a video game. In these strategic and adversarial settings, the environment is likely to change in unpredictable and arbitrary ways. In all of the aforementioned decision problems, bandit feedback seems to be the most realistic feedback model. Although we

make pessimistic assumptions about the world, we emphasize that our assumptions are strictly more general than the alternative: if the agent is lucky enough to find itself in a stochastic or stationary environment, or if richer feedback is available, our setting still applies.

The harsh assumptions about the rewards and the limited feedback are contrasted by the optimistic assumption that the state transition dynamics form a DMDP. In some cases, deterministic state transitions are a realistic assumption while in other cases this assumption may be overly simplistic. A stochastic system is often well approximated by a deterministic system (Bertsekas, 2005, Chapter 2). For instance, consider the motivating example in Even-Dar et al. (2009), where the goal is to drive along the shortest path from point a to point b. Although driving a car involves stochastic uncertainties, it is usually reasonable to assume that we have deterministic control over which streets our car takes along the path to our destination. Additionally, many of the uncertainties of driving a car can be modeled as part of the adversarial rewards. Another situation that leads to modeling using DMDPs is when the adversary is a finite state machine whose transitions depend on (equivalence classes of) the history of the agent's actions (Maillard and Munos, 2011).

Modeling the state transitions as a DMDP enables us to handle the adversarial bandit-feedback setting in a principled and rigorous fashion. Obtaining a similar result in the general weakly communicating MDP setting (where state transitions are stochastic) remains an elusive open problem. We hope that the techniques developed in this paper will prove useful toward solving that problem.

Another important design choice is how to evaluate the agent's actions. For simplicity, we assume that every action is available at each state, and we note that this assumption can be easily relaxed. Since the rewards are controlled by an adversary, they only become semantically meaningful when we compare the agent's cumulative reward with a suitable benchmark. We let Π be the set of all deterministic policies, where each $\pi \in \Pi$ is a mapping from $\mathcal{S}$ to $\mathcal{A}$, and we choose our benchmark to be the maximal reward obtained by any policy in Π. In other words, we compare the agent's rewards to those of the best deterministic policy in hindsight. Letting $r_1, r_2, \ldots$ denote the adversarial sequence of reward functions (chosen in advance by the adversary before the agent begins its moves), letting $(s_t^\pi, a_t^\pi)_{t=1}^\infty$ denote the trajectory of state-action pairs generated by policy π, and letting $(s_t, a_t)_{t=1}^\infty$ denote the trajectory of state-action pairs generated by the agent, we define the agent's undiscounted *regret* after T rounds as

$$\max_{\pi\in\Pi} \sum_{t=1}^{T} r_t(s_t^\pi, a_t^\pi) - \mathbb{E}\left[\sum_{t=1}^{T} r_t(s_t, a_t)\right] \quad .$$

The agent's rewards appear in expectation because we allow randomized decisions. We say that the agent is learning if its regret can be upper-bounded by a sub-linear function of T, uniformly for all sequences of reward functions.

As mentioned above, we allow the adversary to modify the rewards for any state-action pair without any restrictions. Therefore, the same sequence of state-action pairs may have high rewards at one time and low rewards at another time. It could very well be that a given action sequence (starting from a given state s) may produce different rewards depending on whether we start performing the sequence on an odd or even time step. Therefore, it is insufficient to merely discover high-reward paths through the state space; we must also consider timing issues.

The main contribution of this paper is *MarcoPolo*, an efficient algorithm that enjoys a regret bound of $O(T^{3/4}\sqrt{\log T})$ against the best deterministic policy in hindsight (Theorem 2). The name MarcoPolo is an approximate acronym for **M**DP with **A**dversarial **R**ewards, weakly **CO**mmunicating structure, **P**artial feedback, by reduction to **O**nline **L**inear **O**ptimization. Anecdotally, Marco Polo was a famous Venetian merchant traveler who explored the world in search of high rewards, just as our algorithm explores the DMDP state space in search of rewards. Moreover, Marco Polo is the name of a well-known children's game that is played in a swimming pool, where one swimmer has to capture the other swimmers using only bandit feedback.

The basic idea behind MarcoPolo is quite simple. We observe that a deterministic policy repeats the same cycle of actions again and again. We then realize that if an oracle were to tell us the cycle length of the best deterministic policy and some additional information about its trajectory, then we could do as well as the best action cycle via a reduction to the *bandit linear optimization* (BLO) setting. Such an oracle is unavailable to us, but we can do almost as well as the oracle using a *multi-armed bandit* (MAB) algorithm. The MAB algorithm explores different cycle lengths and trajectories by invoking the BLO algorithm multiple times. To the best of our knowledge, this two-tier hierarchy involving a MAB algorithm that invokes a BLO algorithm is a novel conceptual contribution to the design space of regret minimization algorithms.

1.1 RELATED WORK

Our setting has much in common with a line of research initiated by Even-Dar et al. (2009) and further developed by Yu et al. (2009) and Neu et al. (2010), which deals with MDPs with adversarial rewards. Even-Dar et al. (2009) assumes a full-information feedback model while Yu et al. (2009) and Neu et al. (2010) only require bandit feedback. While these papers assume that the state transition dynamics are stochastic, they also assume that these dynamics have a *unichain* structure. This means that *every* policy must lead to a Markov chain with a single recurrent class (plus some possibly empty set of transient states). This is a very restrictive assumption, as we discuss in Sec. 2.1. In our setting, we assume that the state transition dynamics are deterministic and *weakly communicating*, i.e. it is possible to move from any state to any other state under *some* policy. Although deterministic transition dynamics are less general than stochastic ones, our analysis requires a much weaker assumption on the connectivity between states.

The work in Yu and Mannor (2009) also deals with MDPs with adversarial rewards, bandit feedback, and stochastic state transition dynamics. Moreover, it allows the stochastic transition dynamics to change over time in an adversarial way. The analysis in Yu and Mannor (2009) relies on the strong assumption that the MDP has a finite mixing time. Again, our analysis has the advantage that it relies on a weaker assumption on state connectivity.

Ties between the reinforcement learning literature and the area of individual sequence prediction and compression in information theory are further developed in Farias et al. (2010).

There is a well developed regret minimization and PAC-MDP literature that deals with a similar problem, except that the rewards are stochastic and not adversarial. We cannot do justice to that extensive literature but merely refer the reader to the survey by Szepesvari (2010) and the references therein. Our work bears some similarities to the work of Ortner (2010), which considers sequential decision making in DMDPs with bandit feedback. However, the rewards in that paper are stochastic and not adversarial, hence, the motivation and techniques used are rather different.

The importance of developing machine learning algorithms that work in reactive environments (where agent's actions impact the future evolution of rewards) has caught the attention of many researchers. de Farias and Megiddo (2006) propose algorithms that combine expert advice in a reactive environment. Ryabko and Hutter (2008) consider the problem of learnability in a very general reactive setting and show that environments that allow a rapid recovery from mistakes are asymptotically learnable. Arora et al. (2012) introduce the notion of policy regret as a more meaningful alternative to regret for measuring an online algorithm's performance against adaptive adversaries. Arora et al. (2012) also presents a general reduction that converts any bandit algorithm with a sublinear regret into an algorithm with a sublinear policy regret.

2 PRELIMINARIES

Let $\mathcal{S}$ be a set of n states and let $\mathcal{A}$ be a finite set of actions. An *adversarial-reward deterministic Markov decision process* (DMDP) is a tuple $(\mathcal{S}, \mathcal{A}, f, r_{1:T})$ where $\mathcal{S}$ is a finite set of *states*, $\mathcal{A}$ is a finite set of *actions*, $f : \mathcal{S} \times \mathcal{A} \to \mathcal{S}$ is a deterministic *state transition function*, which maps a state-action pair to the next state, and $r_{1:T}$ is a sequence $(r_t)_{t=1}^{T}$ of *reward functions* $r_t : \mathcal{S} \times \mathcal{A} \to [0, 1]$.

We slightly overload our notation and allow the second argument of the state transition function to be a sequence of actions, rather than a single action. Namely, $f\big(s, (a_1, \ldots, a_k)\big)$ is the state we reach if we start from s and perform the action sequence $a_1, \ldots, a_k$. More formally, the extended definition of f is given by the recursion

$$f\big(s, (a_1, \ldots, a_k)\big) \;=\; f\Big(f\big(s, (a_1, \ldots, a_{k-1})\big),\; a_k\Big) \;\; .$$

We also find it useful to denote the set of state-action pairs that lead to a given state s by $\mathrm{I}(s)$. That is,

$$\mathrm{I}(s) = \{(s', a') \;:\; f(s', a') = s\} \;\; .$$

A deterministic *policy* is a mapping $\pi : \mathcal{S} \to \mathcal{A}$. Together with an initial state s_1, each policy defines a sequence of actions and states. Since $\mathcal{S}$ is finite, a state will eventually repeat, and from then onwards the policy will keep repeating the same cycle of actions. We categorize a policy π by the length of this cycle and we let Π_k denote the set of deterministic policies that induce cycles of length k. We prove a regret bound that compares the algorithm's cumulative reward with the reward of the best deterministic policy in $\Pi_{\leq L} = \bigcup_{k \leq L} \Pi_k$, where L is a user-defined constant. Since the cycle length is bounded by n, setting $L = n$ gives a regret bound that compares the algorithm to all deterministic policies. The benefit of proving a regret bound for $L < n$ is to demonstrate how the bound degrades gracefully with the complexity of the competitor class.

Our analysis deals with weakly communicating DMDPs (see Section 2.1 for definitions of weakly communicating MDP and the associated closed set of

states) and requires the following additional assumption.

Assumption 1. *For any pair of states $s \neq s'$ in the closed set, there exists an action sequence $a = (a_1, \ldots, a_d)$ (of length exactly d) such that $f(s, a) = s'$.*

Note that the assumption only talks about *existence* of an action sequence. We note that finding the action sequence can be done efficiently, e.g. using dynamic programming. This assumption is a very mild one and it may well be possible to dispense with it entirely. A simple sufficient condition that implies this assumption is the existence of at least one self-loop in the DMDP. Another sufficient condition is that the transition graph is symmetric (i.e. if $f(s, a) = s'$ then there exists an opposite action $a' \in \mathcal{A}$ such that $f(s', a') = s$) and there exists an odd length cycle in the graph.

2.1 THE UNICHAIN CONDITION IS TOO STRINGENT

The difference between a DMDP and a general MDP is that, in the latter, the transition dynamics are stochastic, i.e. f maps an (s, a) pair to a *distribution* over states. Two well known subclasses of MDPs are *recurrent* (or ergodic) and *communicating* MDPs. In a recurrent MDP, *every* policy π induces a Markov chain with a single recurrent class. The more general notion of a communicating MDP only requires that it be possible to move (with non-zero probability) from any state to any other state using *some* policy. Note the difference in quantifiers — "every" versus "some" — in the definitions of recurrent and communicating MDPs. Thus, the recurrent condition is much more stringent than the communicating condition.

Both notions can be generalized a little bit to allow for some transient states. Thus, we arrive at the classes of *unichain* and *weakly communicating* MDPs. In unichain MDPs, *every* policy induces a Markov chain with a single recurrent class plus a possibly empty set of transient states. In weakly communicating MDPs, there is a *closed* set of states such that each state is accessible, under *some* policy, from any other state in the closed set (with non-zero probability under some policy) plus a possibly empty set of states that are transient under every policy. In the same way as recurrent is a much stronger condition compared to communicating, the unichain condition is much stronger compared to weakly communicating.

We have the (strict) inclusions:

$$\text{recurrent} \subset \text{unichain} \subset \text{weakly communicating} ,$$
$$\text{recurrent} \subset \text{communicating} \subset \text{weakly communicating} .$$

The graph associated with a DMDP is a directed graph with $\mathcal{S}$ as the set of vertices and the set of edges given by

$$\{(s, s') \,:\, \exists a \in \mathcal{A} \text{ s.t. } f(s, a) = s'\} .$$

For DMDPs, the unichain condition can be equivalently stated in terms of its graph. A DMDP is unichain iff *any* two cycles in its graph have a common vertex (Feinberg and Yang, 2008). A DMDP is weakly communicating if, after removing a possibly empty set of states that are transient under all policies, we get a graph that is strongly connected. Thus, any learning algorithm will, after at most n steps, end up in the strongly connected component. Therefore, in our regret analysis, we will assume that the DMDP is communicating.

The "no vertex-disjoint cycles" characterization of the unichain condition for DMDPs shows again why the unichain condition is so stringent. Two self-loops on two distinct states will violate it. It is also not preserved under very simple operations of building larger MDPs from smaller ones. For instance, suppose we start from two unichain DMDPs on disjoint state spaces S_1, S_2 and join them by introducing two actions a_1, a_2 such that $f(s_1, a_1) = s_2$ and $f(s_2, a_2) = s_1$ for some $s_1 \in S_1, s_2 \in S_2$, then the resulting DMDP will not, in general, be unichain (but will be weakly communicating).

3 SOLUTION FOR FIXED LENGTH AND STATE

As a warm-up, we consider a toy version of our problem, where the competitor class is restricted to a smaller subset of $\Pi_{\leq L}$. Assume that we are told to focus on a specific cycle length k and a specific initial state $\bar{s}$. Let $\Pi_{k,\bar{s}}$ denote the subset of policies in Π_k that start in state $\bar{s}$ at time 1 and return to $\bar{s}$ at time $k + 1$. Assume that we are only required to compete with policies in $\Pi_{k,\bar{s}}$.

Next, we characterize the action sequences induced by policies in $\Pi_{k,\bar{s}}$. Define the set

$$\mathcal{C}_{k,\bar{s}} \;=\; \{c \in \mathcal{A}^k \;:\; f(\bar{s}, c) = \bar{s}\} \;\; .$$

$\mathcal{C}_{k,\bar{s}}$ is the set of k-length action sequences such that starting from state $\bar{s}$ and performing an action sequence in $\mathcal{C}_{k,\bar{s}}$ brings us back to state $\bar{s}$. We say that $\mathcal{C}_{k,\bar{s}}$ is the set of *length k action cycles* with respect to a starting state $\bar{s}$. Note that this set contains all of the simple cycles of length k, but may also contain cycles that pass through $\bar{s}$. In this section, we present a randomized online algorithm that competes with any action sequence that consists of recurrences of some cycle in $\mathcal{C}_{k,\bar{s}}$. Note that this set of competitors may

also contain action sequences that are not induced by any policy in $\Pi_{k,\bar{s}}$, for example, due to the fact that $\mathcal{C}_{k,\bar{s}}$ is not restricted to simple cycles.

First, we present a general outline of our algorithm. There is an initial "lock-in" part in the algorithm to take care of the fact that the algorithm will eventually be called as a subroutine when the global time clock reads t_1 units and the agent is in some arbitrary state $s_1 \in \mathcal{S}$. Thus, there is a "phase lock-in" problem: the competitors in $\mathcal{C}_{k,\bar{s}}$ start from $\bar{s}$ at global time 1 and return to it at times $k+1, 2k+1, \ldots$. The agent needs to move from s_1 and get "locked into" one of the cycles so that it is not out of phase. Here is where Assumption 1 comes in handy. The algorithm picks an arbitrary cycle $(c_1, \ldots, c_k) \in \mathcal{C}_{k,\bar{s}}$. At time $t_1 + d$, this competitor will be at state $c_{k'}$ where $k' = (t_1 + d - 1) \mod k + 1$. The algorithm performs a sequence of d actions that bring it to $c_{k'}$ at time $t_1 + d$. Then we waste $k'' = (k - k' + 1) \mod k$ more time steps to come back to $\bar{s}$ and the agent is now "in phase" with $\mathcal{C}_{k,\bar{s}}$.

The algorithm then splits the remaining rounds into epochs of length k, where epoch j starts on round $d + k'' + (j-1)k + 1$ and ends on round $d + k'' + jk$. At the beginning of epoch j, the algorithm defines a distribution θ_j over the set $\mathcal{C}_{k,s}$ and samples an action sequence from this distribution. The algorithm then spends the next k rounds executing the actions in the sequence that it has chosen. The algorithm sticks to the chosen sequence for the duration of the epoch, disregarding the rewards it observes along the way. Only at the end of the epoch does the algorithm look back on its rewards and defines a new distribution θ_{j+1} for the next epoch. In fact, our algorithm will only use the sum of the k rewards, rather than the k individual reward values.

It remains to specify how the algorithm sets the distribution θ_j. It does so via a reduction of our problem to a *bandit linear optimization* (BLO) problem[1]. We briefly describe the BLO problem setting and the interested reader is referred to (Flaxman et al., 2005; Abernethy et al., 2008) for details. A BLO problem is a repeated game between a randomized algorithm and an adversary, which takes place over a predefined polyhedral set $\mathcal{X} \subset \mathbb{R}^n$. Before the game begins, the adversary secretly picks a sequence of vectors $\rho_1, \rho_2, \ldots$, each in $\mathbb{R}^n$. On round i of the game, the algorithm begins by choosing a distribution over $\mathcal{X}$ and sampling a point x_i from that distribution. Next, the adversary

[1]A similar approach is used in (Flaxman et al., 2005; Abernethy et al., 2008) to solve the *bandit shortest path* problem. For more information on the bandit shortest path problem, see (McMahan and Blum, 2004; Awerbuch and Kleinberg, 2004; György et al., 2007)

Algorithm 1: Fixed length k and state $\bar{s}$

input: initial state s_1, global time t_1, length k, state $\bar{s}$, iterations T
initialize: `BLO` with $n = nk|\mathcal{A}|$ and $\mathcal{X}$ as defined in Eqs. (2 – 5)
Pick an arbitrary cycle $(c_1 = \bar{s}, \ldots, c_k) \in \mathcal{C}_{k,\bar{s}}$
Set $k' \leftarrow (t_1 + d - 1) \mod k + 1$
$(a_1, \ldots, a_d) \leftarrow$ get action sequence from s_1 to $c_{k'}$
for $t = 1, \ldots, d$
  perform action a_t: $s_{t+1} \leftarrow f(s_t, a_t)$
  observe (bandit) reward $r_t(s_t, a_t)$
  accumulate $R \leftarrow R + r_t(s_t, a_t)$
Set $k'' \leftarrow (k - k' + 1) \mod k$
Spend k'' time steps visiting the states $c_{k'+1}, \ldots, c_k$
Accumulate the k'' rewards in R
for $j = 1, 2, \ldots$
  $x_j \leftarrow$ get vector from `BLO`
  $\theta_j \leftarrow$ `decompose`(x_j)
  sample action cycle $(c_1 = \bar{s}, \ldots, c_k) \sim \theta_j$
  for $i = 1, \ldots, k$
    $t \leftarrow d + k'' + (j-1)k + i$
    if $t > T$ **then**
      return (R, s_t)
    perform action $a_t = c_i$: $s_{t+1} \leftarrow f(s_t, c_i)$
    observe (bandit) reward $r_t(s_t, c_i)$
    accumulate $R_j \leftarrow R_j + r_t(s_t, c_i)$
  provide R_j as feedback to `BLO`
  $R \leftarrow R + R_j$

computes $\rho_i \cdot x_i$ and reveals the result to the algorithm, while still hiding the vector ρ_i. The value $\rho_i \cdot x_i$ is the algorithm's reward on round i, and cumulative reward over a sequence of m rounds equals $\sum_{i=1}^{m} \rho_i \cdot x_i$. The goal is to accumulate a large reward over time. In this setting, the BLO algorithm presented in Abernethy et al. (2008) guarantees that the algorithm's expected regret after m iterations is bounded as

$$\max_{x \in \mathcal{X}} \sum_{i=1}^{m} \rho_i \cdot x - \mathbb{E}\left[\sum_{i=1}^{m} \rho_i \cdot x_i\right] \leq 4Un^{3/2}\sqrt{m \log(m)} \quad , \tag{1}$$

where U is an upper bound on $\rho_i \cdot x_i$ for all i.

A useful extension to the BLO setting is the double randomization technique, which involves adding an additional layer of randomization to the algorithm's strategy. The algorithm chooses the point x_i normally, but then replaces x_i with an *unbiased estimator* of x_i. In other words, the algorithm can choose any distribution θ_i over $\mathcal{X}$ such that $\mathbb{E}_{X \sim \theta_i}[X] = x_i$. The algorithm then samples a point X_i according to θ_i and plays X_i instead of x_i. Due to linearity, the expected reward $\mathbb{E}[\rho_i \cdot X_i | x_i]$ still equals $\rho_i \cdot x_i$, and the regret bound stated above remains valid. We use this exten-

sion in our reduction below. For more details, please see Abernethy et al. (2008, Section 7).

We are now ready to define the reduction from our problem to the BLO problem. The BLO problem takes place in the space $\mathbb{R}^n$, where $n = n|\mathcal{A}|k$. In this space, each coordinate corresponds to a triplet (s, a, i), where s is a state in $\mathcal{S}$, a is an action in $\mathcal{A}$, and i is a phase index in $[k]$. For any vector $v \in \mathbb{R}^n$, we use the notation $v_{(s,a,i)}$ to refer to the element of v that corresponds to the triplet (s, a, i).

We begin by embedding the sequence of reward functions that occur during epoch j in $\mathbb{R}^n$. The relevant reward functions are $r_{d+k''+jk-k+i}, \ldots, r_{d+k''+jk}$. We represent their values by a vector $\rho_j \in \mathbb{R}^n$ defined as

$$\forall\, s \in \mathcal{S}, a \in \mathcal{A}, i \in [k] \quad \rho_{j,(s,a,i)} = r_{d+k''+jk-k+i}(s, a) \ .$$

Next, we represent each cycle $c \in \mathcal{C}_{s,k}$ by a binary vector $x(c) \in \mathbb{R}^n$ defined as

$$x(c)_{s,a,i} = \begin{cases} 1 & \text{if } a = c_i \text{ and } s = f\big(\bar{s}, (a_1, \ldots, a_{i-1})\big) \\ 0 & \text{otherwise} \end{cases} ,$$

for all $s \in \mathcal{S}, a \in \mathcal{A}$, and $i \in [k]$. Note that $x(c)$ has exactly k non-zero entries that indicate the state-action pairs encountered along the cycle c. Moreover, note that the cumulative reward collected while performing the action sequence c on epoch j simply equals the dot product $\rho_j \cdot x(c)$.

Let $x\big(\mathcal{C}_{k,\bar{s}}\big) = \{x(c)\}_{c \in \mathcal{C}_{k,\bar{s}}}$ denote the set of vectors induced by all of the action cycles in $\mathcal{C}_{k,\bar{s}}$. Selecting a sequence of cycles $c_1, c_2, \ldots$ from the set $\mathcal{C}_{k,\bar{s}}$ so as to maximize the reward defined by the adversarial sequence $r_1, r_2, \ldots$ is equivalent to the problem of selecting a sequence of points $x_1, x_2, \ldots$ from the set $x\big(\mathcal{C}_{k,\bar{s}}\big) \subset \mathbb{R}^n$ so as to maximize the linear rewards defined by the adversarial sequence $\rho_1, \rho_2, \ldots$. However, the latter is not quite a BLO problem yet, since the set of actions $x\big(\mathcal{C}_{k,\bar{s}}\big)$ is not a polyhedral set.

To resolve this problem, we define the set of actions for the BLO algorithm to be $\mathcal{X} = \text{conv}\left(x\big(\mathcal{C}_{k,\bar{s}}\big)\right)$, the convex hull of the set $x\big(\mathcal{C}_{k,\bar{s}}\big)$. Since $x\big(\mathcal{C}_{k,\bar{s}}\big)$ is a finite set, its convex hull is polyhedral. Now, we can use a BLO algorithm to generate a sequence of points in $\mathcal{X}$. The set $\mathcal{X}$ can be defined more concisely using network flow constraints (Bazaraa et al., 2010). In our case, $\mathcal{X}$ can be written as

$$x \geq 0 \ , \quad \textstyle\sum_{a \in \mathcal{A}} x_{(\bar{s},a,1)} = 1 \ , \tag{2}$$

$$\forall s \notin \mathcal{S} \setminus \{\bar{s}\},\ a \in \mathcal{A}, \quad x_{(s,a,1)} = 0 \ , \tag{3}$$

$$\forall (s', a') \notin \mathrm{I}(\bar{s}) \quad x_{(s',a',k)} = 0 \ , \tag{4}$$

$$\forall s \in \mathcal{S},\ 2 \leq i \leq k, \quad \textstyle\sum_{(s',a') \in \mathrm{I}(s)} x_{(s',a',i-1)} - \sum_{a \in \mathcal{A}} x_{(s,a,i)} = 0 \ . \tag{5}$$

Equation (2) ensures convexity: all paths have non-negative weight and the total weight of all paths equals one. The remaining constraints ensure that every vector in the set is indeed a combination of valid cycles that start and end at $\bar{s}$. Specifically, Eqs. (3) and (4) require all paths to begin and end at $\bar{s}$, whereas (5) is the classic flow conservation constraint, which requires that the total weight of paths that enter each state be equal to the total weight that exits that state, at each phase i. This concise representation enables us to run the BLO algorithm efficiently.

However, now the BLO algorithm picks points in $\mathcal{X}$ that do not directly correspond to individual cycles in $\mathcal{C}_{k,\bar{s}}$. Instead, these points are convex combinations of points that correspond to individual cycles. This problem is easily resolved using the double randomization technique described above. Namely, we can find an unbiased estimator of the point chosen by the BLO algorithm that always chooses a vector in the discrete set $x\big(\mathcal{C}_{k,\bar{s}}\big)$. We apply the classic theorem of Carathéodory (1911), which states that any point in the polyhedral set $\mathcal{X} \subset \mathbb{R}^n$ can be represented as a convex combination of at most $n + 1$ extreme points (vertices) of that set. The extreme points of $\mathcal{X}$ are points in the set $x\big(\mathcal{C}_{k,\bar{s}}\big)$ and correspond to individual cycles. Moreover, the decomposition of a point in $\mathcal{X}$ as a convex combination of $n+1$ points in $x\big(\mathcal{C}_{k,\bar{s}}\big)$ can be efficiently computed using a greedy augmenting-path-style algorithm (Bazaraa et al., 2010, Thm. 2.1). In summary, we use the BLO algorithm to choose a point in $\mathcal{X}$, we represent this point as a convex combination of points in $x\big(\mathcal{C}_{k,\bar{s}}\big)$, we interpret this convex combination as a distribution over the respective action cycles in $\mathcal{C}_{k,\bar{s}}$, and we sample a concrete cycle from this distribution.

The pseudo-code of our algorithm is given in Algorithm 1. As mentioned above, the pseudo-code references three external procedures: the procedure that finds a path of length d from s_1 to $\bar{s}$, the BLO algorithm, and the decomposition procedure that represents any point in $\mathcal{X}$ as a distribution over $n+1$ points in $x\big(\mathcal{C}_{k,\bar{s}}\big)$.

Next, we state a regret bound for our algorithm.

Theorem 1. *Let $r_1, r_2, \ldots$ be an arbitrary sequence of reward functions, perhaps adversarially generated. Assume that we run Algorithm 1 for T rounds with this sequence, with parameters $k \leq L$ and $\bar{s} \in \mathcal{S}$, and let $(s_t, a_t)_{t=1}^T$ be the resulting sequence of state-action pairs (see Alg. 1). On the other hand, let $\pi^\star$ be any deterministic policy in $\Pi_{k,\bar{s}}$ and let $(s_t^\star, a_t^\star)_{t=1}^T$ be the sequence of state-action pairs defined by this policy.*

Then the regret is upper bounded by

$$\sum_{t=1}^{T} r_t(s_t^\star, a_t^\star) - \mathbb{E}\left[\sum_{t=1}^{T} r_t(s_t, a_t)\right] \leq 4L^2(n|\mathcal{A}|)^{3/2}\sqrt{T\log(T)} \;+\; (2L+d) \quad .$$

Proof. Since the rewards on each round are bounded in $[0,1]$, the regret on the first d rounds is bounded by d. Then $k'' = (k - k' + 1) \mod k < k$ more rounds are wasted before coming back to $\bar{s}$. The regret on the remaining $T - d - k''$ rounds is bounded by applying the bound for BLO in Eq. (1). Specifically, in our case, we use Hölder's inequality to bound

$$\rho_i \cdot x_i \;\leq\; \|\rho_i\|_\infty \|x_i\|_1 \;\leq\; k \quad ,$$

and therefore we can set U in Eq. (1) to k. The dimensionality is $n|\mathcal{A}|k$. Finally, the number of BLO iterations equals the number of epochs of our algorithm, which is $m = \lfloor (T - d - k'')/k \rfloor \leq T/k$. Plugging these values into Eq. (1) gives the bound

$$4k(nk|\mathcal{A}|)^{3/2}\sqrt{T/k\log(T/k)} \quad ,$$

which is upper bounded by

$$4L^2(n|\mathcal{A}|)^{3/2}\sqrt{T\log(T)} \quad .$$

Finally, if $T - d - k''$ does not divide by k, we have a suffix of at most k actions that incur an additional regret of at most L. □

4 SOLUTION TO THE GENERAL PROBLEM

The result obtained in the previous section can be interpreted as follows. Let $\pi^\star$ be the optimal fixed policy in $\Pi_{\leq L}$, let $k^\star$ be the length of its cycle. Assume, for simplicity, that $\pi^\star$ enters its cycle straightaway and let $s^\star$ be its state at time $t = 1$. If an oracle were to reveal $k^\star$ and $s^\star$ to us, Algorithm 1 would solve the problem with a regret of $O(L^2(n|\mathcal{A}|)^{3/2}\sqrt{T\log(T)})$. Although we do not have access to such an oracle, we can exploit the fact that there are only Ln possible values of (k, s) that we need to explore.

In this section, we present the MarcoPolo algorithm, which solves the general problem defined in Sec. 1. It does so by splitting the online rounds into episodes of length τ (τ is specified later on) and running an instance of Alg. 1 on each episode. At the beginning of episode j, the algorithm chooses values (k_j, s_j) and runs Alg. 1 with these parameters for τ rounds. Note that Alg. 1 starts from scratch on each episode, and does not retain information from previous episodes. Also note that Alg. 1 starts from the state that we happen to be in due to the previous episodes. However, the initial "lock-in" part in Alg. 1 makes sure we get locked in phase with policies in Π_{k_j,s_j}.

Algorithm 2: MarcoPolo

input: episode length τ
initialize: $\hat{s}_1 = s_1, t = 1$
for $j = 1, 2, \ldots$
  $(k_j, s_j) \leftarrow$ get length/state from `MAB`
  $(R_j, \hat{s}_{j+1}) \leftarrow$ Alg. 1 with input $(\hat{s}_j, t, k_j, s_j, \tau)$
  provide R_j as feedback to `MAB`
  $R \leftarrow R + R_j$
  $t \leftarrow t + \tau$

It remains to specify how our algorithm chooses (k_j, s_j) on each episode. Again, we resort to a reduction, this time to the *multi-armed bandit* problem (MAB). The MAB setting is very similar to the BLO setting described above, except that the algorithm's action set is the set of standard unit vectors $\mathcal{X} = \{e_1, \ldots, e_n\}$, rather than a polyhedral set. Namely, the adversary chooses a sequence of reward vectors $\rho_1, \rho_2, \ldots$ before the game begins. On iteration i, the algorithm chooses a standard unit vector x_i, which has a single non-zero coordinate, and its reward $\rho_i \cdot x_i$ is simply the value of ρ_i at that coordinate. The algorithm never sees the full reward vector ρ_j.

The EXP3 algorithm (Auer et al., 2002) solves the MAB problem, and comes with the following regret bound: For any number of iterations m, the expected regret after m iterations is bounded by

$$\max_{x\in\mathcal{X}} \sum_{i=1}^{m} \rho_i \cdot x - \mathbb{E}\left[\sum_{i=1}^{m} \rho_i \cdot x_i\right] \leq U\sqrt{7mn\log(n)} \quad , \quad (6)$$

where U is an upper bound on $\rho_i \cdot x_i$ for all i.

To simplify the presentation and analysis of the reduction to the MAB problem, we slightly modify the algorithm described above. Instead of choosing a single setting (k_j, s_j) on episode j and running Alg. 1 only on that setting, imagine that we run nL copies of Alg. 1 in parallel, one for each choice of (s, k), and then disregard all but the one that corresponds to the chosen setting (k_j, s_j). Clearly, this modified algorithm is equivalent to our original algorithm, albeit its inferior computational complexity. The advantage of thinking of our algorithm in this way is that it makes the reduction to the MAB setting very straightforward.

The MAB problem takes place in the space $\mathbb{R}^n$, with $n = nL$. In this space, each coordinate corresponds to a pair (k, s), where k is a cycle length between 1 and L, and s is a state in $\mathcal{S}$. For any vector $v \in \mathbb{R}^n$, we use the notation $v_{(k,s)}$ to refer to the element of v that corresponds to the pair (k, s). Let $\rho_{j,(k,s)}$ be the

total reward collected by the copy of Alg. 1 that runs with parameters (k, s) on episode j. Note that $\rho_{j,(k,s)}$ takes a random value, since Alg. 1 is a randomized algorithm, but this does not invalidate the reduction. The MAB algorithm chooses a pair (k_j, s_j) on each episode, and this is the pair we use in our algorithm.

Next, we prove a regret bound for our algorithm.

Theorem 2. *Let $r_1, r_2, \ldots$ be an arbitrary sequence of reward functions, perhaps adversarially generated. Assume that we run* MarcoPolo *with this sequence for T rounds and with an episode length of $\tau = \sqrt{T}$, and let $(s_t, a_t)_{t=1}^T$ be the resulting sequence of state-action pairs. On the other hand, let $\pi^\star$ be any deterministic policy in $\Pi_{\leq L}$ and let $(s_t^\star, a_t^\star)_{t=1}^T$ be the sequence of state-action pairs defined by $\pi^\star$. Then the regret is upper bounded by*

$$\sum_{t=1}^T r_t(s_t^\star, a_t^\star) - \mathbb{E}\left[\sum_{t=1}^T r_t(s_t, a_t)\right] \leq CT^{3/4}\sqrt{\log(T)} + o(T^{3/4}) \quad .$$

where $C = 4L^2(n|\mathcal{A}|)^{3/2} + \sqrt{7nL\log(nL)}$.

Proof. Let $\bar{T}$ be the last round on the last full episode performed by the algorithm. The regret suffered on rounds $(\bar{T}+1), \ldots, T$ is trivially bounded by $T - \bar{T} \leq \tau$, and we focus on bounding the regret on rounds $1, \ldots, \bar{T}$.

Recall that we assumed, for the purpose of our analysis, that we run nL parallel instances of Alg. 1 on each episode. Also recall that Alg. 1 starts from scratch when a new episode begins. Let $k^\star$ be the length of the action cycle induced by the policy $\pi^\star$ and let $\tilde{s}^\star$ be the first state that gets repeated under $\pi^\star$ after an initial non-repeating sequence of states of length $t^\star$. Let $s^\star$ be the state that is $t^\star$ time units behind $\tilde{s}^\star$ on the cycle induced by $\pi^\star$. The rewards accumulated by $\pi^\star$ and those by the cycle corresponding to the pair $(k^\star, s^\star)$ differ by at most $t^\star \leq n$. Thus, we compute regret relative to $(k^\star, s^\star)$.

Let $(s'_t, a'_t)_{t=1}^{\bar{T}}$ be the sequence of state-action pairs generated by the copy of Alg. 1 that runs with parameters $(k^\star, s^\star)$. On epoch j we apply Thm. 1 and get

$$\mathbb{E}\left[\sum_{t=j\tau-\tau+1}^{j\tau} r_t(s_t^\star, a_t^\star) - r_t(s'_t, a'_t)\right] \leq 4L^2(n|\mathcal{A}|)^{3/2}\sqrt{\tau\log(\tau)} + (2L+d) \quad .$$

We sum both sides above for $j = 1, \ldots, \bar{T}/\tau$ and get

$$\mathbb{E}\left[\sum_{t=1}^{\bar{T}} r_t(s_t^\star, a_t^\star) - r_t(s'_t, a'_t)\right] \leq 4L^2(n|\mathcal{A}|)^{3/2}T^{3/4}\sqrt{\log(T)/2} + o(T^{3/4}) \quad . \quad (7)$$

Next, we use the regret bound for the EXP3 algorithm, given in Eq. (6), to upper-bound

$$\mathbb{E}\left[\sum_{t=1}^{\bar{T}} r_t(s'_t, a'_t) - r_t(s_t, a_t)\right] = \mathbb{E}\left[\sum_{j=1}^{\bar{T}/\tau} \rho_{j,(k^\star,s^\star)} - \rho_{j,(k_j,s_j)}\right] \quad .$$

We face a minor technical difficulty due to the fact that the EXP3 bound holds for deterministic rewards, whereas the rewards $\rho_1, \rho_2, \ldots$ in our problem are random. However, it is rather straightforward to see that if a bound holds for any individual sequence of reward functions, then it also holds for the expected reward sequence (the skeptical reader is referred to Appendix A in the supplementary material for a rigorous proof).

Since $\rho_{j,(k,s)}$ represents the cumulative reward from τ rounds, and the reward on each round is bounded in $[0, 1]$, then $\|\rho_j\|_\infty \leq \tau \leq \sqrt{T}$. Therefore, we can set $U = \sqrt{T}$ in Eq. (6). Additionally, we have that the number of arms is nL. Finally, the number of MAB iterations is $m \leq T/\tau = \sqrt{T}$. Plugging these values into the bound, we get that

$$\mathbb{E}\left[\sum_{t=1}^{\bar{T}} r_t(s'_t, a'_t) - r_t(s_t, a_t)\right] \leq T^{3/4}\sqrt{7nL\log(nL)} \quad .$$

Summing the above inequality with Eq. (7) proves the theorem. □

5 DISCUSSION

We focused on the sequential decision making setting where the environment changes with time adversarially, state transitions are deterministic, and the algorithm receives bandit feedback. In this setting, we presented the MarcoPolo algorithm, with an undiscounted regret bound of $O(T^{3/4}\sqrt{\log(T)})$ against the best deterministic policy in hindsight. In contrast to previous work, we did not rely on the stringent unichain assumption.

Many interesting open questions remain unanswered: Can we derive a similar result with stochastic transition dynamics; with adversarially changing transition dynamics; when the state is only partially observable? Even in our specific setting, can we prove a lower bound of $O(T^{3/4})$ on regret, or alternatively, can we obtain a better upper bound with a different algorithm?

We also have more general questions regarding the true power of the adversarial DMDP model compared to the classic (fully stochastic) MDP model. The adversarial DMDP model makes a more general assumption on the rewards and a less general assumption on the state transition dynamics. Are the two things somehow interchangeable? In other words, can we identify situations where we can use the power and flexibility of the adversarial reward assumption to capture uncertainty in the state transition dynamics?

These questions are left for future research.

Abstract

We present a system that produces sentential descriptions of video: who did what to whom, and where and how they did it. Action class is rendered as a verb, participant objects as noun phrases, properties of those objects as adjectival modifiers in those noun phrases, spatial relations between those participants as prepositional phrases, and characteristics of the event as prepositional-phrase adjuncts and adverbial modifiers. Extracting the information needed to render these linguistic entities requires an approach to event recognition that recovers object tracks, the track-to-role assignments, and changing body posture.

1 INTRODUCTION

We present a system that produces sentential descriptions of short video clips. These sentences describe *who* did *what* to *whom*, and *where* and *how* they did it. This system not only describes the observed action as a verb, it also describes the participant objects as noun phrases, properties of those objects as adjectival modifiers in those noun phrases, the spatial relations between those participants as prepositional phrases, and characteristics of the event as prepositional-phrase adjuncts and adverbial modifiers. It incorporates a vocabulary of 118 words: 1 coordination, 48 verbs, 24 nouns, 20 adjectives, 8 prepositions, 4 lexical prepositional phrases, 4 determiners, 3 particles, 3 pronouns, 2 adverbs, and 1 auxiliary, as illustrated in Table 1.

auxiliary:	*was*

Table 1: The vocabulary used to generate sentential descriptions of video.

Production of sentential descriptions requires recognizing the primary action being performed, because such actions are rendered as verbs and verbs serve as the central scaffolding for sentences. However, event recognition alone is insufficient to generate the remaining sentential components. One must recognize object classes in order to render nouns. But even object recognition alone is insufficient to generate meaningful sentences. One must determine the *roles* that such objects play in the event. The *agent*, i.e. the doer of the action, is typically rendered as the sentential subject while the *patient*, i.e. the affected object, is typically rendered as the direct object. Detected objects that do not play a role in the observed event, no matter how prominent, should not be incorporated into the description. This means that one cannot use common approaches to event recognition, such as spatiotemporal bags of words [Laptev et al., 2007, Niebles et al., 2008, Scovanner et al., 2007], spatiotemporal volumes [Blank et al., 2005, Laptev et al., 2008, Ro-

driguez et al., 2008], and tracked feature points [Liu et al., 2009, Schuldt et al., 2004, Wang and Mori, 2009] that do not determine the class of participant objects and the roles that they play. Even combining such approaches with an object detector would likely detect objects that don't participate in the event and wouldn't be able to determine the roles that any detected objects play.

Producing elaborate sentential descriptions requires more than just event recognition and object detection. Generating a noun phrase with an embedded prepositional phrase, such as *the person to the left of the bicycle*, requires determining spatial relations between detected objects, as well as knowing which of the two detected objects plays a role in the overall event and which serves just to aid generation of a referring expression to help identify the event participant. Generating a noun phrase with adjectival modifiers, such as *the red ball*, not only requires determining the properties, such as color, shape, and size, of the observed objects, but also requires determining whether such descriptions are necessary to help disambiguate the referent of a noun phrase. It would be awkward to generate a noun phrase such as *the big tall wide red toy cardboard trash can* when *the trash can* would suffice. Moreover, one must track the participants to determine the speed and direction of their motion to generate adverbs such as *slowly* and prepositional phrases such as *leftward*. Further, one must track the identity of multiple instances of the same object class to appropriately generate the distinction between *Some person hit some other person* and *The person hit themselves*.

A common assumption in Linguistics [Jackendoff, 1983, Pinker, 1989] is that verbs typically characterize the interaction between event participants in terms of the gross changing motion of these participants. Object class and image characteristics of the participants are believed to be largely irrelevant to determining the appropriate verb label for an action class. Participants simply fill roles in the spatiotemporal structure of the action class described by a verb. For example, an event where one participant (the agent) *picks up* another participant (the patient) consists of a sequence of two sub-events, where during the first sub-event the agent moves towards the patient while the patient is at rest and during the second sub-event the agent moves together with the patient away from the original location of the patient. While determining whether the agent is a *person* or a *cat*, and whether the patient is a *ball* or a *cup*, is necessary to generate the noun phrases incorporated into the sentential description, such information is largely irrelevant to determining the verb describing the action. Similarly, while determining the shapes, sizes, colors, textures, etc. of the participants is necessary to generate adjectival modifiers, such information is also largely irrelevant to determining the verb. Common approaches to event recognition, such as spatiotemporal bags of words, spatiotemporal volumes, and tracked feature points, often achieve high accuracy because of correlation with image or video properties exhibited by a particular corpus. These are often artefactual, not defining properties of the verb meaning (e.g. recognizing *diving* by correlation with *blue* since it 'happens in a pool' [Liu et al., 2009, p. 2002] or confusing *basketball* and *volleyball* 'because most of the time the [...] sports use very similar courts' [Ikizler-Cinibis and Sclaroff, 2010, p. 506]).

2 THE MIND'S EYE CORPUS

Many existing video corpora used to evaluate event recognition are ill-suited for evaluating sentential descriptions. For example, the WEIZMANN dataset [Blank et al., 2005] and the KTH dataset [Schuldt et al., 2004] depict events with a single human participant, not ones where people interact with other people or objects. For these datasets, the sentential descriptions would contain no information other than the verb, e.g. *The person jumped*. Moreover, such datasets, as well as the SPORTS ACTIONS dataset [Rodriguez et al., 2008] and the YOUTUBE dataset [Liu et al., 2009], often make action-class distinctions that are irrelevant to the choice of verb, e.g. `wave1` vs. `wave2`, `jump` vs. `pjump`, `Golf-Swing-Back` vs. `Golf-Swing-Front` vs. `Golf-Swing-Side`, `Kicking-Front` vs. `Kicking-Side`, `Swing-Bench` vs. `Swing-SideAngle`, and `golf_swing` vs. `tennis_swing` vs. `swing`. Other datasets, such as the BALLET dataset [Wang and Mori, 2009] and the UCF50 dataset [Liu et al., 2009], depict larger-scale activities that bear activity-class names that are not well suited to sentential description, e.g. `Basketball`, `Billiards`, `BreastStroke`, `CleanAndJerk`, `HorseRace`, `HulaHoop`, `MilitaryParade`, `TaiChi`, and `YoYo`.

The year-one (Y1) corpus produced by DARPA for the Mind's Eye program, however, was specifically designed to evaluate sentential description. This corpus contains two parts: the development corpus, C-D1, which we use solely for training, and the evaluation corpus, C-E1, which we use solely for testing. Each of the above is further divided into four sections to support the four task goals of the Mind's Eye program, namely recognition, description, gap filling, and anomaly detection. In this paper, we use only the recognition and description portions and apply our entire sentential-description pipeline to the combination of these portions. While portions of C-E1 overlap with C-D1, ***in this paper we train our methods solely on C-D1 and test our methods solely on the***

portion of C-E1 that does not overlap with C-D1.

Moreover, a portion of the corpus was synthetically generated by a variety of means: computer graphics driven by motion capture, pasting foregrounds extracted from green screening onto different backgrounds, and intensity variation introduced by post-processing. ***In this paper, we exclude all such synthetic video from our test corpus.*** Our training set contains 3480 videos and our test set 749 videos. These videos are provided at 720p@30fps and range from 42 to 1727 frames in length, with an average of 435 frames.

The videos nominally depict 48 distinct verbs as listed in Table 1. However, the mapping from videos to verbs is not one-to-one. Due to polysemy, a verb may describe more than one action class, e.g. *leaving an object on the table* vs. *leaving the scene*. Due to synonymy, an action class may be described by more than one verb, e.g. *lift* vs. *raise*. An event described by one verb may contain a component action described by a different verb, e.g. *picking up an object* vs. *touching an object*. Many of the events are described by the combination of a verb with other constituents, e.g. *have a conversation* vs. *have a heart attack*. And many of the videos depict metaphoric extensions of verbs, e.g. *take a puff on a cigarette*. Because the mapping from videos to verbs is subjective, the corpus comes labeled with DARPA-collected human judgments in the form of a single present/absent label associated with each video paired with each of the 48 verbs, gathered using Amazon Mechanical Turk. We use these labels for both training and testing as described later.

3 OVERALL SYSTEM ARCHITECTURE

The overall architecture of our system is depicted in Fig. 1. We first apply detectors [Felzenszwalb et al., 2010a,b] for each object class on each frame of each video. These detectors are biased to yield many false positives but few false negatives. The Kanade-Lucas-Tomasi (KLT) [Shi and Tomasi, 1994, Tomasi and Kanade, 1991] feature tracker is then used to project each detection five frames forward to augment the set of detections and further compensate for false negatives in the raw detector output. A dynamic-programming algorithm [Viterbi, 1971] is then used to select an optimal set of detections that is temporally coherent with optical flow, yielding a set of object tracks for each video. These tracks are then smoothed and used to compute a time-series of feature vectors for each video to describe the relative and absolute motion of event participants. The person detections

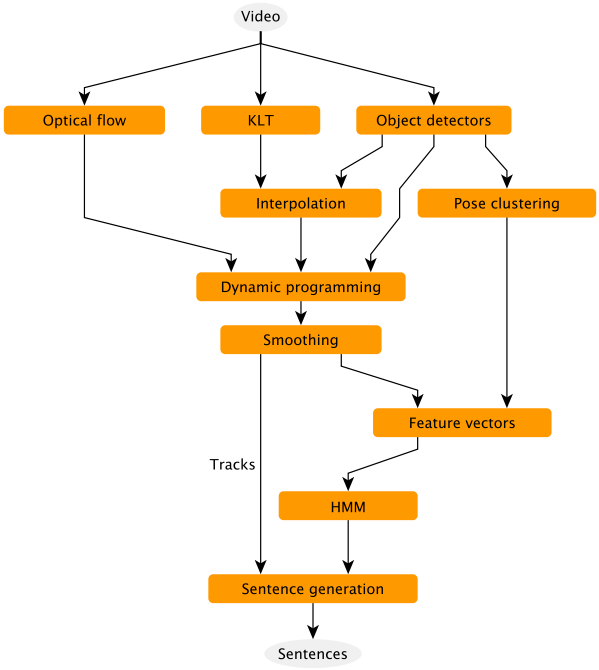

Figure 1: The overall architecture of our system for producing sentential descriptions of video.

are then clustered based on part displacements to derive a coarse measure of human body posture in the form of a body-posture codebook. The codebook indices of person detections are then added to the feature vector. Hidden Markov Models (HMMs) are then employed as time-series classifiers to yield verb labels for each video [Siskind and Morris, 1996, Starner et al., 1998, Wang and Mori, 2009, Xu et al., 2002, 2005], together with the object tracks of the participants in the action described by that verb along with the roles they play. These tracks are then processed to produce nouns from object classes, adjectives from object properties, prepositional phrases from spatial relations, and adverbs and prepositional-phrase adjuncts from track properties. Together with the verbs, these are then woven into grammatical sentences. We describe each of the components of this system in detail below: the object detector and tracker in Section 3.1, the body-posture clustering and codebook in Section 3.2, the event classifier in Section 3.3, and the sentential-description component in Section 3.4.

3.1 OBJECT DETECTION AND TRACKING

In detection-based tracking an object detector is applied to each frame of a video to yield a set of candidate detections which are composed into tracks by selecting a single candidate detection from each frame that maximizes temporal coherency of the track. Felzenszwalb

et al. detectors are used for this purpose. Detection-based tracking requires biasing the detector to have high recall at the expense of low precision to allow the tracker to select boxes to yield a temporally coherent track. This is done by depressing the acceptance thresholds. To prevent massive over-generation of false positives, which would severely impact run time, we limit the number of detections produced per-frame to 12.

Two practical issues arise when depressing acceptance thresholds. First, it is necessary to reduce the degree of non-maximal suppression incorporated in the Felzenszwalb et al. detectors. Second, with the star detector [Felzenszwalb et al., 2010b], one can simply decrease the single trained acceptance threshold to yield more detections with no increase in computational complexity. However, we prefer to use the star cascade detector [Felzenszwalb et al., 2010a] as it is far faster. With the star cascade detector, though, one must also decrease the trained root- and part-filter thresholds to get more detections. Doing so, however, defeats the computational advantage of the cascade and significantly increases detection time. We thus train a model for the star detector using the standard procedure on human-annotated training data, sample the top detections produced by this model with a decreased acceptance threshold, and train a model for the star cascade detector on these samples. This yields a model that is almost as fast as one trained by the star cascade detector on the original training samples but with the desired bias in acceptance threshold.

The Y1 corpus contains approximately 70 different object classes that play a role in the depicted events. Many of these, however, cannot be reliably detected with the Felzenszwalb et al. detectors that we use. We trained models for 25 object classes that can be reliably detected, as listed in Table 2. These object classes account for over 90% of the event participants. Person models were trained with approximately 2000 human-annotated positive samples from C-D1 while nonperson models were trained with approximately 1000 such samples. For each positive training sample, two negative training samples were randomly generated from the same frame constrained to not overlap substantially with the positive samples. We trained three distinct person models to account for body-posture variation and pool these when constructing person tracks. The detection scores were normalized for such pooled detections by a per-model offset computed as follows: A (50 bin) histogram was computed of the scores of the top detection in each frame of a video. The offset is then taken to be the minimum of the value that maximizes the between-class variance [Otsu, 1979] when bipartitioning this histogram and the trained acceptance threshold offset by a fixed, but small, amount (0.4).

We employed detection-based tracking for all 25 object models on all 749 videos in our test set. To prune the large number of tracks thus produced, we discard all tracks corresponding to certain object models on a per-video basis: those that exhibit high detection-score variance over the frames in that video as well as those whose detection-score distributions are neither unimodal nor bimodal. The parameters governing such pruning were determined solely on the training set. The tracks that remain after this pruning still account for over 90% of the event participants.

3.2 BODY-POSTURE CODEBOOK

We recognize events using a combination of the motion of the event participants and the changing body posture of the human participants. Body-posture information is derived using the part structure produced as a by-product of the Felzenszwalb et al. detectors. While such information is far noisier and less accurate than fitting precise articulated models [Andriluka et al., 2008, Bregler, 1997, Gavrila and Davis, 1995, Sigal et al., 2010, Yang and Ramanan, 2011] and appears unintelligible to the human eye, as shown in Section 3.3, it suffices to improve event-recognition accuracy. Such information can be extracted from a large unannotated corpus far more robustly than possible with precise articulated models.

Body-posture information is derived from part structure in two ways. First, we compute a vector of part displacements, each displacement as a vector from the detection center to the part center, normalizing these vectors to unit detection-box area. The time-series of feature vectors is augmented to include these part displacements and a finite-difference approximation of their temporal derivatives as continuous features for person detections. Second, we vector-quantize the part-displacement vector and include the codebook index as a discrete feature for person detections. Such pose features are included in the time-series on a per-frame basis. The codebook is trained by running each pose-specific person detector on the positive human-annotated samples used to train that detector and extract the resulting part-displacement vectors. We then pool the part-displacement vectors from the three pose-specific person models and employ hierarchical k-means clustering using Euclidean distance to derive a codebook of 49 clusters. Fig. 2 shows sample clusters from our codebook. Codebook indices are derived using Euclidean distance from the means of these clusters.

3.3 EVENT CLASSIFICATION

Our tracker produces one or more tracks per object class for each video. We convert such tracks into a time-series of feature vectors. For each video, one track is taken to designate the agent and another track (if present) is taken to designate the patient. During training, we manually specify the track-to-role mapping. During testing, we automatically determine the track-to-role mapping by examining all possible such mappings and selecting the one with the highest likelihood [Siskind and Morris, 1996].

The feature vector encodes both the motion of the event participants and the changing body posture of the human participants. For each event participant in isolation we incorporate the following single-track features:

1. x and y coordinates of the detection-box center
2. detection-box aspect ratio and its temporal derivative
3. magnitude and direction of the velocity of the detection-box center
4. magnitude and direction of the acceleration of the detection-box center
5. normalized part displacements and their temporal derivatives
6. object class (the object detector yielding the detection)
7. root-filter index
8. body-posture codebook index

The last three features are discrete; the remainder are continuous. For each pair of event participants we incorporate the following track-pair features:

1. distance between the agent and patient detection-box centers and its temporal derivative
2. orientation of the vector from agent detection-box center to patient detection-box center

Our HMMs assume independent output distributions for each feature. Discrete features are modeled with discrete output distributions. Continuous features denoting linear quantities are modeled with univariate Gaussian output distributions, while those denoting angular quantities are modeled with von Mises output distributions.

For each of the 48 action classes, we train two HMMs on two different sets of time-series of feature vectors, one containing only single-track features for a single participant and the other containing single-track features for two participants along with the track-pair features. A training set of between 16 and 200 videos was selected manually from C-D1 for each of these 96 HMMs as positive examples depicting each of the 48 action classes. A given video could potentially be included in the training sets for both the one-track and two-track HMMs for the same action class and even for HMMs for different action classes, if the video was deemed to depict both action classes.

During testing, we generate present/absent judgments for each video in the test set paired with each of the 48 action classes. We do this by thresholding the likelihoods produced by the HMMs. By varying these thresholds, we can produce an ROC curve for each action class, comparing the resulting machine-generated present/absent judgments with the Amazon Mechanical Turk judgments. When doing so, we test videos for which our tracker produces two or more tracks against only the two-track HMMs while we test ones for which our tracker produces a single track against only the one-track HMMs.

We performed three experiments, training 96 different 200-state HMMs for each. Experiment I omitted all discrete features and all body-posture related features. Experiment II omitted only the discrete features. Experiment III omitted only the continuous body-posture related features. ROC curves for each experiment are shown in Fig. 3. Note that the incorporation of body-posture information, either in the form of continuous normalized part displacements or discrete codebook indices, improves event-recognition accuracy, despite the fact that the part displacements produced by the Felzenszwalb et al. detectors are noisy and appear unintelligible to the human eye.

3.4 GENERATING SENTENCES

We produce a sentence from a detected action class together with the associated tracks using the templates from Table 3. In these templates, words in *italics* denote fixed strings, words in **bold** indicate the action class, X and Y denote subject and object noun phrases, and the categories Adv, PP_{endo}, and PP_{exo} denote adverbs and prepositional-phrase adjuncts to describe the subject motion. The processes for generating these noun phrases, adverbs, and prepositional-phrase adjuncts are described below. One-track HMMs take that track to be the agent and thus the subject. For two-track HMMs we choose the mapping from tracks to roles that yields the higher likelihood and take the agent track to be the subject and the patient track to be the object except when the action class is either **approached** or **fled**, the agent is (mostly) stationary, and the patient moves more than the agent.

Brackets in the templates denote optional entities. Optional entities containing Y are generated only for two-track HMMs. The criteria for generating optional adverbs and prepositional phrases are described below. The optional entity for **received** is generated when there is a patient track whose category is `mailbox`, `person`, `person-crouch`, or `person-down`.

We use adverbs to describe the velocity of the subject. For some verbs, a velocity adverb would be awkward:

∗X ***slowly*** *had* Y	∗X *had* ***slowly*** Y

Furthermore, stylistic considerations dictate the syntactic position of an optional adverb:

X jumped ***slowly*** over Y	X ***slowly*** jumped over Y
X ***slowly*** *approached* Y	∗X *approached* ***slowly*** Y
?X ***slowly*** *fell*	X *fell* ***slowly***

The verb-phrase templates thus indicate whether an adverb is allowed, and if so whether it occurs, preferentially, preverbally or postverbally. Adverbs are chosen subject to three thresholds $v_1^{\text{action class}}$, $v_2^{\text{action class}}$, and $v_3^{\text{action class}}$ determined empirically on a per-action-class basis: We select those frames from the subject track where the magnitude of the velocity of the box-detection center is above $v_1^{\text{action class}}$. An optional adverb is generated by comparing the magnitude of the average velocity v of the subject track box-detection centers in these frames to the per-action-class thresholds:

quickly	$v > v_2^{\text{action class}}$
slowly	$v_1^{\text{action class}} \leq v \leq v_3^{\text{action class}}$

We use prepositional-phrase adjuncts to describe the motion direction of the subject. Again, for some verbs, such adjuncts would be awkward:

∗X *had* Y ***leftward***	∗X *had* Y ***from the left***

Moreover, for some verbs it is natural to describe the motion direction endogenously, from the perspective of the subject, while for others it is more natural to describe the motion direction exogenously, from the perspective of the viewer:

X *fell* ***leftward***	X *fell* ***from the left***
X *chased* Y ***leftward***	∗X *chased* Y ***from the left***
∗X *arrived* ***leftward***	X *arrived* ***from the left***

The verb-phrase templates thus indicate whether an adjunct is allowed, and if so whether it is preferentially endogenous or exogenous. The choice of adjunct is determined from the orientation of v, as computed above and depicted in Fig. 4(a,b). We omit the adjunct when $v < v_1^{\text{action class}}$.

We generate noun phrases X and Y to refer to event participants according to the following grammar:

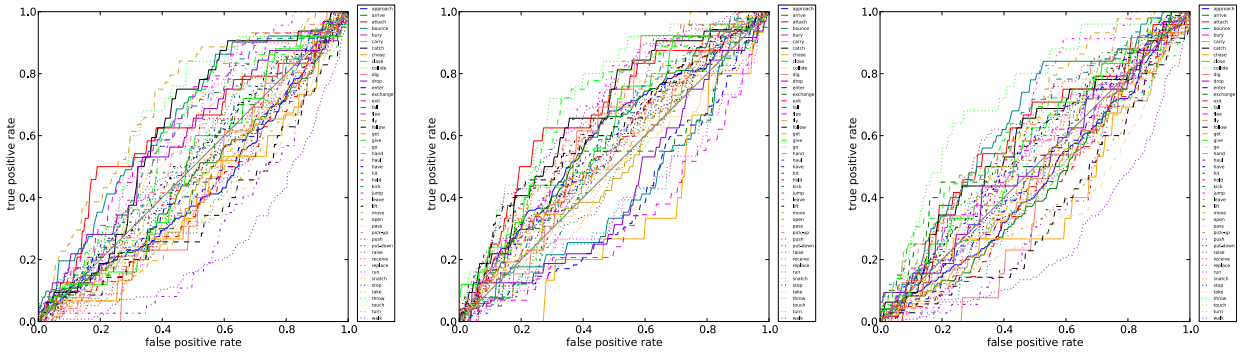
NP → *themselves* | *itself* | *something* | D A^* N [PP]
D → *the* | *that* | *some*

When instantiating a sentential template that has a required object noun-phrase Y for a one-track HMM, we generate a pronoun. A pronoun is also generated when the action class is **entered** or **exited** and the patient class is not `car`, `door`, `suv`, or `truck`. The anaphor *themselves* is generated if the action class is **attached** or **raised**, the anaphor *itself* if the action class is **moved**, and *something* otherwise.

As described below, we generate an optional prepositional phrase for the subject noun phrase to describe the spatial relation between the subject and the object. We choose the determiner to handle coreference, generating *the* when a noun phrase unambiguously refers to the agent or the patient due to the combination of head noun and any adjectives,

The *person jumped over* ***the*** *ball.*
The *red ball collided with* ***the*** *blue ball.*

that for an object noun phrase that corefers to a track referred to in a prepositional phrase for the subject,



(a) (b) (c)

Figure 3: ROC curves for each of the 48 action classes for (a) Experiment I, omitting all discrete and body-posture-related features, (b) Experiment II, omitting only the discrete features, and (c) Experiment III, omitting only the continuous body-posture-related features.

X [Adv] **approached** Y [PP_{exo}]	X [Adv] **entered** Y [PP_{endo}]	X **had** Y	X **put** Y **down**
X **arrived** [Adv] [PP_{exo}]	X [Adv] **exchanged** *an object with* Y	X **hit** [*something with*] Y	X **raised** Y
X [Adv] **attached** *an object to* Y	X [Adv] **exited** Y [PP_{endo}]	X **held** Y	X **received** [*an object from*]Y
X **bounced** [Adv] [PP_{endo}]	X **fell** [Adv] [*because of* Y] [PP_{endo}]	X **jumped** [Adv] [*over* Y] [PP_{endo}]	X [Adv] **replaced** Y
X **buried** Y	X **fled** [Adv] [*from* Y] [PP_{endo}]	X [Adv] **kicked** Y [PP_{endo}]	X **ran** [Adv] [*to* Y] [PP_{endo}]
X [Adv] **carried** Y [PP_{endo}]	X **flew** [Adv] [PP_{endo}]	X **left** [Adv] [PP_{endo}]	X [Adv] **snatched** *an object from* Y
X **caught** Y [PP_{exo}]	X [Adv] **followed** Y [PP_{endo}]	X [Adv] **lifted** Y	X [Adv] **stopped** [Y]
X [Adv] **chased** Y [PP_{endo}]	X **got** *an object from* Y	X [Adv] **moved** Y [PP_{endo}]	X [Adv] **took** *an object from* Y
X **closed** Y	X **gave** *an object to* Y	X **opened** Y	X [Adv] **threw** Y [PP_{endo}]
X [Adv] **collided** *with* Y [PP_{exo}]	X **went** [Adv] *away* [PP_{endo}]	X [Adv] **passed** Y [PP_{exo}]	X **touched** Y
X *was* **digging** [*with* Y]	X **handed** Y *an object*	X **picked** Y **up**	X **turned** [PP_{endo}]
X **dropped** Y	X [Adv] **hauled** Y [PP_{endo}]	X [Adv] **pushed** Y [PP_{endo}]	X **walked** [Adv] [*to* Y] [PP_{endo}]

Table 3: Sentential templates for the action classes indicated in bold.

> ***The*** *person to the right of* ***the*** *car approached* ***that*** *car.*
> ***Some*** *person to the right of* ***some*** *other person approached* ***that*** *other person.*

and *some* otherwise:

> ***Some*** *car approached* ***some*** *other car.*

We generate the head noun of a noun phrase from the object class using the mapping in Table 2(a). Four different kinds of adjectives are generated: color, shape, size, and restrictive modifiers. An optional color adjective is generated based on the average HSV values in the eroded detection boxes for a track: *black* when $V \leq 0.2$, *white* when $V \geq 0.8$, one of *red*, *blue*, *green*, *yellow*, *teal*, or *pink* based on H, when $S \geq 0.7$. An optional size adjective is generated in two ways, one from the object class using the mapping in Table 2(c), the other based on per-object-class image statistics. For each object class, a mean object size $\bar{a}_{\text{object class}}$ is determined by averaging the detected-box areas over all tracks for that object class in the training set used to train HMMs. An optional size adjective for a track is generated by comparing the average detected-box area a for that track to $\bar{a}_{\text{object class}}$:

big	$a \geq \beta_{\text{object class}} \bar{a}_{\text{object class}}$
small	$a \leq \alpha_{\text{object class}} \bar{a}_{\text{object class}}$

The per-object-class cutoff ratios $\alpha_{\text{object class}}$ and $\beta_{\text{object class}}$ are computed to equally tripartition the distribution of per-object-class mean object sizes on the training set. Optional shape adjectives are generated in a similar fashion. Per-object-class mean aspect ratios $\bar{r}_{\text{object class}}$ are determined in addition to the per-object-class mean object sizes $\bar{a}_{\text{object class}}$. Optional shape adjectives for a track are generated by comparing the average detected-box aspect ratio r and area a for that track to these means:

tall	$r \leq 0.7\bar{r}_{\text{object class}} \wedge a \geq \beta_{\text{object class}} \bar{a}_{\text{object class}}$
short	$r \geq 1.3\bar{r}_{\text{object class}} \wedge a \leq \alpha_{\text{object class}} \bar{a}_{\text{object class}}$
narrow	$r \leq 0.7\bar{r}_{\text{object class}} \wedge a \leq \alpha_{\text{object class}} \bar{a}_{\text{object class}}$
wide	$r \geq 1.3\bar{r}_{\text{object class}} \wedge a \geq \beta_{\text{object class}} \bar{a}_{\text{object class}}$

To avoid generating shape and size adjectives for unstable tracks, they are only generated when the detection-score variance and the detected aspect-ratio variance for the track are below specified thresholds. Optional restrictive modifiers are generated from the object class using the mapping in Table 2(b). Person-pose adjectives are generated from aggregate body-posture information for the track: object class, normalized part displacements, and body-posture codebook indices. We generate all applicable adjectives except for color and person pose. Following the Gricean Maxim of Quantity [Grice, 1975], we only generate

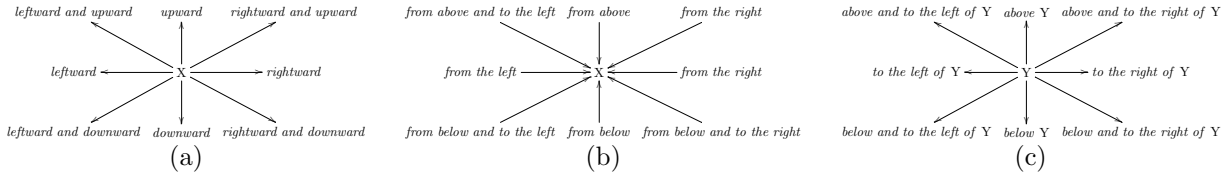


Figure 4: (a) Endogenous and (b) exogenous prepositional-phrase adjuncts to describe subject motion direction. (c) Prepositional phrases incorporated into subject noun phrases describing viewer-relative 2D spatial relations between the subject X and the reference object Y.

color and person-pose adjectives if needed to prevent coreference of nonhuman event participants. Finally, we generate an initial adjective *other*, as needed to prevent coreference. Generating *other* does not allow generation of the determiner *the* in place of *that* or *some*. We order any adjectives generated so that *other* comes first, followed by size, shape, color, and restrictive modifiers, in that order.

For two-track HMMs where neither participant moves, a prepositional phrase is generated for subject noun phrases to describe the static 2D spatial relation between the subject X and the reference object Y from the perspective of the viewer, as shown in Fig. 4(c).

4 EXPERIMENTAL RESULTS

We used the HMMs generated for Experiment III to compute likelihoods for each video in our test set paired with each of the 48 action classes. For each video, we generated sentences corresponding to the three most-likely action classes. Fig. 5 shows key frames from four videos in our test set along with the sentence generated for the most-likely action class. Human judges rated each video-sentence pair to assess whether the sentence was true of the video and whether it described a salient event depicted in that video. 26.7% (601/2247) of the video-sentence pairs were deemed to be true and 7.9% (178/2247) of the video-sentence pairs were deemed to be salient. When restricting consideration to only the sentence corresponding to the single most-likely action class for each video, 25.5% (191/749) of the video-sentence pairs were deemed to be true and 8.4% (63/749) of the video-sentence pairs were deemed to be salient. Finally, for 49.4% (370/749) of the videos at least one of the three generated sentences was deemed true and for 18.4% (138/749) of the videos at least one of the three generated sentences was deemed salient.

5 CONCLUSION

Integration of Language and Vision [Aloimonos et al., 2011, Barzialy et al., 2003, Darrell et al., 2011, McKevitt, 1994, 1995–1996] and recognition of action in video [Blank et al., 2005, Laptev et al., 2008, Liu et al., 2009, Rodriguez et al., 2008, Schuldt et al., 2004, Siskind and Morris, 1996, Starner et al., 1998, Wang and Mori, 2009, Xu et al., 2002, 2005] have been of considerable interest for a long time. There has also been work on generating sentential descriptions of static images [Farhadi et al., 2009, Kulkarni et al., 2011, Yao et al., 2010]. Yet we are unaware of any prior work that generates as rich sentential video descriptions as we describe here. Producing such rich descriptions requires determining event participants, the mapping of such participants to roles in the event, and their motion and properties. This is incompatible with common approaches to event recognition, such as spatiotemporal bags of words, spatiotemporal volumes, and tracked feature points that cannot determine such information. The approach presented here recovers the information needed to generate rich sentential descriptions by using detection-based tracking and a body-posture codebook. We demonstrated the efficacy of this approach on a corpus of 749 videos.

Abstract

We address the problem of estimating the effect of intervening on a set of variables X from experiments on a different set, Z, that is more accessible to manipulation. This problem, which we call z-identifiability, reduces to ordinary identifiability when $Z = \emptyset$ and, like the latter, can be given syntactic characterization using the *do-calculus* [Pearl, 1995; 2000]. We provide a graphical necessary and sufficient condition for z-identifiability for arbitrary sets X, Z, and Y (the outcomes). We further develop a complete algorithm for computing the causal effect of X on Y using information provided by experiments on Z. Finally, we use our results to prove completeness of *do*-calculus relative to z-identifiability, a result that does not follow from completeness relative to ordinary identifiability.

1 Introduction

The relation between passive and experimental observations, and how they can aid the estimation of causal effects, is of central interest in the empirical sciences.

In this line of research, the *identification* problem ($I\mathcal{D}$, for short) asks whether causal effects can be computed from the joint distribution P over the observed variables, and theoretical knowledge encoded in the form of a causal diagram G.

This problem has been extensively studied in the literature, and [Pearl, 1995; 2000] gave it rigorous mathematical treatment based on the structural semantics, and introduced several graphical conditions such as the "back-door" and "front-door" criteria, which was later generalized by his *do-calculus*. In the last decades, a number of conditions had emerged for non-parametric identifiability such as the ones given by [Spirtes, Glymour, and Scheines, 1993; Galles and Pearl, 1995; Pearl and Robins, 1995; Halpern, 1998; Kuroki and Miyakawa, 1999]. In a series of breakthrough results starting with the development of the concept of C-component [Tian and Pearl, 2002], the *do-calculus* was finally shown to be complete [Huang and Valtorta, 2006; Shpitser and Pearl, 2006]. This result implies that there exists a finite sequence of applications of the rules of do-calculus that derives the target causal effect Q in terms of the observational distribution P if (and only if) Q is identifiable. The same work also provided algorithms that return a mapping from P to Q whenever Q is identifiable.

In real world applications, it is not uncommon that the quantity Q is unidentifiable, i.e., the distribution P together with the graph G are not able to unambiguously determine Q. A natural question arises whether the investigator could perform some auxiliary experiments (not necessary spelled out in Q), which would enable him/her to estimate the desired causal effects.

For instance, consider the causal diagram G in Fig. 1(a). Suppose one is interested in assessing the effect Q of cholesterol levels (X) on heart disease (Y), and data about subjects' diet (Z) is also collected. It is clear that Q is unidentifiable from the assumptions embodied in G, but it is infeasible in reality to control subjects' cholesterol level by intervention. Assume that an experiment can be conducted in which the subjects' diet (Z) is randomized; a natural question emerges whether Q is computable given this additional piece of experimental information?

Surprisingly, this ubiquitous problem has not received a thorough formal treatment. We introduce a variation of the $I\mathcal{D}$ problem to fill in this gap. Consider a setting in which, in addition to the information available in an ordinary $I\mathcal{D}$ instance (distribution P and graph G), further experiments can be performed over a set of variables Z; decide whether the target causal effects can be computed from the available information at hand. This extension generalizes the $I\mathcal{D}$ problem (when $Z = \emptyset$ the two problems coincide) and is called here the z-identification problem ($zI\mathcal{D}$, for short). The Z is called surrogate experiments, for obvious reasons.

Syntactically, the *zID* problem amounts to transforming $P(y|\hat{x})$[1] into an equivalent expressions in *do*-calculus such that only members of Z may contain the hat symbol. Applying this rationale for the example given above (Fig. 1(a)) entails the following reduction in the *do*-calculus. First apply Rule 3 to add $\hat{z}$,

$$P(y|\hat{x}) = P(y|\hat{x},\hat{z}) \quad \text{since } (Y \perp\!\!\!\perp Z|X)_{G_{\overline{X}\overline{Z}}}$$

Then apply Rule 2 to exchange $\hat{x}$ with x:

$$P(y|\hat{x},\hat{z}) = P(y|x,\hat{z}) \quad \text{since } (Y \perp\!\!\!\perp X|Z)_{G_{\underline{X}\overline{Z}}}$$

This last expression can be rewritten as,

$$P(y|x,\hat{z}) = \frac{P(y,x|\hat{z})}{P(x|\hat{z})} \tag{1}$$

This expression shows that performing an experiment on Z suffices to yield "identifiability" of the causal effect of X on Y without experimenting over X. [2]

The subtlety of this problem can be illustrated by noting that in the graph in Fig. 1(a) the effect is z-identifiable from $P(V)$ and $P(X,Y|\hat{Z})$ in G, whereas in the graph in Fig. 1(b) it is not (to be shown later). The only difference between these two graphs is the bidirected edge between the pairs (X,Z) and (X,Y).

One might surmise that *zID* can be represented by a mutilated graph in which the edges incoming to Z are cut, and the problem would then be solved as ordinary identifiability. Unfortunately, this is not the case as shown in the graph in Fig. 1(c) where $Q = P(y|\hat{x})$. The option of manipulating Z does not enable us to compute the Z-specific causal effect of X on Y, $P(y|\hat{x},z)$ which , if available, would allow us to compute the overall causal effect by averaging over Z. Although $Q' = P(y|\hat{x},\hat{z})$ can be established from the mutilated graph, it does not help in establishing the Z-specific causal effect, or Q.

The first formal treatment of this problem [Pearl, 1995] led to the following sufficient condition for admitting a surrogate variable Z for the causal effect $P(y|\hat{x})$:

(i) X intercepts all directed paths from Z to Y, and

(ii) $P(y|\hat{x})$ is identifiable in $G_{\overline{Z}}$.

These conditions are satisfied indeed in the model of Fig. 1(a) but not in 1(b) or 1(c). Pearl's criterion is sufficient but was not shown to be necessary. Additionally, it was not extended to the case where Z and X are sets of variables. At the same time, the syntactic condition above, which requires the existence of a do-calculus transformation expression containing only do(z) terms is declarative, but is not computationally effective, since it does not specify the sequence of rules leading to the needed transformation, nor does it tell us if such a sequence exists. Even though do-calculus is complete for identifying causal effects, it is not immediately clear whether it is complete for *zID*.

[1] We will use $P(y|\hat{x})$ interchangeably with $P_x(y)$ or $P(y|do(x))$. We also will call the interventional operator *do()* as the "hat" operator.

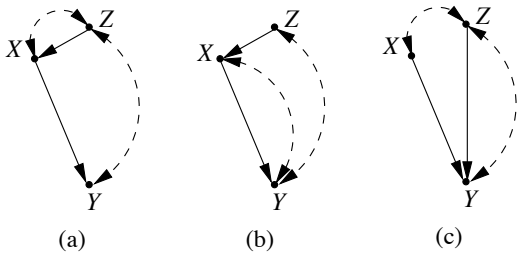

Figure 1: Causal diagrams illustrating z-identifiability of the causal effect $Q = P(y|\hat{x})$. Q can be identified by experiments on Z in model (a), but not in (b) and (c).

This paper provides a systematic study of z-identifiability building on Pearl's condition and the previous results from the identifiability literature; our contributions are as follows:

- We provide a necessary and sufficient graphical condition for the problem of z-identification when $\mathbf{Z}$ is a set of variables.
- We then construct a complete algorithm for deciding z-identification of joint causal effects and returning the correct formula whenever those effects are z-identifiable.
- We further show that *do*-calculus is complete for the task of z-identification.

2 Notation and Definitions

The basic semantical framework in our analysis rests on *probabilistic causal models* as defined in [Pearl, 2000, pp. 205], which are also called structural causal models or data-generating models. In the structural causal framework [Pearl, 2000, Ch. 7], actions are modifications of functional relationships, and each action $do(\mathbf{X} = \mathbf{x})$ on a causal model M produces a new model

[2] The expression also shows that only one level of Z suffices for the identification of $P(y|\hat{x})$ for any value of y and x. In other words, Z need not be varied at all; it can simply be held constant by external means and, if the assumptions embodied in G are valid, the r.h.s. of eq. (1) should attain the same value regardless of the (constant) level at which Z is being held constant. In practice, however, several levels of Z will be needed to ensure that enough samples are obtained for each desired value of X.

$M_{\mathbf{x}} = \langle \mathbf{U}, \mathbf{V}, \mathbf{F}_{\mathbf{x}}, P(\mathbf{U}) \rangle$, where $F_{\mathbf{x}}$ is obtained after replacing $f_X \in \mathbf{F}$ for every $X \in \mathbf{X}$ with a new function that outputs a constant value x given by $do(\mathbf{X} = \mathbf{x})$.

We follow the conventions given in [Pearl, 2000]. We will denote variables by capital letters and their values by small letters. Similarly, sets of variables will be denoted by bold capital letters, sets of values by bold letters. We will use the typical graph-theoretic terminology with the corresponding abbreviations $Pa(\mathbf{Y})_G$, $An(\mathbf{Y})_G$, and $De(\mathbf{Y})_G$, which will denote respectively the set of observable parents, ancestors, and descendants of the node set $\mathbf{Y}$ in G. By convention, these sets will include the arguments as well, for instance, the ancestral set $An(\mathbf{Y})_G$ will include $\mathbf{Y}$. We will usually omit the graph subscript whenever the graph in question is assumed or obvious. A graph $G_{\mathbf{Y}}$ will denote the induced subgraph G containing nodes in $\mathbf{Y}$ and all arrows between such nodes. Finally, $G_{\overline{\mathbf{X}}\underline{\mathbf{Z}}}$ stands for the edge subgraph of G where all incoming arrows into $\mathbf{X}$ and all outgoing arrows from $\mathbf{Z}$ are removed.

We build on the problem of identifiability, defined below, which expresses the requirement that causal effects must be computable from a combination of passive data P and the assumptions embodied in a causal graph G (*without* assuming any availability of additional experimental information).

Definition 1 (Causal Effects Identifiability (Pearl))**.** *Let $\mathbf{X}, \mathbf{Y}$ be two sets of disjoint variables, and let G be the causal diagram. The causal effect of an action $do(\mathbf{X} = \mathbf{x})$ on a set of variables $\mathbf{Y}$ is said to be identifiable from P in G if $P_{\mathbf{x}}(\mathbf{y})$ is (uniquely) computable from $P(V)$ in any model that induces G.*

The following Lemma is the operational way to prove that a causal quantity is not identifiable given the assumptions embedded in G.

Lemma 1. *Let $\mathbf{X}, \mathbf{Y}$ be two sets of disjoint variables, and let G be the causal diagram. $P_{\mathbf{x}}(\mathbf{y})$ is not identifiable in G if there exist two causal models M^1 and M^2 compatible with G such that $P_1(\mathbf{V}) = P_2(\mathbf{V})$, and $P_1(\mathbf{y}|do(\mathbf{x})) \neq P_2(\mathbf{y}|do(\mathbf{x}))$.*

Proof. The latter inequality rules out the existence of a function from P to $P_{\mathbf{x}}(\mathbf{y})$. □

Next, we formally introduce the problem of z-identifiability that generalizes the problem of identifiability whereas it is no longer assumed that experimental information is not available at all, but there exists a set of variable $\mathbf{Z}$ in which experiments were performed and now is available for use. In other words, the explicit acknowledgement of the existence of the set $\mathbf{Z}$ adds a degree of freedom for the researcher, making the analysis more flexible and perhaps realistic.

Definition 2 (Causal Effects z-Identifiability)**.** *Let $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ be disjoint sets of variables, and let G be the causal diagram. The causal effect of an action $do(\mathbf{X} = \mathbf{x})$ on a set of variables $\mathbf{Y}$ is said to be z-identifiable from P in G, if $P_{\mathbf{x}}(\mathbf{y})$ is (uniquely) computable from $P(\mathbf{V})$ together with the interventional distributions $P(\mathbf{V} \setminus \mathbf{Z}'|do(\mathbf{Z}'))$, for all $\mathbf{Z}' \subseteq \mathbf{Z}$, in any model that induces G.*

Armed with this new definition, we state next the sufficiency of the *do*-calculus for $zI\mathcal{D}$ that is analogous to [Pearl, 2000, Corol. 3.4.2] in respect to identification.

Theorem 1. *Let $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ be disjoint sets of variables, let G be the causal diagram, and $Q = P(\mathbf{y}|do(\mathbf{x}))$. Q is $zI\mathcal{D}$ from P in G if the expression $P(\mathbf{y}|do(\mathbf{x}))$ is reducible, using the rules of do-calculus, to an expression in which only elements of $\mathbf{Z}$ may appear as interventional variables.*

Proof. The result follows from soundness of do-calculus and the definition of z-identifiability. □

It is clear that if we have an efficient procedure to establish $zI\mathcal{D}$, we can immediately decide $I\mathcal{D}$ by setting $\mathbf{Z} = \emptyset$. On the other hand, to be able to establish the converse of Theorem 1, we need to understand the conditions for non-$zI\mathcal{D}$, and so, we state next the analogous of Lemma 1 in this context.

Lemma 2. *Let $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ be disjoint sets of variables, and let G be the causal diagram. $P_{\mathbf{x}}(\mathbf{y})$ is not z-identifiable in G if there exist two causal models M^1 and M^2 compatible with G such that $P^1(\mathbf{V}) = P^2(\mathbf{V})$, $P^1(\mathbf{V} \setminus \mathbf{Z}'|do(\mathbf{Z}')) = P^2(\mathbf{V} \setminus \mathbf{Z}'|do(\mathbf{Z}'))$, for all $\mathbf{Z}' \subseteq \mathbf{Z}$, and $P^1_{\mathbf{x}}(\mathbf{y}) \neq P^2_x(\mathbf{y})$.*

Proof. Let I be the set of interventional distributions $P(\mathbf{V} \setminus \mathbf{Z}'|do(\mathbf{Z}'))$, for any $\mathbf{Z}' \subseteq \mathbf{Z}$. The latter inequality rules out the existence of a function from P, I to $P_{\mathbf{x}}(\mathbf{y})$. □

While Lemma 2 might appear convoluted, it is nothing more than a formalization of the statement "Q cannot be computed from information set S alone." Naturally, when S has two components, $\langle P, I \rangle$, the Lemma becomes lengthy. Even though the problems of $I\mathcal{D}$ and $zI\mathcal{D}$ are related, Lemma 2 indicates that proofs of non-$zI\mathcal{D}$ are at least as hard as the ones for non-$I\mathcal{D}$, given that to prove the former requires the construction of two models to agree on $\langle P, I \rangle$, while to prove the latter it is only required for the two models to agree on the distribution P.

3 Characterizing $zI\mathcal{D}$ Relations

The concept of confounded component (or *C-component*) was introduced in [Tian and Pearl, 2002]

to represent clusters of variables connected through bidirected edges, and was instrumental in establishing a number of conditions for ordinary identification (Def. 1). If G is not a C-component itself, it can be uniquely partitioned into a set $\mathcal{C}(G)$ of C-components. We state below this definition that will also play a key role in the problem of $z\mathcal{ID}$. [3]

Definition 3 (C-component)**.** *Let G be a causal diagram such that a subset of its bidirected arcs forms a spanning tree over all vertices in G. Then G is a C-component (confounded component).*

A special subset of C-components that embraces the ancestral set of Y was noted by [Shpitser and Pearl, 2006] to play an important role in deciding identifiability – this observation can also be applied to z-identifiability, as formulated next.

Definition 4 (C-forest)**.** *Let G be a causal diagram, where $\mathbf{Y}$ is the maximal root set. Then G is a $\mathbf{Y}$-rooted C-forest if G is a C-component and all observable nodes have at most one child.*

We next introduce a structure based on C-forests that witnesses unidentifiability characterized by a pair of C-forests. $\mathcal{ID}$ was shown by [Shpitser and Pearl, 2006] infeasible if and only if such structure exists as an edge subgraph of the given causal diagram.

Definition 5 (hedge)**.** *Let $\mathbf{X}, \mathbf{Y}$ be set of variables in G. Let F, F' be $\mathbf{R}$-rooted C-forests such that $F \cap X \neq 0$, $F' \cap X = 0$, $F' \subseteq F$, $\mathbf{R} \subset An(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$. Then F and F' form a hedge for $P_{\mathbf{x}}(\mathbf{Y})$ in G.*

The presence of this structure will prove to be an obstacle to z-identifiability of causal effects in various scenarios. For instance, the p-graph in Fig. 1(b) is a Y-rooted C-forest in which $P_x(y)$ will show not to be z-identifiable. However, different than in the $\mathcal{ID}$ case, there is no sharp boundary here, since Fig. 1(a) also contains a Y-rooted C-forest but $P_x(y)$ was already shown to be $z\mathcal{ID}$.

We formally show next that there is a variation of this structure that is able to capture non-$z\mathcal{ID}$ for a broad set of cases.

Theorem 2. *Let $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z}$ be disjoint sets of variables and let G be the causal diagram. Then, the causal effects $Q = P_{\mathbf{x}}(\mathbf{y})$ is not $z\mathcal{ID}$ if there exists a hedge $\mathcal{F} = \langle F, F' \rangle$ for Q in $G_{\overline{Z}}$.*

Proof. The result is immediate. The existence of the hedge $\mathcal{F}$ for Q in $G_{\overline{\mathbf{Z}}}$ implies that $\mathbf{Z}$ cannot help in the (ordinary) identification of Q. Let us assume that Q is $z\mathcal{ID}$. Note that $\mathbf{Z}$ does not participate in the hedge $\mathcal{F}$ since there is no bidirected edge going towards any of its elements in $G_{\overline{\mathbf{Z}}}$, which is required by the definition of C-forest. Further, consider a parametrization such that all elements of $\mathbf{Z}$ are simply fair coins and disconnected from $\mathbf{V} \setminus \mathbf{Z}$ in G.

We can now use the same proof of non-$\mathcal{ID}$ based on $\mathcal{F}$ to prove non-$z\mathcal{ID}$ in G. The inequality of Q between the two models is obvious, and the agreement of the interventional distributions $do(\mathbf{Z})$ follows since $\mathbf{Z}$ is disconnected from $\mathbf{V} \setminus \mathbf{Z}$ by the chosen parametrization. This is a contradiction since $z\mathcal{ID}$ has to be valid for any parametrization compatible with G, which suffices to prove the result. □

[3] The advent of C-components complements the notion of *inducing path*, which was introduced earlier in [Verma and Pearl, 1990].

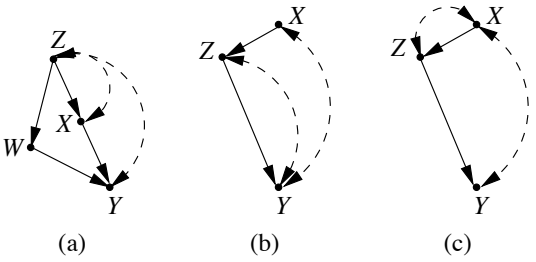

Figure 2: Graphs in which $P(y|\hat{x})$ is non-$z\mathcal{ID}$ from $do(Z)$ and there is no hedge in $G_{\overline{Z}}$.

Consider the next Corollary in regard to the p-graph, which is the smallest example in which Z could aid in the z-identification of Q but Q is still not z-identifiable from $do(Z)$. This and similar structures that prevent $z\mathcal{ID}$ will be one of the base cases for our proof of completeness, which requires a demonstration that whenever the algorithm fails to z-identify a causal relation, the relation is indeed non-$z\mathcal{ID}$.

Corollary 1. *$P_x(y)$ is not $z\mathcal{ID}$ in the p-graph.*

Proof. This follows directly from Theorem 2 since there exists a hedge in $G_{\overline{Z}}$. □

The result of Theorem 2 still does not characterize the $z\mathcal{ID}$ class, which suggests that the machinery used to prove completeness in the $\mathcal{ID}$ class is not immediately applicable to the $z\mathcal{ID}$ class.

For instance, consider the graph in Fig. 2(a) (called here bv-graph), which does not have a hedge for Q in $G_{\overline{Z}}$ but is still non-$z\mathcal{ID}$. The bv-graph coincides as an edge subgraph with Fig. 1(a) (note C-component induced over $\{X, Y, Z\}$), which turns out to be $z\mathcal{ID}$.

This is an interesting case, since up to this point, in ordinary identification, it was enough to locate a hedge for Q as an edge subgraph of the inputted diagram, and all graphs sharing this substructure were equally

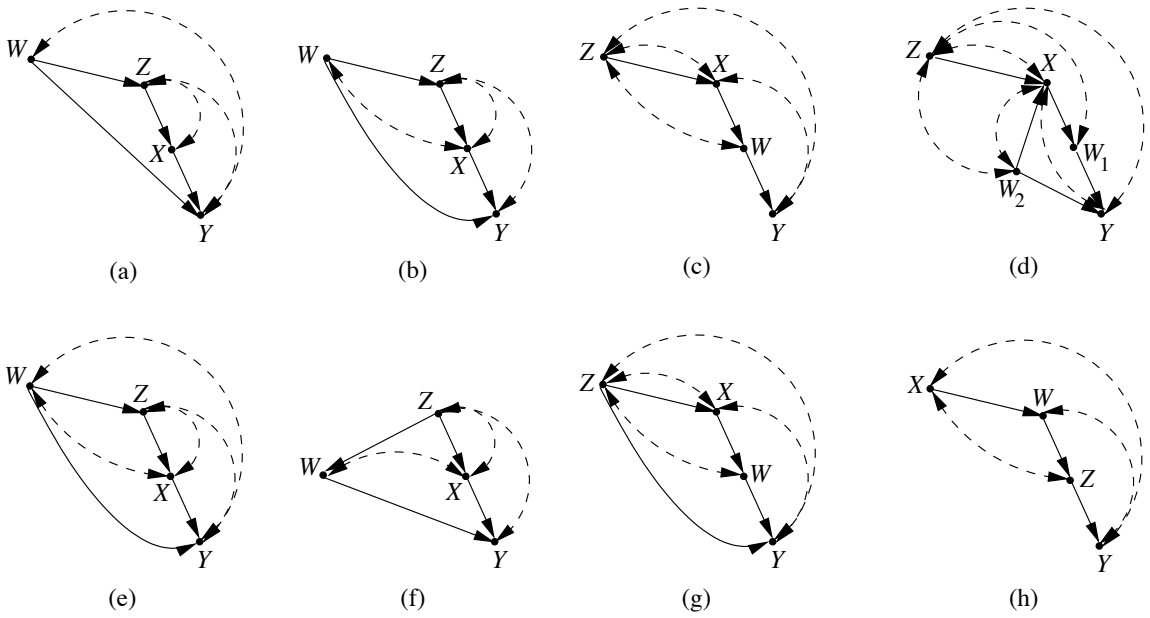

Figure 3: $P(y|\hat{x})$ is $zI\mathcal{D}$ from $\langle P, do(Z)\rangle$ in the graphs in the first row (a–d), but not in the the second row (e–h).

unidentifiable (see Thm. 4 in [Shpitser and Pearl, 2006]) – this is no longer true here since $\mathbf{Z}$ needs to be taken into account. Mainly, note that the directed edges outside a C-component play a very critical role for the $zI\mathcal{D}$ problem as the *bv*-graph demonstrates.

Finally, we expand Pearl's condition [Pearl, 2000, pp. 87] in the following directions. We extend, in the intuitive way, his condition to consider when $\mathbf{Z}$ is a set of variables and, in turn, we supplement the sufficient part with its necessary counterpart. We finally have a complete characterization for the $zI\mathcal{D}$ class as shown below.

Theorem 3. *Let* $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z}$ *be disjoint sets of variables and let* G *be the causal diagram. The causal effect* $Q = P(\mathbf{y}|do(\mathbf{x}))$ *is* $zI\mathcal{D}$ *in* G *if and only if one of the following conditions hold:*

a. Q *is identifiable in* G*; or,*

b. There exists $\mathbf{Z}' \subseteq \mathbf{Z}$ *such that the following conditions hold,*

(i) $\mathbf{X}$ *intercepts all directed paths from* $\mathbf{Z}'$ *to* $\mathbf{Y}$*, and*

(ii) Q *is identifiable in* $G_{\overline{\mathbf{Z}'}}$.[4]

Proof. See Appendix. □

Let $Q = P(y|\hat{x})$ be the effect of interest and assume that experiments were performed over $\{Z\}$. Q is $zI\mathcal{D}$ from P and $do(Z)$ in the graphs in Fig. 3(a-d), while they are non-$zI\mathcal{D}$ in the graphs in Fig. 3(e-h). Except for the trivial case, Theorem 3 is existentially quantified and it is not immediately obvious how to efficiently select the covariates simultaneously satisfying both conditions of the Theorem. Clearly, a naive approach could lead to an exponential number of tests.

For example, consider the graph in Fig. 3(a) that is a variation of the *bv*-graph. In this graph, Q is $zI\mathcal{D}$ using experiments from $\{Z\}$. In turn, consider the graph in Fig. 3(e), which is the same as 3(a) but with the bidirected edge $W \leftarrow\rightarrow X$ added. Now, Q is no longer $zI\mathcal{D}$ for $\{Z\}$ nor $\{Z, W\}$. If we further consider the graph in Fig. 3(b) with the bidirected edge $W \leftarrow\rightarrow X$ removed from 3(e), not only Q becomes $zI\mathcal{D}$ for $\{Z\}$ but also for $\{Z, W\}$. This is a border case, note that if we input $\{Z, W\}$ as the surrogate variables for Pearl's criterion, it will not be able to recognize Q as $zI\mathcal{D}$ given the existence of the directed path $W \rightarrow Y$. Finally, if we consider the graph in Fig. 3(f) in which the directed edge $W \rightarrow Z$ is flipped from 3(b), Q is no longer $zI\mathcal{D}$ for neither $\{Z, W\}$ nor $\{Z\}$.

This example can be extended indefinitely but it is clear that finding a set that satisfies both conditions of the Theorem, in structures more intricate than the given 4-node example, does not follow immediately. The subject of the next section is about finding an efficient (and complete) algorithm to solve this problem.

But for now, consider the following Lemma that confirms our intuition that surrogate experiments should not disturb the causal paths (non-descendents) of the variables that are being analyzed.

[4]This condition can be rephrased graphically as "There exists no hedge for Q as an edge subgraph in $G_{\overline{\mathbf{Z}'}}$."

Corollary 2. *Let G be the causal diagram, $\mathbf{X}$, $\mathbf{Y} \subset \mathbf{V}$ be disjoint sets of variables, and $\mathbf{Z} \subseteq De(\mathbf{X})_{G_{An(\mathbf{Y})}}$. The causal effect $Q = P(\mathbf{y}|do(\mathbf{x}))$ is not zID from P and $do(\mathbf{Z})$ in G, if Q is not ID from P in G.*

Proof. The result follows directly from Theorem 3. □

4 A Complete Algorithm for *zID*

In this section, we propose a simple extension of the ordinary identification algorithms to solve the problem of z-identifiability, which we call $\mathbf{ID^z}$ (see Fig. 4).

We build on previous analysis of identifiability given in [Pearl, 1995; Kuroki and Miyakawa, 1999; Tian and Pearl, 2002; Shpitser and Pearl, 2006; Huang and Valtorta, 2006], and we choose to start with the version provided by Shpitser (called **ID**) since the hedge structure is explicitly employed, which will show to be instrumental to prove completeness.

Before considering the technical results, we explain our strategy and how our version of the algorithm relates to the existent ones for ordinary identifiability.

(i) z-identifiability (sufficiency): Causal relations can be solved in our context through ordinary identifiability or identifiability relying on the experiments performed over $\mathbf{Z}$. The current algorithms already operate on the first part, and they proceed exploring a sequence of equalities in do-calculus based on the C-component decomposition. (The idea is to apply a divide-and-conquer strategy breaking the problem into smaller, more manageable pieces, and then to assemble them back when it is possible.) It turns out that the equalities used by the algorithm are all in the interventional space (between interventional distributions except for the base cases), which is attractive for the *zID* problem since certain interventional distributions $\mathbf{Z}$ are already available to use.

For instance, when steps 3 or 4 succeed in their tests and, at the same time, have non-empty intersection with $\mathbf{Z}$, we exploit the common variables, updating the graph and respective data structures accordingly. We then continue solving an ordinary *ID* instance but no longer have to identify these variables and they possibly can help in the identifiability of others.

(ii) Non-z-identifiability (necessity): The algorithm proceeds until it is not able to resolve a certain subproblem, which implies the existence of a certain hedge. Note that the given hedge can be different than the one used for *ID* in the same graph since the experiments over $\mathbf{Z}$ possibly destroyed the original ones. Further, note that to use the given hedge to prove non-*zID* is not immediate since, in the light of Lemma 2, more constraints need to be satisfied in order to support such claim. Still, it is clear that if $\mathbf{Z}$ is not involved in the hedge, it can be shown that the two problems coincide. The other cases in which $\mathbf{Z}$ has non-empty intersection with the hedge have to be handled more carefully.

function $\mathbf{ID^z}(\mathbf{y}, \mathbf{x}, \mathbf{Z}, \mathcal{I}, \mathcal{J}, P, G)$
INPUT: $\mathbf{x}, \mathbf{y}$: value assignments; $\mathbf{Z}$: variables with interventions available; $\mathcal{I}, \mathcal{J}$: see caption; P: current probability distribution $do(\mathcal{I}, \mathcal{J}, x)$ (observational when $\mathcal{I} = \mathcal{J} = \emptyset$); G: causal graph.
OUTPUT: Expression for $P_{\mathbf{x}}(\mathbf{y})$ in terms of $P, P_{\mathbf{z}}$ or $\mathbf{FAIL}(F, F')$.

1 **if** $\mathbf{x} = \emptyset$, **return** $\sum_{\mathbf{v}\setminus\mathbf{y}} P(\mathbf{v})$.
2 **if** $\mathbf{V} \setminus An(\mathbf{Y})_G \neq \emptyset$,
return $\mathbf{ID^z}(\mathbf{y}, \mathbf{x} \cap An(\mathbf{Y})_G, \mathbf{Z}, \mathcal{I}, \mathcal{J}, \sum_{\mathbf{v}\setminus An(\mathbf{Y})_G} P, An(\mathbf{Y})_G)$.
3 Set $\mathbf{Z_w} = ((\mathbf{V} \setminus (\mathbf{X} \cup \mathcal{I} \cup \mathcal{J})) \setminus An(\mathbf{Y})_{G_{\overline{\mathbf{X}\cup\mathcal{I}\cup\mathcal{J}}}}) \cap \mathbf{Z}$.
Set $\mathbf{W} = ((\mathbf{V} \setminus (\mathbf{X} \cup \mathcal{I} \cup \mathcal{J})) \setminus An(\mathbf{Y})_{G_{\overline{\mathbf{X}\cup\mathcal{I}\cup\mathcal{J}}}}) \setminus \mathbf{Z}$.
if $(\mathbf{Z_w} \cup \mathbf{W}) \neq \emptyset$,
return $\mathbf{ID^z}(\mathbf{y}, \mathbf{x} \cup \mathbf{w}, \mathbf{Z} \setminus \mathbf{Z_w}, \mathcal{I} \cup \mathbf{z_w}, \mathcal{J}, P, G)$.
4 **if** $\mathcal{C}(G \setminus (\mathbf{X} \cup \mathcal{I} \cup \mathcal{J})) = \{S_0, S_1, ..., S_k\}$,
return $\sum_{\mathbf{v}\setminus\{\mathbf{y},\mathbf{x},\mathcal{I}\}} \prod_i \mathbf{ID^z}(s_i, (\mathbf{v} \setminus s_i) \setminus \mathbf{Z}, \mathbf{Z} \setminus (\mathbf{V} \setminus S_i), \mathcal{I}, \mathcal{J} \cup (\mathbf{Z} \cap (\mathbf{v} \setminus \mathbf{s_i})), P, G)$.
if $\mathcal{C}(G \setminus (\mathbf{X} \cup \mathcal{I} \cup \mathcal{J})) = \{S\}$,
5 **if** $\mathcal{C}(G) = \{G\}$, $\mathbf{FAIL}(G, S)$.
6 **if** $S \in \mathcal{C}(G)$,
return $\sum_{s\setminus\mathbf{y}} \prod_{i|V_i \in S} P(v_i|v_G^{(i-1)} \setminus (\mathcal{I} \cup \mathcal{J}))$.
7 **if** $(\exists S')S \subset S' \in \mathcal{C}(G)$,
return $\mathbf{ID^z}(\mathbf{y}, \mathbf{x} \cap S', \mathbf{Z}, \mathcal{I}, \mathcal{J}, \prod_{i|V_i \in C'} P(V_i|V_G^{(i-1)} \cap S', v_G^{(i-1)} \setminus (S' \cup \mathcal{I} \cup \mathcal{J})), S')$.

Figure 4: $\mathbf{ID^z}$: Modified version of *ID* algorithm capable of recognizing *zID*; The variables $\mathcal{I}, \mathcal{J}$ represent indices for currently active Z-interventions introduced respectively by steps 3 or 4. Note that P is sensitive to current instantiations of $\mathcal{I}, \mathcal{J}$.

Note that the key difference between $\mathbf{ID^z}$ and the original **ID** implementation is in steps 3 and 4 in which possibly some $\mathbf{Z}' \subseteq \mathbf{Z}$ is added as an interventional set, and kept as so until the end of the execution. It is clear that these additions just can represent a benefit in computing the target Q since is always easier to identify a quantity in a subgraph of the original input.

We prove next soundness and completeness of $\mathbf{ID^z}$.

Theorem 4 (soundness)**.** *Whenever $\mathbf{ID^z}$ returns an expression for $P_{\mathbf{x}}(\mathbf{y})$, it is correct.*

Proof. The result is immediate since the soundness of **ID** was already established [Shpitser and Pearl, 2006, Thm. 5], which is inherited by $\mathbf{ID^z}$ by construction. Note that adding $\mathbf{Z}' \subseteq \mathbf{Z}$ as an interventional set and

not trying to "identify" it later does not represent a problem, in the zID sense, since by assumption we can use the interventional distributions $do(\mathbf{Z})$ in the final expression returned by the procedure. □

Theorem 5. *Assume* $\mathbf{ID^z}$ *fails to z-identify* $P_{\mathbf{x}}(\mathbf{y})$ *from* P *and* $do(\mathbf{Z})$ *in* G *(executes line 5). Then there exists* $\mathbf{X}' \subseteq \mathbf{X}$, $\mathbf{Y}' \subseteq \mathbf{Y}$, $\mathbf{Z}', \mathbf{Z}'' \subseteq \mathbf{Z}$ *such that the graph pair* G, S *returned by the fail condition of* $\mathbf{ID^z}$ *contain as edge subgraphs C-forests* F, F' *that form a hedge for* $P_{\mathbf{x}',\mathbf{z}'}(\mathbf{y}', \mathbf{z}'')$.

Proof. This property is just partly inherited from the original **ID** since we can add $\mathbf{Z}' \subseteq \mathbf{Z}$ as interventional nodes along the execution of $\mathbf{ID^z}$; we also keep track of $\mathbf{Z}'' \subseteq \mathbf{Z}$ that are related to $An(\mathbf{Y})$ during the execution of the procedure (to be specified below).

Consider G, $\mathbf{Y_f}$, $\mathcal{I}$ and $\mathcal{J}$ local to the call in which $\mathbf{ID^z}$ exited with failure (line 5). It is true that the set $\mathbf{Y_f}$ is such that $\mathbf{Z}'' = \mathbf{Y_f} \cap \mathbf{Z}$ and $\mathbf{Y}' = \mathbf{Y_f} \cap \mathbf{Y}$. Let $\mathbf{Z}' \subseteq \mathbf{Z}$ be the active part of $\mathbf{Z}$ in the faulty call, which we kept track through $\mathcal{I} \cup \mathcal{J}$. The condition that triggered failure is that the whole graph was a single C-component. Let $\mathbf{R}$ be the root set of G. We can remove a set of directed arrows while keeping the root $\mathbf{R}$ such that the resulting F is an $\mathbf{R}$-rooted C-forest.

Similarly to **ID**, note that since $F' = F \cap S$ is closed under descendent and only single directed arrows were removed from S to obtain F', F' is also a C-forest. Now, $F' \cap (\mathbf{X} \cup \mathbf{Z}') = \emptyset$ and $F' \cap (\mathbf{X} \cup \mathbf{Z}') \neq \emptyset$, by construction. Also, $\mathbf{R} \subseteq An(\mathbf{Y}', \mathbf{Z}'')_{G_{\overline{\mathbf{X},\mathbf{Z}'}}}$ and $\mathbf{Z}'' \subseteq An(\mathbf{Y})_{G_{\overline{\mathbf{X},\mathbf{Z}'}}}$, by line 2 and 3 of the algorithm. □

Theorem 6 (completeness)**.** $\mathbf{ID^z}$ *is complete.*

Proof. By Theorem 5, $\mathbf{ID^z}$ failure implies the existence of $\mathbf{X}' \subseteq \mathbf{X}$, $\mathbf{Y}' \subseteq \mathbf{Y}$, $\mathbf{Z}', \mathbf{Z}'' \subseteq \mathbf{Z}$, and C-forests F, F' that form a hedge for $P_{\mathbf{x}',\mathbf{z}'}(\mathbf{y}', \mathbf{z}'')$. Let us proceed our analysis by cases:

Case $\mathbf{Z}' = \emptyset, \mathbf{Z}'' = \emptyset$. The construction provided by [Shpitser and Pearl, 2006, Corollary 2] can be used here since this case reduces to ordinary identifiability.

Case $\mathbf{Z}' = \emptyset, \mathbf{Z}'' \neq \emptyset$. Even though $\mathbf{Z}''$ is in the root set of the hedge, and not related to the interventional part $(F \setminus F')$ where the asymmetry in the construction usually resides (to generate inequality in Q), the previous construction have to be used with certain caution, as given by case 1 of Thm. 3.

There is an interesting border subcase when $\mathbf{Y}' = \emptyset$. We need to keep track of $\{\mathcal{I}, \mathcal{J}\}$ since if the Z-interventions are added in step 3, we should not be concerned with summing over the assignments of the variables added, but if the Z-interventions are added in step 4, we do have to take care of this case. Note that we would have some hedge in a do-equality in the form $Q = \sum_{\mathbf{z}''} P_{\mathbf{x}'}(\mathbf{z}'') f(\mathbf{x}, \mathbf{y}, ...)$, in which if $f(.)$ is identifiable and uniformly distributed, Q would equate in both models and spoil the counter-example. The problem is not difficult to fix, and we just have to create a map for $f()$ that is non-uniform. (See Thm. 3.)

Case $\mathbf{Z}' \neq \emptyset, \mathbf{Z}'' = \emptyset$. The construction provided in cases 2 and 3 of Thm. 3 were more involved since it was not know a priori which C-factor yielded the "faulty" call. In the $\mathbf{ID^z}$ case, we already located the hedge based on the trace of the algorithm, then we can essentially use the same construction of these cases to provide a counterexample.

Case $\mathbf{Z}' \neq \emptyset, \mathbf{Z}'' \neq \emptyset$. The construction provided in the two previous cases are not incompatible, and they can be combined to provide a counter-example to this scenario.

Moreover, the previous constructions were given over the subgraph H of G, and how to extend the counter-example to G is discussed in Theorem 3. □

Corollary 3. *The rules of do-calculus, together with standard probability manipulations are complete for determining z-identifiability of* $P_{\mathbf{x}}(\mathbf{y})$.

Proof. It was already shown [Shpitser and Pearl, 2006, Thm. 7] that the operations of **ID** correspond to sequences of standard probability manipulations and application of the rules of do-calculus, which is also true by construction for $\mathbf{ID^z}$, and so the result follows. □

Conclusion

This paper was concerned with a variation of the identifiability problem in which experiments can be conducted over a subset of the variables $\mathbf{Z}$ in addition to the assumptions embodied in a causal digram G and the statistical knowledge given as a probability distribution. (If $\mathbf{Z}$ is an empty set, the two problems coincide.)

We provide a graphical necessary and sufficient condition for the cases when the causal effect of an arbitrary set of variables on another arbitrary set can be determined uniquely from the available information. We further provide a complete algorithm for computing the resulting mapping, that is, a formula fusing available observational and experimental data to synthesize an estimate of the desired causal effects. Furthermore, we use our results to prove completeness of *do*-calculus in respect to the z-identifiability class.

Our results were developed in a non-parametric setting in the tradition of the do-calculus. For a future

research direction, it would be interesting to explore how experimental data can aid the identification in the linear case. This is a harder problem, since a complete characterization of ordinary identifiability (i.e., $\mathbf{Z} = \emptyset$) in the linear case is still an open problem.

This paper complements two recent works on generalizability of causal and statistical knowledge. The first, dubbed "transportability" [Pearl and Bareinboim, 2011; Bareinboim and Pearl, 2012b] , deals with transferring causal information from an experimental to an observational environment, potentially different from the first. The second, called "selection bias" [Bareinboim and Pearl, 2012c], deals with extrapolation between an environment in which samples are selected preferentially and one in which no preferential sampling takes place. The extrapolation involved in z-Identification problems takes place between two different regimes; one in which experiments are performed over $\mathbf{Z}$, and one in which future experiments are anticipated over $\mathbf{X}$. Extensions to "meta synthesis" tasks, where information from multiple heterogeneous sources are combined to increase the effective sample size, are considered in [Pearl, 2012b; 2012a].

An Efficient Message-Passing Algorithm for the M-Best MAP Problem

Dhruv Batra
TTI-Chicago
dbatra@ttic.edu

Abstract

Much effort has been directed at algorithms for obtaining the highest probability configuration in a probabilistic random field model – known as the maximum a posteriori (MAP) inference problem. In many situations, one could benefit from having not just a single solution, but the top M most probable solutions – known as the M-Best MAP problem.

In this paper, we propose an efficient message-passing based algorithm for solving the M-Best MAP problem. Specifically, our algorithm solves the recently proposed Linear Programming (LP) formulation of M-Best MAP [7], while being *orders of magnitude* faster than a generic LP-solver. Our approach relies on studying a particular partial Lagrangian relaxation of the M-Best MAP LP which exposes a natural combinatorial structure of the problem that we exploit.

1 Introduction

A large number of problems in computer vision, natural language processing and computational biology can be formulated as the search for the most probable state under a discrete probabilistic graphical model – known the MAP inference problem.

In a number of such applications, one can benefit from having not just a single best solution, rather a list of M-best hypotheses. For example, sentences are often ambiguous and machine translation systems benefit from working with multiple plausible parses of a sentence. In computational biology, practitioners are often interested in computing the top M most stable configurations of a protein structure. Moreover, computing such a set of M-best hypotheses is useful for assessing the sensitivity of the model w.r.t. variations in the input and/or the parameters of the model.

In the graphical models literature, this problem is known as the M-Best MAP problem [7, 18, 28]. Interestingly (and perhaps understandably), algorithms for the M-Best MAP problem have closely followed the development of the algorithms for solving the MAP problem. Similar to MAP, the first family of algorithms for M-Best MAP [18,20] were junction-tree based exact algorithms, feasible only for low-treewidth graphs. For high-treewidth models, where Belief Propagation (BP) is typically used to perform approximate MAP inference, Yanover and Weiss [28] showed how the pseudo-max-marginals produced by BP may be used to compute approximate M-Best MAPs.

However, with the development of Linear Programming (LP) relaxations for MAP, this concurrence between MAP and M-Best MAP is no longer true. While message-passing algorithms for solving the MAP LP were available as soon as the LPs were studied [8, 13, 19, 24, 26], no such algorithm is known for solving the M-Best MAP LP [7]. This discrepancy is not merely a theoretical concern – large-scale empirical comparisons [27] have found that message-passing algorithms for MAP significantly outperform commercial LP solvers (like CPLEX). More importantly, message-passing algorithms can be applied to large-scale problems where solvers like CPLEX simply would not scale. Thus, if we are to apply M-Best MAP to real instances appearing in computational biology, computer vision and NLP, we must develop scalable distributed message-passing algorithms.

Overview. The principal contribution of this paper is to develop an efficient message-passing algorithm for the M-Best MAP problem in discrete undirected graphical models, specifically Markov Random Fields (MRFs). Our approach studies a particular partial Lagrangian relaxation of the M-Best MAP LP [7] which exposes the natural modular structure in the problem. For graphs with cycles, this Lagrangian relaxation involves an exponentially large set of dual variables, and we use a dynamic subgradient method (DSM) [4] for solving this Lagrangian dual. DSMs are a recently formalized class of methods that interleave a separation

oracle procedure (that selects a subset of active dual variables), with the dual update procedure (that takes a step in the direction of the subgradient).

At a high-level, our algorithm brings MAP and M-Best MAP to an equal footing vis-a-vis a message-passing algorithm for solving the corresponding LP-relaxation. Importantly, our algorithm retains all the guarantees of the LP formulation of Fromer and Globerson [7], while being *orders of magnitude* faster. Similar to the observations in [27] for MAP, we find that our algorithm enables solving M-Best MAP on large instances that were unsolvable with generic LP solvers.

Outline. We begin with a brief history of the M-Best MAP problem in Section 2; present preliminaries and background in Section 3; revisit the M-Best MAP LP formulation of Fromer and Globerson [7] in Section 4; study the Lagrangian dual of this LP and present a message-passing dual ascent algorithm for tree-MRF in Section 5 and for general MRFs in Section 6.

2 Previous Work on M-Best MAP

The problem of finding the top M solutions to a general combinatorial optimization problem (not just inference in MRFs) has typically been studied in the context of k-shortest paths [6] in a search graph. Lawler [16] proposed a general algorithm to compute the top M solutions for a large family of discrete optimization problems, and the ideas used in Lawler's algorithm form the basis of most algorithms for the M-Best MAP problem. If the complexity of finding the best solution is $T(n)$, where n is the number of variables, Lawler's algorithm solves n new problems. The best solution among these n problems is the second best solution to the original problem. Thus at an $O(nM)$ multiplicative overhead, the top M solutions can be iteratively found. Hamacher and Queyranne [10] reduced this overhead to $O(M)$ by assuming access to an algorithm that can compute the first and the second best solutions.

Dechter and colleagues [5, 17] have recently provided dynamic-programming algorithms for M-Best MAP, but these are exponential in treewidth. Yanover and Weiss [28] proposed an algorithm that requires access only to max-marginals. Thus, for certain classes of MRFs that allow efficient exact computation of max-marginals, *e.g.* binary pairwise supermodular MRFs [11], M-Best solutions can be found for arbitrary treewidth graphs. Moreover, *approximate* M-Best solutions may be found by approximating the max-marginal computation, *e.g.* via loopy BP.

More recently, Fromer and Globerson [7] provided a LP view of the M-Best MAP problem. They proposed an algorithm (STRIPES) that repeatedly partitions the space of solutions and solves a 2^{nd}-Best MAP LP within each partition (with a generic LP-solver). We revisit [7] in detail in Section 4, and describe a significantly more efficient message-passing algorithm for solving the LP in the remainder of the paper.

3 Preliminaries: MAP-MRF Inference

Notation. For any positive integer n, let $[n]$ be shorthand for the set $\{1, 2, \ldots, n\}$. We consider a set of discrete random variables $\mathbf{x} = \{x_i \mid i \in [n]\}$, each taking value in a finite label set, $x_i \in X_i$. For a set $A \subseteq [n]$, we use x_A to denote the tuple $\{x_i \mid i \in A\}$, and X_A to be the cartesian product of the individual label spaces $\times_{i \in A} X_i$. For ease of notation, we use x_{ij} as a shorthand for $x_{\{i,j\}}$. For two vector $\boldsymbol{a}, \boldsymbol{b} \in \mathbb{R}^d$, we use $\boldsymbol{a} \cdot \boldsymbol{b}$ to denote the inner product.

MAP. Let $G = (\mathcal{V}, \mathcal{E})$ be a graph defined over these variables, *i.e.* $\mathcal{V} = [n]$, $\mathcal{E} \subseteq \binom{\mathcal{V}}{2}$, and let $\theta_A : X_A \to \mathbb{R}$, $(\forall A \in \mathcal{V} \cup \mathcal{E})$ be functions defining the energy at each node and edge for the labeling of variables in scope. The goal of MAP inference is to find the labeling $\mathbf{x}$ of the variables that minimizes this real-valued energy function:

$$\min_{\mathbf{x} \in X_{\mathcal{V}}} \sum_{A \in \mathcal{V} \cup \mathcal{E}} \theta_A(x_A) \tag{1a}$$

$$= \min_{\mathbf{x} \in X_{\mathcal{V}}} \sum_{i \in \mathcal{V}} \theta_i(x_i) + \sum_{(i,j) \in \mathcal{E}} \theta_{ij}(x_i, x_j). \tag{1b}$$

The techniques developed in this paper are naturally applicable to higher-order MRFs as well. However, to simplify the exposition we restrict ourselves to pairwise energy functions.

MAP Integer Program. MAP inference is typically set up as an integer programming problem over boolean variables. For each node and edge $A \in \mathcal{V} \cup \mathcal{E}$, let $\boldsymbol{\mu}_A = \{\mu_A(s) \mid s \in X_A,\ \mu_A(s) \in \{0, 1\}\}$, be a vector of indicator variables encoding all possible configurations of x_A. If $\mu_A(s)$ is set to 1, this implies that x_A takes label s. Moreover, let $\boldsymbol{\theta}_A = \{\theta_A(s) \mid s \in X_A\}$ be a vector holding energies for all possible configurations of x_A, and $\boldsymbol{\mu} = \{\boldsymbol{\mu}_A \mid A \in \mathcal{V} \cup \mathcal{E}\}$ be a vector holding the entire configuration. Using this notation, the MAP inference integer program can be written as:

$$\min_{\boldsymbol{\mu}_i, \boldsymbol{\mu}_{ij}} \quad \sum_{i \in \mathcal{V}} \boldsymbol{\theta}_i \cdot \boldsymbol{\mu}_i + \sum_{(i,j) \in \mathcal{E}} \boldsymbol{\theta}_{ij} \cdot \boldsymbol{\mu}_{ij} \tag{2a}$$

$$s.t. \quad \sum_{s \in X_i} \mu_i(s) = 1 \qquad \forall i \in \mathcal{V} \tag{2b}$$

$$\sum_{s \in X_i} \mu_{ij}(s, t) = \mu_j(t) \qquad \forall \{i, j\} \in \mathcal{E} \tag{2c}$$

$$\sum_{t \in X_j} \mu_{ij}(s, t) = \mu_i(s) \qquad \forall \{i, j\} \in \mathcal{E} \tag{2d}$$

$$\mu_i(s), \mu_{ij}(s, t) \in \{0, 1\} \quad \forall i \in \mathcal{V}, \forall \{i, j\} \in \mathcal{E} \tag{2e}$$

Here (2b) enforces that exactly one label is assigned to a variable, and (2c),(2d) that assignments are consistent across edges. To be concise, we will use $\mathcal{P}(G)$ to denote the set of $\boldsymbol{\mu}$ that satisfy the three constraints (2b),(2c),(2d). Thus,

the above problem (2) can be written concisely as: $\min_{\boldsymbol{\mu}\in\mathcal{P}(G),\ \mu_A(s)\in\{0,1\}} \sum_{A\in\mathcal{V}\cup\mathcal{E}} \boldsymbol{\theta}_A\cdot\boldsymbol{\mu}_A$.

MAP LP. Problem (2) is known to be NP-hard in general [21]. A number of techniques [8, 13, 19, 24, 26] solve a Linear Programming (LP) relaxation of this problem, which is given by relaxing the boolean constraints (2e) to the unit interval, *i.e.* $\mu_i(s), \mu_{ij}(s,t) \geq 0$. Thus, the MAP LP minimizes the energy over the following polytope: $\mathcal{L}(G) = \{\mu_A(\cdot) \geq 0, \mid \boldsymbol{\mu} \in \mathcal{P}(G)\}$, also known as the *local polytope*. The LP relaxation of MAP is known to be *tight* for special cases like tree-graphs and binary submodular energies [25], meaning that the optimal vertex of the local polytope is an integer $\boldsymbol{\mu}_A \in \{0,1\}$, for these special cases.

4 M-Best MAP Linear Program

Let us now revisit the M-Best MAP LP formulation [7]. Let $\boldsymbol{\mu}^m$ denote the m^{th}-best MAP. Thus $\boldsymbol{\mu}^1$ is the MAP, $\boldsymbol{\mu}^2$ is the second-best MAP and so on. The M-Best MAP integer program is given by

$$\boldsymbol{\mu}^M = \operatorname*{argmin}_{\boldsymbol{\mu}\in\mathcal{P}(G),\ \mu_A(s)\in\{0,1\}} \sum_{A\in\mathcal{V}\cup\mathcal{E}} \boldsymbol{\theta}_A\cdot\boldsymbol{\mu}_A \tag{3a}$$

$$s.t. \qquad \boldsymbol{\mu} \neq \boldsymbol{\mu}^m \quad \forall m \in [M-1] \tag{3b}$$

While the MAP integer program suggested a natural LP relaxation, that is not the case with the M-Best MAP integer program due to the exclusion constraints (3b), which are not linear constraints. Fromer and Globerson [7] introduced a concise representation of a polytope called *assignment-excluding local polytope* $\mathcal{L}(G, \{\boldsymbol{\mu}^m\}_1^{M-1})$ that excludes previous solutions $\{\boldsymbol{\mu}^m \mid m \in [M-1]\}$ with the help of additional linear inequalities, called the *spanning-tree inequalities*.

Spanning Tree Inequalities. Let $T \subseteq \mathcal{E}$ be a spanning tree of G, and $\mathcal{T}(G)$ be the set of all such spanning trees in G. Let d_i^T be the degree of node i in T. Let us define $I^T(\boldsymbol{\mu}, \boldsymbol{\mu}^m) \triangleq \sum_{i\in\mathcal{V}} (1-d_i^T)\,\boldsymbol{\mu}_i\cdot\boldsymbol{\mu}_i^m + \sum_{(i,j)\in T} \boldsymbol{\mu}_{ij}\cdot\boldsymbol{\mu}_{ij}^m$.

Now, a spanning tree inequality is defined as: $I^T(\boldsymbol{\mu}, \boldsymbol{\mu}^m) \leq 0$.

Notice that $I^T(\boldsymbol{\mu}^m, \boldsymbol{\mu}^m) = 1$. Moreover, it can be shown [7] that $I^T(\boldsymbol{\mu}, \boldsymbol{\mu}^m) \leq 0,\ \forall \boldsymbol{\mu} \neq \boldsymbol{\mu}^m$. Thus, the spanning tree inequality *separates* the vertex $\boldsymbol{\mu}^m$ from other vertices in the polytope.

Assignment-Excluding Local Polytope (AELP) is defined as:

$$\mathcal{L}(G, \{\boldsymbol{\mu}^m\}_1^{M-1}) = \Big\{ \boldsymbol{\mu} \;\Big|\; \boldsymbol{\mu} \in \mathcal{L}(G),\ I^T(\boldsymbol{\mu}, \boldsymbol{\mu}^m) \leq 0, \quad \forall T \in \mathcal{T}(G), \forall m \in [M-1] \Big\}. \tag{4}$$

Thus, we can see that the AELP excludes each of the previous solutions $\{\boldsymbol{\mu}^m \mid m \in [M-1]\}$ with the help of spanning tree inequalities.

Recall that the LP relaxation over the local polytope for a tree-structured MRFs is tight. It can also be shown [7] that the LP relaxation over AELP for tree MRFs is tight for $m = 2$. However, for $m \geq 3$ in tree MRFs and any for any $m \geq 1$ in loopy MRFs, the AELP is not guaranteed to be a tight relaxation.

Efficient Separation Oracle. Note that for tree MRFs, there is a single spanning tree inequality for each previous solution since $|\mathcal{T}(G)| = 1$, while for general graphs there may be an exponentially large collection of spanning trees, *e.g.* $|\mathcal{T}(G)| = n^{n-2}$ for complete graphs. However, not all such inequalities need to be explicitly included. We can use a cutting-plane algorithm that maintains a working set of spanning trees $\mathcal{T}'$ and incrementally adds the most violated inequality: $\mathcal{T}' \longleftarrow \mathcal{T}' \cup \operatorname{argmax}_{T\in\mathcal{T}(G)} I^T(\boldsymbol{\mu}, \boldsymbol{\mu}^m)$. For a given $\boldsymbol{\mu}$, Fromer and Globerson [7] showed that this separation oracle can be efficiently implemented with a maximum-weight spanning tree algorithm with the edge weights given by $w_{ij} = \boldsymbol{\mu}_{ij}\cdot\boldsymbol{\mu}_{ij}^m - \boldsymbol{\mu}_i\cdot\boldsymbol{\mu}_i^m - \boldsymbol{\mu}_j\cdot\boldsymbol{\mu}_j^m$.

Notice that this algorithm requires solving a linear program over the AELP in each iteration. For large problems arising in computer vision and computational biology, solving this LP with a standard LP-solver *even once* may be infeasible. In the next section, we present our proposed message-passing algorithm for solving the M-Best MAP LP.

5 M-Best MAP Lagrangian Relaxation: Tree-MRF

Let us first restrict our attention to tree-structured MRFs. This is simple enough a scenario to describe the main elements of our approach; we then discuss the general case in Section 6. For tree MRFs, there is a single spanning tree inequality (for each m), and to simplify notation we will refer to $I^T(\boldsymbol{\mu}, \boldsymbol{\mu}^m)$ simply as $I(\boldsymbol{\mu}, \boldsymbol{\mu}^m)$. Then M-Best MAP LP can be written as:

$$\min_{\boldsymbol{\mu}\in\mathcal{L}(G)} \quad \sum_{A\in\mathcal{V}\cup\mathcal{E}} \boldsymbol{\theta}_A\cdot\boldsymbol{\mu}_A \tag{5a}$$

$$s.t. \qquad I(\boldsymbol{\mu}, \boldsymbol{\mu}^m) \leq 0 \quad \forall m \in [M-1] \tag{5b}$$

Now instead of solving the above problem in the primal with an LP-solver as Fromer and Globerson [7] did, we will study the Lagrangian relaxation of this LP, formed by dualizing the spanning tree constraints:

$$f(\boldsymbol{\lambda}) = \min_{\boldsymbol{\mu}\in\mathcal{L}(G)} \sum_{A\in\mathcal{V}\cup\mathcal{E}} \boldsymbol{\theta}_A\cdot\boldsymbol{\mu}_A + \sum_{m=1}^{M-1} \lambda_m I(\boldsymbol{\mu}, \boldsymbol{\mu}^m), \tag{6}$$

where $\boldsymbol{\lambda} = \{\lambda_m \mid m \in [M-1]\}$ is the set of Lagrange multipliers, that determine the weight of the penalty imposed for violating the spanning tree constraints.

Note that this is a partial Lagrangian because we have only dualized the spanning tree constraints (5b), and have not dualized the constraints hidden inside the local polytope $\mathcal{L}(G)$.

Key Idea: Exploiting Structure. The partial Lagrangian immediately exposes a structure in the problem that the primal formulation was obfuscating, namely that the spanning tree inequality distributes according to a tree structure, *i.e.*

$$f(\boldsymbol{\lambda}) = \min_{\boldsymbol{\mu}\in\mathcal{L}(G)} \left\{ \sum_{i\in\mathcal{V}} \left(\boldsymbol{\theta}_i + \sum_{m=1}^{M-1} \lambda_m(1-d_i)\boldsymbol{\mu}_i^m\right)\cdot\boldsymbol{\mu}_i + \sum_{(i,j)\in\mathcal{E}} \left(\boldsymbol{\theta}_{ij} + \sum_{m=1}^{M-1}\lambda_m\boldsymbol{\mu}_{ij}^m\right)\cdot\boldsymbol{\mu}_{ij} \right\}. \quad (7)$$

Also recall that for a tree the local polytope $\mathcal{L}(G)$ has integral vertices. Thus the minimization above can be efficiently performed by running a combinatorial optimization algorithm (the standard two-pass max-product BP) on this perturbed MRF, and does not need to be solved with a generic LP solver. As we will see next, being able to efficiently *evaluate* the Lagrangian is all we need to be able to *optimize* the Lagrangian dual.

5.1 Projected Supergradient Ascent on the Lagrangian Dual

From the theory of Lagrangian duality, we know that for all values of $\boldsymbol{\lambda} \geq 0$, $f(\boldsymbol{\lambda})$ is a lower-bound on the value of the primal problem (5). The tightest lower-bound is obtained by solving the Lagrangian dual problem: $\max_{\boldsymbol{\lambda}\geq 0} f(\boldsymbol{\lambda})$. Since f is a non-smooth concave function, this can be achieved by the *supergradient ascent* algorithm, analogous to the subgradient descent for minimizing non-smooth convex functions [22]. Since $\boldsymbol{\lambda}$ is a constrained variable, we follow the projected supergradient ascent algorithm: iteratively updating the Lagrange multipliers according to the following update rule: $\boldsymbol{\lambda}^{(t+1)} \longleftarrow \left[\boldsymbol{\lambda}^{(t)} + \alpha_t \nabla f(\boldsymbol{\lambda}^{(t)})\right]_+$, where $\nabla f(\boldsymbol{\lambda}^{(t)})$ is the supergradient of f at $\boldsymbol{\lambda}^{(t)}$, α_t is the step-size and $[\cdot]_+$ is the projection operator that projects a vector onto the positive orthant. If the sequence of multipliers $\{\alpha_t\}$ satisfies $\alpha_t \geq 0$, $\lim_{t\to\infty}\alpha_t = 0$, $\sum_{t=0}^{\infty}\alpha_t = \infty$, then projected supergradient ascent converges to the optimum of the Lagrangian dual [22].

To find the supergradient of $f(\boldsymbol{\lambda})$, consider the following lemma (proved in [14]):

Lemma 1 *If $g(\boldsymbol{\lambda})$ is a point-wise minimum of linear functions:* i.e. $g(\boldsymbol{\lambda}) = \min_{\boldsymbol{\mu}} \boldsymbol{a}_{\boldsymbol{\mu}}\cdot\boldsymbol{\lambda} + b_{\boldsymbol{\mu}}$, *then one supergradient of g is given by $\nabla g(\boldsymbol{\lambda}) = \boldsymbol{a}_{\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda})}$, where $\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda}) \in \operatorname{argmin}_{\boldsymbol{\mu}} \boldsymbol{a}_{\boldsymbol{\mu}}\cdot\boldsymbol{\lambda} + b_{\boldsymbol{\mu}}$.*

Notice that f is indeed a point-wise minimum of linear functions. Mapping this lemma to (5), we can see that the supergradient of f for our formulation is given by:

$$\nabla f(\boldsymbol{\lambda}) = \left[I(\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda}), \boldsymbol{\mu}^1),\ \ldots,\ I(\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda}), \boldsymbol{\mu}^{M-1})\right]^T \quad (8)$$

where $\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda})$ is an optimal primal solution of (5) for the current setting of $\boldsymbol{\lambda}$. Thus the computation of the supergradient can be done with the same dynamic programming algorithm as for evaluating the Lagrangian.

This supergradient (and the update procedure) has an intuitive interpretation. Recall that the Lagrangian relaxation minimizes a linear combination of the energy and the value of the spanning tree inequality, with the weighting given by $\boldsymbol{\lambda}$. If $\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda}^{(t)})$ violates one of the spanning tree constraints, *i.e.* is not different from a previous solution $\boldsymbol{\mu}^m$, then the supergradient w.r.t. $\lambda_m^{(t)}$ will be positive and the cost for violating the constraint will increase after the update, thus encouraging the next solution $\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda}^{(t+1)})$ to satisfy the spanning tree constraints. Conversely, if the constraints are (strictly) satisfied, the supergradient is negative indicating that $\lambda_m^{(t)}$ may be over-penalizing for violations and may be reduced to allow lower energy solutions.

Tightness of the Lagrangian Relaxation. The primal problem (5) is an LP, and strong duality holds. Thus, the projected supergradient algorithm described above exactly solves the M-Best MAP LP of Fromer and Globerson [7]. The total complexity of the algorithm is $O(knL^2)$, where k is the number of dual ascent iterations, n is the number of nodes and L is the largest label space, *i.e.* $L = \max_i |X_i|$.

6 M-Best MAP Lagrangian Relaxation: General MRFs

In this section, we build on the basic ideas from the previous section to develop an algorithm for general graphs, which may contain exponentially many spanning trees. Recall that the M-Best MAP LP for general graphs is given by:

$$\min_{\boldsymbol{\mu}\in\mathcal{L}(G)} \sum_{A\in\mathcal{V}\cup\mathcal{E}} \boldsymbol{\theta}_A\cdot\boldsymbol{\mu}_A \quad (9a)$$

$$s.t. \quad I^T(\boldsymbol{\mu}, \boldsymbol{\mu}^m) \leq 0, \quad \forall T\in\mathcal{T}(G), \forall m\in[M-1] \quad (9b)$$

where $\mathcal{T}(G)$ is the set of all spanning trees in G. As before, the Lagrangian formed by dualizing the spanning tree constraints is given by:

$$f(\boldsymbol{\lambda}) = \min_{\boldsymbol{\mu}\in\mathcal{L}(G)} \sum_{A\in\mathcal{V}\cup\mathcal{E}} \boldsymbol{\theta}_A\cdot\boldsymbol{\mu}_A + \sum_{m=1}^{M-1}\sum_{T\in\mathcal{T}(G)} \lambda_{mT} I^T(\boldsymbol{\mu}, \boldsymbol{\mu}^m) \quad (10)$$

There are two main concerns that prevent us from directly solving this Lagrangian relaxation as before. First, the set of Lagrange multipliers $\boldsymbol{\lambda} = \{\lambda_{mT} \mid m \in [M-1], T\in\mathcal{T}(G)\}$ is exponentially large. And second, the graph is no longer a tree, so the supergradient can no longer be computed by max-product BP. We address both these concerns in the next subsections.

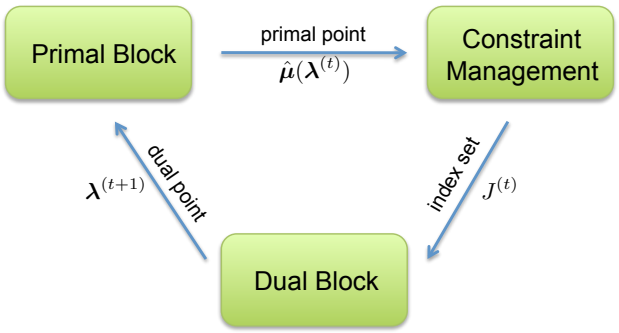

Figure 1: Overview of a Dynamic Supergradient Method. Figure adapted from [4].

6.1 Optimizing over Exponentially Many Dual Variables with a Dynamic Supergradient Method

In order to optimize over the exponentially large set of dual variables, we follow a *dynamic* supergradient method (DSM) (see [4] for an overview). Intuitively, DSMs can be thought of as the dual-procedure to the cutting-plane algorithm.

A DSM maintains an index set of *active* dual variables ($J = \cup_m J^m$, where $J^m \subset \{1, \ldots, |T(G)|\}$), and all inactive dual variables are fixed to zero, *i.e.* $\lambda_{mj} = 0,\ \forall j \notin J^m$. As visualized in Fig. 1, DSMs consist of three kinds of operations:

1. **Primal Block:** Given the current dual variable $\boldsymbol{\lambda}^{(t)}$, the primal block evaluates the Lagrangian (10) to find a new primal point $\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda}^{(t)})$.
2. **Constraint Management Block:** Given the current primal point $\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda}^{(t)})$, the constraint management block augments the index set of active dual variables to get the new index set $J^{(t)}$. Optionally, this block may also choose to drop some dual variables from the index set. This block is described in detail below.
3. **Dual Block:** Given the current index $J^{(t)}$, the dual block constructs the dual update direction (the supergradient) and stepsize to produce a new dual variable $\boldsymbol{\lambda}^{(t+1)}$ with $\lambda_{mj}^{(t+1)} = 0,\ \forall j \notin J^{m(t)}$.

The primal and dual blocks will be discussed in the next subsection, where we describe how the supergradient may be efficiently computed for general graphs.

We now describe the constraint management block in detail. To develop an intuition for this step, recall that the complementary slackness condition [2] tells us that given a pair of optimal primal dual variables ($\boldsymbol{\mu}^*$ and $\boldsymbol{\lambda}^*$): $I^T(\boldsymbol{\mu}^*, \boldsymbol{\mu}^m) < 0 \implies \lambda^*_{mT} = 0$. Thus, intuitively the active set $J^{(t)}$ must focus on the dual variables corresponding to the violated inequalities. We use a maximum violated oracle that adds to the active set $J^{m(t)}$, the index of the dual variable corresponding to the most violated inequality, *i.e.*

$$J^{m(t+1)} \longleftarrow J^{m(t)} \cup \text{index}(\hat{T}) \tag{11}$$

where,

$$\hat{T} = \operatorname*{argmax}_{T \in \mathcal{T}(G)} \sum_{(i,j) \in T} w_{ij}, \qquad \textbf{[Max-Wt Span-Tree]} \tag{12a}$$

$$w_{ij} = \hat{\boldsymbol{\mu}}_{ij}(\boldsymbol{\lambda}^{(t)}) \cdot \boldsymbol{\mu}^m_{ij} - \hat{\boldsymbol{\mu}}_i(\boldsymbol{\lambda}^{(t)}) \cdot \boldsymbol{\mu}^m_i - \hat{\boldsymbol{\mu}}_j(\boldsymbol{\lambda}^{(t)}) \cdot \boldsymbol{\mu}^m_j. \tag{12b}$$

We note that this process is the dualized version of the cutting-plane method of Fromer and Globerson [7], where instead of adding the most violated spanning tree inequality to the LP, we include the index of its dual variable to the working set.

It can be shown that a dynamic supergradient method with such a maximum-violation-oracle constraint management block is guaranteed to converge to the optimum of the Lagrangian relaxation with the same choice of stepsize rules as standard supergradient methods. A rigorous proof can be found here [4]. DSMs actually allow for dual variables to be removed from the active set as well, under certain conditions. However, to keep the exposition simple and to match our implementation, we do not discuss that here, and refer the reader to [4].

The theory allows for several iterations of primal and dual blocks to be performed for each constraint management step. We found this to be crucial in practice.

6.2 Computing the Supergradient for General Graphs

Now let us address the problem of computing the supergradient, and implementing the primal and dual blocks. Given the current index set of active dual variables $J = \cup_m J^m$, the supergradient w.r.t. the active dual variables $\boldsymbol{\lambda}_J$ is given by:

$$\nabla_{\lambda_{mj}} f(\boldsymbol{\lambda}) = I^j(\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda}), \boldsymbol{\mu}^m) \qquad \forall j \in J^m \tag{13}$$

where $\hat{\boldsymbol{\mu}}(\boldsymbol{\lambda})$ is an optimal primal solution of (10) for the current setting of $\boldsymbol{\lambda}$. For the case of tree-MRFs we could compute the optimal solution via dynamic programming. For general MRFs, the supergradient computation involves solving:

$$f(\boldsymbol{\lambda}) = \min_{\boldsymbol{\mu} \in \mathcal{L}(G)} \left\{ \sum_{i \in \mathcal{V}} \left(\boldsymbol{\theta}_i + \sum_{m=1}^{M-1} \sum_{j \in J^m} \lambda_{mj} (1 - d_i^{T_j}) \boldsymbol{\mu}_i^m \right) \cdot \boldsymbol{\mu}_i + \sum_{(i,j) \in \mathcal{E}} \left(\boldsymbol{\theta}_{ij} + \sum_{m=1}^{M-1} \sum_{j \in J^m} \lambda_{mj} \boldsymbol{\mu}_{ij}^m \right) \cdot \boldsymbol{\mu}_{ij} \right\}, \tag{14}$$

where G is now a graph with loops. Evaluating the above Lagrangian involves solving a MAP inference LP (with modified potentials) and thus any message-passing algorithm for MAP (MPLP [8], Dual-Decomposition [13], or Max-Sum Diffusion [26]) may

be used to solve this problem. However, unlike the two-pass max-product BP used for tree-MRFs, these message-passing algorithms typically require many hundreds of iterations to converge. Running these iterations for each step of supergradient ascent can (and in practice does) become prohibitively slow.

The key to speeding up this process is to realize that $f(\boldsymbol{\lambda})$ is a *partial* Lagrangian, and if evaluating it is difficult, then this suggests that some more constraints should be dualized till the partial Lagrangian becomes tractable. This is precisely what we do, using ideas from the dual-decomposition literature [9, 13].

Expanding the Partial Lagrangian. In order to expand the partial Lagrangian, we will first try to identify tractable (tree-structured) subcomponents. The spanning-tree inequalities are already tree structured. G is not, but we can convert it into a collection of tree-structured factors.

Let $TC(G) = \{T_1, \ldots, T_p\}$ be a *spanning-tree cover* of G, *i.e.* a collection of spanning trees such that each edge of G appears in at least one tree in $TC(G)$. Our approach doesn't really need the trees to be spanning, but we describe the following with a spanning-tree cover to keep the notation simple. With a slight abuse of notation, we use $TC(i,j)$ to denote the subset of trees that contain edge $(i,j) \in \mathcal{E}$. Moreover, we decompose the original energy function $\boldsymbol{\theta}$ into a collection of energy functions $\{\boldsymbol{\theta}^T \mid T \in TC(G)\}$, one for each tree in the tree cover, such that:

$$\sum_{T \in TC(G)} \boldsymbol{\theta}_i^T = \boldsymbol{\theta}_i \;\; \forall i \in \mathcal{V} \quad \& \quad \sum_{T \in TC(i,j)} \boldsymbol{\theta}_{ij}^T = \boldsymbol{\theta}_{ij} \;\; \forall (i,j) \in \mathcal{E} \tag{15a}$$

$$\implies \sum_{T \in TC(G)} \boldsymbol{\theta}^T \cdot \boldsymbol{\mu} = \boldsymbol{\theta} \cdot \boldsymbol{\mu} \tag{15b}$$

This can be easily satisfied by distributing the node and edge energies "evenly", *i.e.* $\boldsymbol{\theta}_i^T = \frac{1}{|T(G)|}\boldsymbol{\theta}_i$, $\boldsymbol{\theta}_{i,j}^T = \frac{1}{|T(i,j)|}\boldsymbol{\theta}_{ij}$. Thus, these energies specify a tree decomposition [24] of $\boldsymbol{\theta}$.

Let us now assign to each tree in $TC(G)$, its own copy of the primal variables $\boldsymbol{\mu}^T$, $\forall T \in TC(G)\}$. Also assign to each spanning tree inequality in the active set J^m, its own copy of the primal variables $\boldsymbol{\mu}^{mj}$, $\forall j \in J^m$. Finally, we use $\boldsymbol{\theta}_i^{mj} \triangleq \lambda_{mj}(1-d_i)\boldsymbol{\mu}_i^m$ to denote the node energy of the spanning tree factor $j \in J^m$, and $\boldsymbol{\theta}_i^{mj} = \lambda_{mj}\boldsymbol{\mu}_{ij}^m$ to denote the edge energy.

With these new variables, we can now write the existing partial Lagrangian as:

$$f(\boldsymbol{\lambda}) = \min_{\boldsymbol{\mu} \in \mathcal{L}(G), \tilde{\boldsymbol{\mu}}} \left\{ \sum_{T \in TC(G)} \boldsymbol{\theta}^T \cdot \boldsymbol{\mu}^T + \sum_{m=1}^{M-1} \sum_{j \in J^m} \boldsymbol{\theta}^{mj} \cdot \boldsymbol{\mu}^{mj} \right\} \tag{16a}$$

$$s.t. \quad \boldsymbol{\mu}_i^\tau = \tilde{\boldsymbol{\mu}}_i \qquad \forall \tau \in TC(G) \cup J, \;\; \forall i \in \mathcal{V} \tag{16b}$$

This formulation of the partial Lagrangian uses a global variable $\tilde{\boldsymbol{\mu}}$ to force all tree-structured subproblems to agree on the labellings at the nodes, and thus is equivalent to the earlier formulation (14). However, we can now expand this partial Lagrangian by further dualizing these constraints (16b):

$$f(\boldsymbol{\lambda}, \boldsymbol{\delta}) = \min_{\boldsymbol{\mu}^\tau \in \mathcal{L}(\tau), \tilde{\boldsymbol{\mu}}} \left\{ \sum_{T \in TC(G)} \boldsymbol{\theta}^T \cdot \boldsymbol{\mu}^T + \sum_{m=1}^{M-1} \sum_{j \in J^m} \boldsymbol{\theta}^{mj} \cdot \boldsymbol{\mu}^{mj} + \sum_{\tau \in TC(G) \cup J} \sum_{i \in \mathcal{V}} \boldsymbol{\delta}_{\tau i} \cdot \left(\boldsymbol{\mu}_i^\tau - \tilde{\boldsymbol{\mu}}_i \right) \right\} \tag{17}$$

where $\boldsymbol{\delta} = \{\boldsymbol{\delta}_{\tau i} \mid \forall \tau \in TC(G) \cup J, \;\; \forall i \in \mathcal{V}\}$ is the set of Lagrangian multipliers for the dualized equality constraints, and $\mathcal{L}(\tau)$ is now the local polytope of each of the tree-structured subproblems.

Notice that this expanded partial Lagrangian completely decouples into independent minimizations over tree-structured subproblems:

$$f(\boldsymbol{\lambda}, \boldsymbol{\delta}) = \sum_{\tau \in TC(G) \cup J} \min_{\boldsymbol{\mu}^\tau \in \mathcal{L}(\tau)} \left\{ \sum_{i \in \mathcal{V}} \left(\boldsymbol{\theta}_i^\tau + \boldsymbol{\delta}_{\tau i} \right) \cdot \boldsymbol{\mu}_i^\tau + \sum_{(i,j) \in \mathcal{E}} \boldsymbol{\theta}_{ij}^\tau \cdot \boldsymbol{\mu}_{ij}^\tau \right\} - \min_{\tilde{\boldsymbol{\mu}}} \left(\sum_{\tau \in TC(G) \cup J} \sum_{i \in \mathcal{V}} \boldsymbol{\delta}_{\tau i} \right) \cdot \tilde{\boldsymbol{\mu}}_i \tag{18}$$

We can see that the unconstrained minimization over $\tilde{\boldsymbol{\mu}}$ forces a constraint on the Lagrangian variables, *i.e.* $\sum_{\tau \in TC(G) \cup J} \sum_{i \in \mathcal{V}} \boldsymbol{\delta}_{\tau i} = 0$; otherwise the Lagrangian will not have finite value. We denote by $\Delta \triangleq \{\boldsymbol{\delta} \mid \sum_{\tau \in TC(G) \cup J} \sum_{i \in \mathcal{V}} \boldsymbol{\delta}_{\tau i} = 0\}$, the set of all feasible Lagrangian multipliers $\boldsymbol{\delta}$.

Note that the expanded partial Lagrangian can be efficiently evaluated by running two-pass max-product BP on each of the tree-structured subproblems. The number of such tree-structured subproblems is equal to $|TC(G)|+|J|$, *i.e.* the size of the spanning-tree cover (upper bounded by n, and typically a small constant) and the number of active spanning tree inequalities.

Optimizing the Expanded Partial Lagrangian. The dual problem for the expanded partial Lagrangian is given by $\max_{\boldsymbol{\lambda} \geq 0, \boldsymbol{\delta} \in \Delta} f(\boldsymbol{\lambda}, \boldsymbol{\delta})$. In the previous section, we described how the dual of the partial Lagrangian $f(\boldsymbol{\lambda})$ can be optimized with a dynamic supergradient method. Optimizing the dual of the expanded Lagrangian is very similar to the described procedure, with the minor modification that the dual variable $\boldsymbol{\delta}$ always stays in the active set J.

The supergradient w.r.t. $\boldsymbol{\delta}$ is given by:

$$\nabla_{\boldsymbol{\delta}_{\tau i}} f(\boldsymbol{\lambda}, \boldsymbol{\delta}) = \hat{\boldsymbol{\mu}}_i^\tau(\boldsymbol{\lambda}, \boldsymbol{\delta}) \quad \forall \tau \in TC(G) \cup J \;\; \forall i \in \mathcal{V}, \tag{19}$$

where $\hat{\boldsymbol{\mu}}_i^\tau(\boldsymbol{\lambda}, \boldsymbol{\delta})$ is an optimal primal solution of the tree suproblem τ for the current setting of $\boldsymbol{\lambda}$ and $\boldsymbol{\delta}$.

The projection step onto Δ is fairly simple – it involves satisfying the zero-sum constraint, which can

be enforced by subtracting the mean of the dual variables. Overall, the dual update w.r.t. $\boldsymbol{\delta}$ is given by $\boldsymbol{\delta}^{(t+1)} = \left[\boldsymbol{\delta}^{(t)} + \alpha_t \nabla_{\boldsymbol{\delta}} f(\boldsymbol{\lambda}^{(t)}, \boldsymbol{\delta}^{(t)})\right]_0$, where α_t is the stepsize and $[\cdot]_0$ is the zero-projection operator *i.e.* $[\boldsymbol{\delta}^{(t)}]_0 = \{\boldsymbol{\delta}^{(t)}_{\tau i} - s \mid \forall \tau \in TC(G) \cup J,\ \forall i \in \mathcal{V}\}$, where $s = \frac{1}{|\boldsymbol{\delta}|} \sum_{\tau' \in TC(G) \cup J} \sum_{j \in \mathcal{V}} \boldsymbol{\delta}^{(t)}_{\tau' j}$.

The entire algorithm is summarized in Algorithm 1. We call our algorithm STEELARS for Spanning TrEe inEquality LAgrangian Relaxation Scheme.

Algorithm 1 STEELARS

$(\boldsymbol{\mu}^*, \{\boldsymbol{\lambda}^*, \boldsymbol{\delta}^*\}) = \text{STEELARS}(G, \theta, \{\boldsymbol{\mu}^m\})$
Input: $G = (\mathcal{V}, \mathcal{E})$, graph instance,
$\boldsymbol{\theta} = \{\theta_A \mid A \in \mathcal{V} \cup \mathcal{E}\}$ energy vector
$\{\boldsymbol{\mu}^m \mid m \in [M-1]\}$, $M-1$ previous solutions
Output: $\boldsymbol{\mu}^*_A \in [0,1]^{X_A}$, optimum solution vector to M-Best MAP LP
$\{\boldsymbol{\lambda}^*, \boldsymbol{\delta}^*\}$, optimum dual variables
Algorithm:
Construct a tree-decomposition of G: $TC(G), \{\boldsymbol{\theta}^T \mid T \in TC(G)\}$

Tightness of STEELARS. At first glance, it may seem like the expanded partial Lagrangian (18) solves a weaker relaxation than our original partial Lagrangian (10). However, similar to our argument in the tree-MRF case, problem (9) is an LP. Thus, strong duality holds and *all* partial Lagrangians achieve the same optimum. This implies that even for non-tree MRFs, STEELARS *exactly* solves the M-Best MAP LP of Fromer and Globerson [7] and does not introduce any new approximation gap to the integer program. Moreover, this guarantee this does not depend on the choice of the spanning-tree cover $TC(G)$; in fact, any tree cover (even non-spanning) may be used.

Finally, note that we described the expanded partial Lagrangian in terms of tree-structured subproblems. However, any efficient subproblem may be used, *e.g.* submodular subproblems solved with graph-cuts [12].

7 Experiments

Setup. We tested our algorithm in three scenarios:

1. Tree MRFs with $M = 2$. This is the simplest case, where the M-Best MAP LP is guaranteed to be tight. Moreover, there is a single spanning tree inequality and the constraint management block plays no role.
2. 2-label Submodular MRFs with $M = 5$. For such problems the MAP LP is guaranteed to be tight, but not the M-Best MAP LP. Moreover, a tree decomposition is not required because the 2-label submodular factor may be efficiently minimized via graph-cuts [12].
3. General 4-label loopy MRFs with $M = 5$. This is the most general case described in Section 6.

Baselines. We compared our algorithm with the STRIPES algorithm of Fromer and Globerson [7], the Lawler-Nilsson algorithm [16,18], and the BMMF algorithm of Yanover and Weiss [28]. Recall that STRIPES does not directly solve the M-Best MAP LP, but rather solves a sequence of 2nd-Best MAP LPs encapsulated in the Lawler-Nilsson [16, 18] partitioning scheme. This is a tradeoff between efficiency and accuracy – it would be more efficient to directly solve the M-Best MAP LP, but the LP is fractional and thus the partitioning scheme performs better. Note that STEELARS could also be encapsulated in the Lawler-Nilsson [16, 18] partitioning scheme in a straightforward manner. However, we wish to study the performance of the Lagrangian relaxation for the M-Best MAP LP directly, and leave this partitioning scheme extension for future work.

Implementation details. The implementations for STRIPES and Lawler-Nilsson were provided by the authors of [7], while BMMF is provided by the authors of [28]. For STRIPES, the LPs in each iteration were solved using the `GNU LPK` library. STEELARS is implemented in MATLAB, but max-product BP is

written in C++ for efficiency. All experiments are performed on a 64-bit 8-Core Intel i7 machine with 12GB RAM and the timing reported is cputime. Following [15], we chose the stepsize at iteration t to be $\alpha_t = \frac{1}{\eta_t+1}$, where η_t is the number of times the objective value $f(\boldsymbol{\lambda}^{(t)}, \boldsymbol{\delta}^{(t)})$ has decreased from one iteration to the next. This rule has the same convergence guarantees as the standard $\alpha_t = \frac{1}{t}$ decaying rule, but empirically performs much better.

Integer Primal Extraction. STEELARS is a dual-ascent algorithm and thus always maintains a feasible dual solution, but not necessarily an (integer) primal feasible solution, which is what we are interested in. However, since the primal block is repeatedly called for computing the supergradient, we simply keep track of the best (integer) primal feasible solution produced so far, and output that at the end of the algorithm.

Evaluation. We compare different algorithms on two metrics – run-time and accuracy of solutions returned. For tree-MRFs with $M = 2$ all methods are guaranteed to return exact solutions, and thus we can simply compare the run-times. For general MRFs, we follow the protocol of [7] and measure relative accuracy of different methods. Specifically, we pool all solutions returned by all methods, note the top M solutions in this pool, and then for each method report the fraction of these solutions that it contributed.

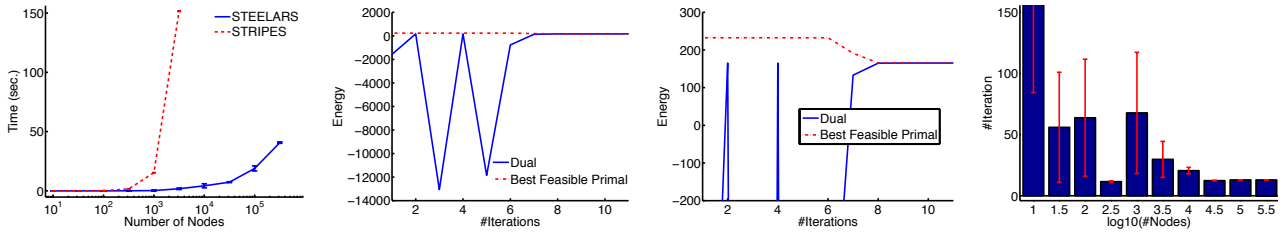
Our results will demonstrate the effectiveness of STEELARS primarily in terms of efficiency. We will show that since STEELARS is a message-passing algorithm it is significantly faster than a generic LP solver (`GLPK`), sometimes by *orders of magnitude* even though it is guaranteed to converge to the same solution. STEELARS naturally scales to large instances that were previously unsolvable using LP solvers.

Tree MRFs with $M = 2$. We generated synthetic problems by sampling random spanning trees on n nodes. Each variable could take 4 labels. Node and edge potentials were sampled from standard Gaussians. For $M = 2$ the M-Best MAP LP is guaranteed to be tight, and thus both STRIPES and STEELARS produces precisely the same answers. Fig. 2a shows the time taken by both algorithms as a function of the size of the tree n, averaged over 5 samplings of the parameters. Note that the x-axis is in log-scale. As n increase, STRIPES very quickly becomes intractable, with `GPLK` ultimately running out of memory. However, STEELARS shows a much better behaviour in runtime. Fig. 2 also shows the value of the dual and best feasible integer primal produced by STEELARS as a function of the number of iterations. Recall that for STEELARS each iteration corresponds to running max-product BP on a single tree. Fig. 2d shows that generally the number of such iterations is pretty low $\sim$ 12. Note that since this is a tree MRF, BMMF would only require 2 call to BP to compute max-marginals under its partitioning scheme (assuming it was carefully implemented to recognize a tree-graph and not run asynchronous BP). Thus STEELARS is not too much slower than the optimal thing to do for a tree. Of course, BMMF would also require multiple iterations of synchronous BP on loopy graphs, which is what we checked next.

2-label Submodular MRFs. For this scenario, we constructed $\sqrt{n} \times \sqrt{n}$ grids. Each variable could take 2 labels. We again sampled node and edge energies from Gaussians, but ensured that edge energies were submodular. This allows for the use of graph-cuts [12] for optimizing the submodular factor. Fig. 3 shows the value of the dual and best feasible integer primal as a function of the number of iterations. The sharp falls in the dual correspond to the constraint management block calling the separation oracle to increment the working set. Each iteration now involves one call to graph-cuts and $|J^{(t)}|$ calls to two-pass max-product BP. Notice that the number of iterations are much larger than for the tree MRF ($\sim$150 as opposed to 12). However, max-flow algorithms in general and the implementation of [12] in particular, are highly efficient. Fig. 3a shows the run-time of all algorithms as a function of n. We can see that STEELARS is by far the fastest, with other algorithms becoming intractable very quickly. Unfortunately, as Fig. 3d shows it is also the least accurate, validating the choice of Fromer and Globerson [7] to not solve the LP directly, and use a partitioning scheme instead. We plan to follow up on this direction.

Interestingly, Fig. 3a seems to suggest that BMMF performs worse than STRIPES, even though BMMF simply involves M calls to loopy BP. We believe this an artifact caused by the fact that the BMMF implementation of [28] is written in MATLAB, and not particularly optimized. Moreover, in this specific experiment, it could be made faster by computing max-marginals via the approach of [11] instead of loopy BP. At a high-level, the key difference between BMMF and STEELARS is analogous to the difference between loopy BP and MPLP – both are message-passing algorithms, but only one solves the LP relaxation and provides improving lower-bounds.

General MRFs. For this scenario, we constructed $\sqrt{n} \times \sqrt{n}$ grid graphs as well, but each variable could take 4-labels and edge energies were not restricted to be "attractive". We used a standard two-tree decomposition of the grid graph. Thus, each iteration of supergradient ascent involved $2 + |J^{(t)}|$ calls to max-product BP. We observed trends similar to the submodular MRFs case, both in terms of number of iterations required for STEELARS to converge, and in the relative standing w.r.t. the baselines. This case is



(a) Time vs. n (b) Primal and Dual vs. Iterations. (c) Primal and Dual vs. Iterations (Zoomed). (d) No. of Supergradient Iterations.

specially interesting because for small values of $|J^{(t)}|$, the work done by STEELARS (*i.e.* ∼150 iteration of two-pass BP) for solving M-Best MAP is comparable to running TRW [13,24] for MAP. Moreover, we could run STEELARS on a 300×500 image labelling problem, but similar to the observation of [27], could not even solve the MAP LP with `GLPK`.

8 Conclusions

In conclusion, we presented the *first* message-passing algorithm for solving the LP relaxation of the M-Best MAP problem in discrete undirected graphical models. Our approach used a particular Lagrangian relaxation to construct a partial Lagrangian that allowed the use of combinatorial optimization algorithms. To handle the exponentially large set of constraints, we used a dynamic supergradient scheme that is essentially a dual procedure to the cutting-plane algorithm. Our message-passing algorithm retains all the guarantees of the LP formulation of Fromer and Globerson [7], while being *orders of magnitude* faster.

Extracting Diverse M-Best Solutions. In a number of applications, especially computer vision, the M-Best MAP solutions are essentially minor perturbations of each other. In concurrent work [1], we have also presented a solution to the *Diverse* M-Best MAP problem, where given a measure of 'distance' between two solutions, we block all solutions within some k-distance-ball of the previous solutions.

We hope that both these algorithms will be useful for practitioners where the problem size prohibits the use of generic LP-solvers.

Future Work. There are a number of interesting directions in front of us. In the short-term, we are interested in encapsulating STEELARS inside the Lawler-Nilsson partitioning scheme, similar to STRIPES to further increase the accuracy of the method. Since the M-Best MAP LP is so often fractional, another direction is to *tighten* the LP, *e.g.* using techniques proposed by Sontag *et al.* [23]. It would also be interesting to compare LP-relaxation based methods like STRIPES and STEELARS with heurisitic-search methods [3].

Acknowledgements. We thank Sebastian Nowozin for being the human encyclopedia of optimization and pointing us to the literature of Dynamic Subgradient Methods; Amir Globerson for sharing the STRIPES implementation and useful discussions; Danny Tarlow for discussions that helped formalize the formulation.

Abstract

We propose an approach to lifted approximate inference for first-order probabilistic models, such as Markov logic networks. It is based on performing exact lifted inference in a simplified first-order model, which is found by relaxing first-order constraints, and then compensating for the relaxation. These simplified models can be incrementally improved by carefully recovering constraints that have been relaxed, also at the first-order level. This leads to a spectrum of approximations, with lifted belief propagation on one end, and exact lifted inference on the other. We discuss how relaxation, compensation, and recovery can be performed, all at the first-order level, and show empirically that our approach substantially improves on the approximations of both propositional solvers and lifted belief propagation.

1 INTRODUCTION

Probabilistic logic models combine aspects of first-order logic and probabilistic graphical models, enabling them to model complex logical and probabilistic interactions between large numbers of objects (Getoor and Taskar, 2007; De Raedt et al., 2008). This level of expressivity comes at the cost of increased complexity of inference, motivating a new line of research in lifted inference algorithms (Poole, 2003). These algorithms exploit logical structure and symmetries in probabilistic logics to perform efficient inference in these models.

For exact inference, lifted variants of variable elimination (Poole, 2003; de Salvo Braz et al., 2005; Milch et al., 2008; Taghipour et al., 2012) and weighted model counting (Gogate and Domingos, 2011; Van den Broeck et al., 2011) have been proposed. With some exceptions, lifted approximate inference has focused on lifting iterative belief propagation (Singla and Domingos, 2008; Kersting et al., 2009).

In this paper, we propose an approach to *approximate* lifted inference that is based on performing *exact* lifted inference in a simplified first-order model. Namely, we simplify the structure of a first-order model until it is amenable to exact lifted inference, by relaxing first-order equivalence constraints in the model. Relaxing equivalence constraints ignores (many) dependencies between random variables, so we compensate for this relaxation by restoring a weaker notion of equivalence, in a lifted way. We then incrementally improve this approximation by recovering first-order equivalence constraints back into the model.

In fact our proposal corresponds to an approach to approximate inference, called Relax, Compensate and then Recover (RCR) for (ground) probabilistic graphical models.[1] For such models, the RCR framework gives rise to a spectrum of approximations, with iterative belief propagation on one end (when we use the coarsest possible model), and exact inference on the other (when we use the original model). In this paper, we show how relaxations, compensations and recovery can all be performed at the first-order level, giving rise to a spectrum of first-order approximations, with lifted first-order belief propagation on one end, and exact lifted inference in the other.

We evaluate our approach on benchmarks from the lifted inference literature. Experiments indicate that recovering a small number of first-order equivalences can improve on the approximations of lifted belief propagation by several orders of magnitude. We show that, compared to Ground RCR, Lifted RCR can re-

*Part of this research was conducted while the author was a visiting student at UCLA.

[1] A solver based on the RCR framework won first place in two categories evaluated at the UAI'10 approximate inference challenge (Elidan and Globerson, 2010).

cover many more equivalences in the same amount of time, leading to better approximations.

2 RCR FOR GROUND MLNs

While our main objective is to present a lifted version of the RCR framework, we start by adapting RCR to ground Markov logic networks (MLNs). This is meant to both motivate the specifics of Lifted RCR and to provide a basis for its semantics (i.e., the correctness of Lifted RCR will be against Ground RCR). RCR can be understood in terms of three steps: Relaxation (R), Compensation (C), and Recovery (R). Next, we introduce MLNs and examine each of these steps.

2.1 MARKOV LOGIC NETWORKS

We first introduce some standard concepts from function-free first-order logic. An *atom* $\mathrm{p}(t_1, \ldots, t_n)$ consists of a predicate p/n of arity n followed by n arguments, which are either (lowercase) *constants* or (uppercase) *logical variables*. A formula combines atoms with logical connectives (e.g., $\wedge$, $\Leftrightarrow$). A formula is *ground* if it does not contain any logical variables. The groundings of a formula are the formulas obtained by substituting all variables for constants.

Many probabilistic logical languages have been proposed in recent years. We will work with one such language: Markov logic networks (MLN) (Richardson and Domingos, 2006). An MLN is a set of tuples (w, f), where w is a real number representing a weight and f is a formula in function-free first-order logic. First-order logic formulas without a weight are called *hard formulas* and correspond to formulas with an infinite weight. We will assume that all logical variables in f are universally quantified.[2] Consider the MLN

$$1.3 \quad \mathrm{smokes}(X) \Rightarrow \mathrm{cancer}(X) \tag{1}$$
$$1.5 \quad \mathrm{smokes}(X) \wedge \mathrm{friends}(X, Y) \Rightarrow \mathrm{smokes}(Y) \tag{2}$$

which states that (1) smokers are more likely to get cancer and (2) smokers are more likely to be friends with other smokers (Singla and Domingos, 2008). This MLN will be a running example throughout this paper.

The *grounding* of an MLN Δ is the MLN which results from replacing each formula in Δ with all its groundings (using the same weight). For the domain $\{a, b\}$, the above first-order MLN represents the following ground MLN:

$$1.3 \quad \mathrm{smokes}(a) \Rightarrow \mathrm{cancer}(a) \tag{3}$$
$$1.3 \quad \mathrm{smokes}(b) \Rightarrow \mathrm{cancer}(b)$$
$$1.5 \quad \mathrm{smokes}(a) \wedge \mathrm{friends}(a, a) \Rightarrow \mathrm{smokes}(a)$$
$$1.5 \quad \mathrm{smokes}(a) \wedge \mathrm{friends}(a, b) \Rightarrow \mathrm{smokes}(b)$$
$$1.5 \quad \mathrm{smokes}(b) \wedge \mathrm{friends}(b, a) \Rightarrow \mathrm{smokes}(a)$$
$$1.5 \quad \mathrm{smokes}(b) \wedge \mathrm{friends}(b, b) \Rightarrow \mathrm{smokes}(b)$$

This ground MLN contains eight different random variables, which correspond to all groundings of atoms $\mathrm{smokes}(X)$, $\mathrm{cancer}(X)$ and $\mathrm{friends}(X, Y)$. This leads to a distribution over 2^8 possible worlds. The weight of each world is simply the product of all weights e^w, where (w, f) is a ground MLN formula and f is satisfied by the world. The weights of worlds that do not satisfy a hard formula are set to zero. The probabilities of worlds are obtained by normalizing their weights. The *ground distribution* of Δ is the distribution induced by the grounding of Δ.

2.2 GROUND RELAXATION

Relaxation is the process of ignoring interactions between the formulas of a ground MLN. An interaction takes place when the same ground atom a_g appears in more than one ground formula in an MLN. We can ignore this interaction via a two step process. First, we rename one occurrence of a_g into, say, a'_g, through a process that we call *cloning*. We then assert an equivalence constraint between the original ground atom a_g and its clone, $a_g \Leftrightarrow a'_g$. At this point, we can ignore the interaction by simply dropping the equivalence constraint, through a process that we call *relaxation*. Bringing back the equivalence is known as *recovery* and will be discussed in more detail later.

The $\mathrm{smokes}(a)$ atom in Formula 3 leads to an interaction between this formula and some of the other five formulas in the ground MLN. To ignore this interaction, we first rename this atom occurrence into $\mathrm{smokes}_1(a)$ leading to the modified formula

$$1.3 \quad \mathrm{smokes}_1(a) \Rightarrow \mathrm{cancer}(a) \tag{4}$$

which replaces Formula 3 in the MLN. The corresponding equivalence constraint is

$$\mathrm{smokes}_1(a) \Leftrightarrow \mathrm{smokes}(a) \tag{5}$$

Dropping this constraint amounts to removing the interaction between Formula 4 and the rest of the MLN.

2.3 GROUND COMPENSATION

When relaxing a constraint $a_g \Leftrightarrow a'_g$, we ignore a connection between the ground atoms a_g and a'_g. We can *compensate* for this loss by adding two weighted atoms

$$w: \quad a_g \qquad \text{and} \qquad w': \quad a'_g$$

If the weights w and w' are chosen carefully, one can reestablish a weaker connection between the ground

[2] We transform existential quantifiers into disjunctions.

atoms. For example, one can choose these weights to ensure that the ground atoms have the same probability, establishing a weaker notion of equivalence.

We will now suggest a specific compensation scheme based on a key result from Choi and Darwiche (2006). Suppose that we relax a single equivalence constraint, $a_g \Leftrightarrow a'_g$, which splits the MLN into two disconnected components, one containing atom a_g and another containing atom a'_g. Suppose further that we choose the compensations w and w' such that

$$\Pr(a_g) = \Pr(a'_g) = \frac{e^{w+w'}}{1+e^{w+w'}}. \quad (6)$$

We now have a number of guarantees. First, the resulting MLN will yield exact results when computing the probability of any ground atom. Second, the compensations w and w' can be identified by finding a fixed point for the following equations:

$$\begin{aligned} w_{i+1} &= \log\left(\Pr_i(a'_g)\right) - \log\left(\Pr_i(\neg a'_g)\right) - w'_i \\ w'_{i+1} &= \log\left(\Pr_i(a_g)\right) - \log\left(\Pr_i(\neg a_g)\right) - w_i. \end{aligned} \quad (7)$$

Following Choi and Darwiche (2006), we will seek compensations using these update equations even when the relaxed equivalence constraint does not disconnect the MLN, and even when relaxing multiple equivalence constraints. In this more general case, a fixed-point to the above equations will still guarantee the weak equivalence given in (6). However, when computing the probabilities of ground atoms, we will only get approximations instead of exact results.[3]

Searching for compensations using Equations 7 will lead to the generation of a sequence of MLNs that differ only on the weights of atoms added during the compensation process. The first MLN in this sequence is obtained by using zero weights for all compensating atoms, leading to an initial ground distribution $\Pr_0$. Each application of Equations 7 will then lead to a new MLN (with new compensations) and, hence, a new ground distribution, $\Pr_{i+1}$. Upon convergence, the resulting MLN and its ground distribution will then be used for answering queries. This is typically done using an exact inference algorithm as one usually relaxes enough equivalence constraints to make the ground MLN amenable to exact inference. Note that applying Equations 7 also requires exact inference, as one must compute the probabilities $\Pr_i(a_g)$ and $\Pr_i(a'_g)$.

2.4 GROUND RECOVERY

Now that we can relax equivalences and compensate for their loss, the remaining question is which equivalences to relax. In general, deciding which equivalences to relax is hard, because it requires inference in the original model, which is intractable. Instead, Choi and Darwiche (2006) take the approach of relaxing every equivalence constraint and then incrementally recovering them as time and exact inference allow.

It follows from their results that when (i) relaxing all equivalence constraints, (ii) using the above compensation scheme and (iii) doing exact inference in the approximate model, the approximate marginals found correspond to the approximations found by *iterative belief propagation* (IBP) (Pearl, 1988). The connection to IBP is even stronger: the compensating weights computed in each iteration of Equations 7 exactly correspond to the messages passed by IBP.

Several heuristics have been proposed to decide which equivalences to recover, by doing inference in the relaxed model. We will work with the *residual recovery* heuristic (Choi and Darwiche, 2011). It is based on the practical observation that when IBP converges easily, the quality of its approximation is high. The heuristic tries to recover those constraints that have the most difficulty converging throughout the iterative process, i.e., those that least satisfy Equation 6. We measure this by keeping track of the three-way symmetric KL divergence between the three terms of Equation 6.

3 LIFTED RCR

We now introduce a lifted version of the relax, compensate and recover framework, which is meant to operate directly on first-order MLNs without necessarily having to ground them. Lifted RCR is based on first-order relaxation, compensation and recovery.

3.1 FIRST-ORDER RELAXATION

We will now discuss a first-order notion of relaxation where the goal is to ignore interactions between ground MLN formulas, yet without necessarily having to fully ground the MLN. This requires a first-order version of atom cloning and first-order equivalences.

Definition 1 (First-Order Cloning)**.** Cloning an atom occurrence in an MLN formula amounts to renaming the atom by concatenating its predicate with (i) an identifier of the formula, (ii) an identifier of the occurrence of the atom within the formula, and (iii) the logical variables appearing in the atom's formula.

For example, the first-order cloning of the atom occurrence $\text{smokes}(Y)$ in Formula 2 gives

$$1.5 \quad \text{smokes}(X) \wedge \text{friends}(X,Y) \Rightarrow \text{smokes}_{2b<X,Y>}(Y) \quad (8)$$

[3] In this more general case, there is no longer a guarantee that Equations 7 will converge to a fixed point. Convergence can be improved by using damping in Equations 7.

Here, 2 is an identifier of the formula, b is an identifier of the atom occurrence in the formula, and $<X, Y>$ are the logical variables appearing in the formula.

As in the ground case, each first-order cloning is associated with a corresponding equivalence between the original atom and its clone, except that the equivalence is first-order in this case. The first-order cloning of atom occurrence $\text{smokes}(Y)$ into $\text{smokes}_{2b<X,Y>}(Y)$ in the example above leads to introducing the following first-order equivalence:

$$\text{smokes}(Y) \Leftrightarrow \text{smokes}_{2b<X,Y>}(Y) \tag{9}$$

Let us now consider the groundings of Formulas 8 and 9, assuming a domain of $\{a, b\}$:

$$\begin{aligned}
1.5 \quad & \text{smokes}(a) \wedge \text{friends}(a,a) \Rightarrow \text{smokes}_{2b<a,a>}(a) \\
1.5 \quad & \text{smokes}(a) \wedge \text{friends}(a,b) \Rightarrow \text{smokes}_{2b<a,b>}(b) \\
1.5 \quad & \text{smokes}(b) \wedge \text{friends}(b,a) \Rightarrow \text{smokes}_{2b<b,a>}(a) \\
1.5 \quad & \text{smokes}(b) \wedge \text{friends}(b,b) \Rightarrow \text{smokes}_{2b<b,b>}(b) \\
& \text{smokes}(a) \Leftrightarrow \text{smokes}_{2b<a,a>}(a) \\
& \text{smokes}(b) \Leftrightarrow \text{smokes}_{2b<a,b>}(b) \\
& \text{smokes}(a) \Leftrightarrow \text{smokes}_{2b<b,a>}(a) \\
& \text{smokes}(b) \Leftrightarrow \text{smokes}_{2b<b,b>}(b)
\end{aligned}$$

We have a few observations on the proposed cloning and relaxation techniques. First, the four groundings of (8) contain distinct groundings of the clone $\text{smokes}_{2b<X,Y>}(Y)$. Second, if we relax the equivalence in (9), the ground formulas of (8) will no longer interact through the clone $\text{smokes}_{2b<X,Y>}(Y)$. Third, if we did not append the logical variables $<X, Y>$ during the cloning process, the previous statement would no longer hold. In particular, without appending logical variables, the four groundings of (8) would have contained only the two distinct clone groundings, $\text{smokes}_{2b}(a)$ and $\text{smokes}_{2b}(b)$. This will lead to continued interactions between the four groundings of (8).[4]

The proposed cloning technique leads to MLNs in which one quantifies over predicate names (as in second-order logic). This can be avoided, but it leads to less transparent semantics. In particular, we can avoid quantifying over predicate names by using ground predicate names with increased arity. For example, $\text{smokes}_{2b<X,Y>}(Y)$ could have been written as $\text{smokes}_{2b}(X, Y)$ where we pushed $<X, Y>$ into the predicate arguments. The disadvantage of this, however, is that the semantics of the individual arguments is lost as the arguments become overloaded.

[4]We need to remove all interactions among groundings of the same formula because otherwise the formula might not even be tractable for exact inference. For example, there is currently no exact lifted inference algorithm that can handle the formula $w: \quad \text{p}_a(X, Y) \wedge \text{p}_b(Y, Z) \Rightarrow \text{p}_c(X, Z)$ without grounding it first (Van den Broeck, 2011).

We now have the following key theorem.

Theorem 1. *Let Δ^r be the MLN resulting from cloning all atom occurrences in MLN Δ and then relaxing all introduced equivalences. Let Δ^g be the grounding of Δ^r. The formulas of Δ^g are then fully disconnected (i.e., they share no atoms).*

With this theorem, the proposed first-order cloning and relaxation technique allows one to fully disconnect the grounding of an MLN by simply relaxing first-order equivalences in the first-order MLN.

3.2 FIRST-ORDER COMPENSATION

In principle, one can just clone atom occurrences, relax some equivalence constraints, and then use the resulting MLN as an approximation of the original MLN. By relaxing enough equivalences, the approximate MLN can be made arbitrarily easy for exact inference. Our goal in this section, however, is to improve the quality of approximations by compensating for the relaxed equivalences, yet without making the relaxed MLN any harder for exact inference. This will be done through a notion of first-order compensation.

3.2.1 Equiprobable Equivalences

The proposed technique is similar to the one for ground MLNs, that is, using *weighted atoms* whose weights will allow for compensation. The key, however, is to use first-order weighted atoms instead of ground ones. For this, we need to define the following notions.

Definition 2 (Equiprobable Set)**.** A set of random variables V is called equiprobable w.r.t. distribution Pr iff for all $v_1, v_2 \in V : \Pr(v_1) = \Pr(v_2)$.

Definition 3 (Equiprobable Equivalence)**.** Let Δ be an MLN from which a first-order equivalence $a \Leftrightarrow a'$ was relaxed. Let $a_1 \Leftrightarrow a'_1, \ldots, a_n \Leftrightarrow a'_n$ be all groundings of $a \Leftrightarrow a'$. The equivalence $a \Leftrightarrow a'$ is equiprobable iff the sets $\{a_1, \ldots, a_n\}$ and $\{a'_1, \ldots, a'_n\}$ are both equiprobable w.r.t the ground distribution of MLN Δ.

The basic idea of first-order compensation is that when relaxing an equiprobable equivalence $a \Leftrightarrow a'$, under certain conditions, one can compensate for its loss using only two weighted first-order atoms of the form:

$$w: \quad a \qquad \text{and} \qquad w': \quad a'$$

This follows because if we were to fully ground the equivalence into $a_1 \Leftrightarrow a'_1, \ldots, a_n \Leftrightarrow a'_n$ and then apply ground compensation, the relevant ground atoms will attain the same weights. That is, by the end of ground compensation, the weighted ground atoms,

$$w_i: \quad a_i \qquad \text{and} \qquad w'_i: \quad a'_i$$

will have $w_i = w_j$ and $w'_i = w'_j$ for all i and j.

3.2.2 Partitioning Equivalences

To realize first-order compensation, one must address two issues. First, a relaxed first-order equivalence may not be equiprobable to start with. Second, even when the equivalence is equiprobable, it may cease to be equiprobable as we adjust the weights during the compensation process. Recall that equiprobability is defined with respect to the ground distribution of an MLN. Yet, this distribution changes during the compensation process, which iteratively changes the weights of compensating atoms and, hence, also iteratively changes the ground distribution.

Consider for example the following relaxed equivalences: $\mathrm{p}(X) \Leftrightarrow \mathrm{q}(X)$ and $\mathrm{q}(X) \Leftrightarrow \mathrm{r}(X)$. Suppose the domain is $\{a, b\}$ and the current ground distribution, $\Pr_i$, is such that $\Pr_i(\mathrm{p}(a)) = \Pr_i(\mathrm{p}(b))$, $\Pr_i(\mathrm{q}(a)) = \Pr_i(\mathrm{q}(b))$, and $\Pr_i(\mathrm{r}(a)) \neq \Pr_i(\mathrm{r}(b))$. In this case, the equivalence $\mathrm{p}(X) \Leftrightarrow \mathrm{q}(X)$ is equiprobable, but $\mathrm{q}(X) \Leftrightarrow \mathrm{r}(X)$ is not equiprobable.

If an equivalence constraint is not equiprobable, one can always partition it into a set of equiprobable equivalences — in the worst case, the partition will include all groundings of the equivalence. In the above example, one can partition the equivalence $\mathrm{q}(X) \Leftrightarrow \mathrm{r}(X)$ into the equivalences $\mathrm{q}(a) \Leftrightarrow \mathrm{r}(a)$ and $\mathrm{q}(b) \Leftrightarrow \mathrm{r}(b)$, which are trivially equiprobable.

Given this partitioning, the compensation algorithm will add distinct weights for the compensating atoms $\mathrm{q}(a)$ and $\mathrm{q}(b)$. Therefore, the set $\{\mathrm{q}(a), \mathrm{q}(b)\}$ will no longer be equiprobable in the next ground distribution, $\Pr_{i+1}$. As a result, the equivalence $\mathrm{p}(X) \Leftrightarrow \mathrm{q}(X)$ will no longer be equiprobable w.r.t. the ground distribution $\Pr_{i+1}$, even though it was equiprobable with respect to the previous ground distribution $\Pr_i$.

3.2.3 Strongly Equiprobable Equivalences

To attain the highest degree of lifting during compensation, one needs to dynamically partition equivalences after each iteration of the compensation algorithm, to ensure equiprobability. We defer the discussion on dynamic partitioning to Appendix A, focusing here on a strong version of equiprobability that allows one to circumvent the need for dynamic partitioning.

The mentioned technique is employed by our current implementation of Lifted RCR, which starts with equivalences that are *strongly equiprobable.* An equivalence is strongly equiprobable if it is equiprobable w.r.t all ground distributions induced by the compensation algorithm (i.e., ground distributions that result from only modifying the weights of compensating atoms).

Consider again Formula 2 where we cloned the atom occurrence $\mathrm{smokes}(Y)$ and relaxed its equivalence, leading to the MLN:

$$1.5\ \ \mathrm{smokes}(X) \wedge \mathrm{friends}(X, Y) \Rightarrow \mathrm{smokes}_{2b<X,Y>}(Y)$$

and relaxed equivalence

$$\mathrm{smokes}(Y) \Leftrightarrow \mathrm{smokes}_{2b<X,Y>}(Y) \tag{10}$$

Suppose we partition this equivalence as follows:[5]

$$X = Y,\ \ \mathrm{smokes}(Y) \Leftrightarrow \mathrm{smokes}_{2b<X,Y>}(Y)$$
$$X \neq Y,\ \ \mathrm{smokes}(Y) \Leftrightarrow \mathrm{smokes}_{2b<X,Y>}(Y)$$

These equivalences are not only equiprobable w.r.t. the relaxed MLN, but also strongly equiprobable. That is, suppose we add to the relaxed model the compensating atoms

$$w_1 :\ \ \mathrm{smokes}(X)$$
$$w_1' :\ X = Y,\ \ \mathrm{smokes}_{2b<X,Y>}(Y)$$
$$w_2 :\ \ \mathrm{smokes}(X)$$
$$w_2' :\ X \neq Y,\ \ \mathrm{smokes}_{2b<X,Y>}(Y)$$

The two equivalences will be equiprobable w.r.t. any ground distribution that results from adjusting the weights of these compensating atoms. We will present an equivalence partitioning algorithm in Section 4 that guarantees strong equiprobability of the partitioned equivalences. This algorithm is employed by our current implementation of Lifted RCR and will be used when reporting experimental results later.

3.3 COUNT-NORMALIZATION

We are one step away from presenting our first-order compensation scheme. What is still missing is a discussion of *count-normalized* equivalences, which are also required by our compensation scheme.

Consider Equivalence 10, which has four groundings

$$\mathrm{smokes}(a) \Leftrightarrow \mathrm{smokes}_{2b<a,a>}(a)$$
$$\mathrm{smokes}(b) \Leftrightarrow \mathrm{smokes}_{2b<a,b>}(b)$$
$$\mathrm{smokes}(a) \Leftrightarrow \mathrm{smokes}_{2b<b,a>}(a)$$
$$\mathrm{smokes}(b) \Leftrightarrow \mathrm{smokes}_{2b<b,b>}(b)$$

for the domain $\{a, b\}$. There are two distinct groundings of the original atom $\mathrm{smokes}(Y)$ in this case and each of them appears in two groundings. When each grounding of the original atom appears in exactly the

[5]We are using an extension of MLNs that allows constraints, such as $X \neq Y$. Our implementation is in terms of parfactor graphs, which are more expressive than standard MLNs and do allow for the representation of such constraints. In extended MLNs, we will write $C,\ f$ to mean that C is a constraint that applies to formula f.

same number of ground equivalences, we say that the first-order equivalence is count-normalized.

Consider now a constrained version of Equivalence 10

$$X \neq b \vee Y \neq b,\ \text{smokes}(Y) \Leftrightarrow \text{smokes}_{2b<X,Y>}(Y)$$

which has the following groundings

$$\text{smokes}(a) \Leftrightarrow \text{smokes}_{2b<a,a>}(a)$$
$$\text{smokes}(b) \Leftrightarrow \text{smokes}_{2b<a,b>}(b)$$
$$\text{smokes}(a) \Leftrightarrow \text{smokes}_{2b<b,a>}(a)$$

This constrained equivalence is not count-normalized since the atom smokes(a) appears in two ground equivalences while the atom smokes(b) appears in only one. More generally, we have the following definition.

Definition 4. Let $C,\ a \Leftrightarrow a'$ be a first-order equivalence. Let α be an instantiation of the variables in original atom a and assume that α satisfies constraint C. The equivalence is *count-normalized* iff $C \wedge \alpha$ has the same number of solutions for each instantiation α. Moreover, the number of groundings for $C,\ a$ is called the *original count* and the number of groundings for $C,\ a'$ is called the *clone count.*

Count-normalization can only be violated by constrained equivalences. Moreover, for a certain class of constraints, count-normalization is always preserved. The algorithm we shall present in Section 4 for partitioning equivalences takes advantage of this observation. In particular, the algorithm generates constrained equivalences whose constraint structure guarantees count-normalization.

3.4 THE COMPENSATION SCHEME

We now have the following theorem.

Theorem 2. *Let Δ_i be an MLN with relaxed equivalences $C,\ a \Leftrightarrow a'$ and, hence, corresponding compensating atoms:*

$$w_i:\quad C,\ a \qquad \text{and} \qquad w_i':\quad C,\ a'$$

Suppose that the equivalences are count-normalized and strongly equiprobable. Let $a_g \Leftrightarrow a_g'$ be one grounding of equivalence $C,\ a \Leftrightarrow a'$, let n be its original count and n' be its clone count. Consider now the MLN Δ_{i+1} obtained using the following updates:

$$w_{i+1} = \frac{n'}{n}\left(\log\left(\Pr_i(a_g')\right) - \log\left(\Pr_i(\neg a_g')\right) - w_i'\right)$$
$$w_{i+1}' = \log\left(\Pr_i(a_g)\right) - \log\left(\Pr_i(\neg a_g)\right) - w_i \qquad (11)$$

The ground distribution of MLN Δ_{i+1} equals the one obtained by applying Ground RCR to MLN Δ_i.

Note that first-order compensation requires exact inference on the MLN Δ_i, which is needed for computing $\Pr_i(a_g)$ and $\Pr_i(a_g')$. Moreover, these computations will need to be repeated until one obtains a fixed point of the update equations given by Theorem 2.

3.5 FIRST-ORDER RECOVERY

Recovering a first-order equivalence $C,\ a \Leftrightarrow a'$ amounts to removing its compensating atoms

$$w_i:\quad C,\ a \qquad \text{and} \qquad w_i':\quad C,\ a'$$

and then adding the equivalence back to the MLN.

Adapting the ground recovery heuristic suggested earlier, one recovers the first-order equivalence that maximizes the symmetric pairwise KL-divergence

$$n' \cdot \text{KLD}\left(\Pr(a_g), \Pr(a_g'), \frac{e^{w_i + w_i'}}{1 + e^{w_i + w_i'}}\right),$$

where n' is the clone count of the equivalence. Note here that n' is also the number of equivalence groundings since, by definition, the clone atom contains all logical variables that appear in the equivalence.

Note that recovering first-order equivalences may violate the equiprobability of equivalences that remain relaxed, which in turn may require re-partitioning.

4 PARTITIONING EQUIVALENCES

We will now discuss a method for partitioning first-order equivalences, which guarantees both strong equiprobability and count-normalization. This method is used by our current implementation of Lifted RCR that we describe in Section 6.

Our method is based on the procedure of *preemptive shattering* given by Poole et al. (2011), which is a conceptually simpler version of the influential *shattering* algorithm proposed by Poole (2003) and de Salvo Braz et al. (2005) in the context of exact lifted inference. We will first describe this shattering procedure, which partitions atoms. We will then use it to partition all atoms in a relaxed MLN. We will finally show how these atom partitions can be used to partition first-order equivalences.

4.1 PREEMPTIVE SHATTERING

Preemptive shattering takes as input an atom $p(X_1, \ldots, X_n)$ and a set of constants $K = \{k_1, \ldots, k_m\}$. It then returns a set of constrained atoms of the form $C,\ p(X_1, \ldots, X_n)$ which represent a partitioning of the input atom. That is, the groundings of constrained atoms are guaranteed to be disjoint and cover all groundings of the input atom.

We start with an intuitive description of preemptive shattering. The set of constants K are the ones explicitly mentioned in the MLN of interest. If an argument X_i of the input atom $p(X_1, \ldots, X_n)$ can take on one of the constants $k_j \in K$, preemptive shattering splits the atom into two constrained atoms: one where X_i is substituted by constant k_i and one where the constant k_j is excluded from the domain of X_i. Moreover, when two arguments X_i and X_j of the input atom can take on the same value, preemptive shattering splits the atom into two constrained atoms: one with the constraint $X_i = X_j$ and another with $X_i \neq X_j$.

We will next describe the shattering procedure and its complexity more formally. We need some definitions first. For each argument X_i of the input atom, let

$$C_i = \{(X_i = k_1), \ldots, (X_i = k_m), \\ (X_i \neq k_1, \ldots, X_i \neq k_m)\}.$$

Preemptive shattering generates all possible combinations of the above constraints:

$$\mathbf{C}_A = \{c_1 \wedge \cdots \wedge c_n \mid (c_1, \ldots, c_n) \in \times_{i=1}^{n} C_i\},$$

where $\times_{i=1}^{n} C_i$ is the cartesian product of $C_1, \ldots, C_n$.

Consider now a subset $\mathcal{X} \subseteq \{X_1, \ldots, X_n\}$ of the input atom arguments and let

$$\mathbf{C}(\mathcal{X}) = \bigwedge_{X_i, X_j \in \mathcal{X}} (X_i = X_j) \wedge \bigwedge_{i=1}^{n} \bigwedge_{X_j \notin \mathcal{X}} (X_i \neq X_j)$$
$$\mathbf{C}_B = \{\mathbf{C}(\mathcal{X}) \mid \mathcal{X} \subseteq \{X_1, \ldots, X_n\}\}$$

Preemptive shattering will then create the following partition of the input atom $p(X_1, \ldots, X_n)$:

$$A = \{c_a \wedge c_b,\ \mathrm{p}(X_1, \ldots, X_n) \mid c_a \in \mathbf{C}_A, c_b \in \mathbf{C}_B\}$$

Many of the generated constraints $c_a \wedge c_b$ will have no solutions and can be dropped. What remains is a set of constrained atoms whose groundings form a partition of the groundings for the input atom. Preemptive shattering can be implemented in time that is exponential in the arity n of input atom and polynomial in the number of input constants m.

For an example, consider the formula $\mathrm{smokes}(X) \Leftrightarrow \mathrm{smokes}_{<X,Y>}(X)$ and assume we have evidence $\mathrm{smokes}(a)$ and therefore $K = \{a\}$. Preemptive shattering of the input atom $\mathrm{smokes}(X)$ returns back

$$X = a,\ \mathrm{smokes}(X)$$
$$X \neq a,\ \mathrm{smokes}(X)$$

Preemptive shattering of the input atom $\mathrm{smokes}_{<X,Y>}(X)$ returns back

$$X = a, Y = a,\ \mathrm{smokes}_{<X,Y>}(X)$$
$$X = a, Y \neq a,\ \mathrm{smokes}_{<X,Y>}(X)$$
$$X \neq a, Y = a,\ \mathrm{smokes}_{<X,Y>}(X)$$
$$X \neq a, Y \neq a, X = Y,\ \mathrm{smokes}_{<X,Y>}(X)$$
$$X \neq a, Y \neq a, X \neq Y,\ \mathrm{smokes}_{<X,Y>}(X)$$

We will next show how this shattering procedure forms the basis of a method for partitioning equivalence constraints, with the aim of ensuring both strong equiprobability and count-normalization.

4.2 PARTITIONING EQUIVALENCES BY PREEMPTIVE SHATTERING

Consider an MLN which results from cloning some atom occurrences and then adding corresponding equivalence constraints. Let K be all the constants appearing explicitly in the MLN.

To partition a first-order equivalence $a \Leftrightarrow a'$, our method will first apply preemptive shattering to the original atom a and clone atom a', yielding a partition for each. Suppose that $C_1,\ a_1, \ldots, C_n,\ a_n$ is the partition returned for original atom a. Suppose further that $C'_1,\ a'_1, \ldots, C'_m,\ a'_m$ is the partition returned for clone atom a'. By definition of cloning, all variables that appear in original atom a must also appear in clone atom a'. This implies the following property. For every (original) constraint C_i, there is a corresponding set of (clone) constraints C'_j that partition C_i. Each pair of constraints C_i and C'_j will then generate a member of the equivalence partition: $C_i \wedge C'_j,\ a_i \Leftrightarrow a'_j$. Note that $C_i \wedge C'_j = C'_j$ since C'_j implies C_i.

Let us consider an example. Suppose we are partitioning the equivalence $\mathrm{smokes}(X) \Leftrightarrow \mathrm{smokes}_{<X,Y>}(X)$. Section 4.1 showed the preemptive shattering of the atoms $\mathrm{smokes}(X)$ and $\mathrm{smokes}_{<X,Y>}(X)$. These give rise to the following equivalence partition:

$$X = a, Y = a,\ \mathrm{smokes}(X) \Leftrightarrow \mathrm{smokes}_{<X,Y>}(X)$$
$$X = a, Y \neq a,\ \mathrm{smokes}(X) \Leftrightarrow \mathrm{smokes}_{<X,Y>}(X)$$
$$X \neq a, Y = a,\ \mathrm{smokes}(X) \Leftrightarrow \mathrm{smokes}_{<X,Y>}(X)$$
$$X \neq a, Y \neq a, X = Y,\ \mathrm{smokes}(X) \Leftrightarrow \mathrm{smokes}_{<X,Y>}(X)$$
$$X \neq a, Y \neq a, X \neq Y,\ \mathrm{smokes}(X) \Leftrightarrow \mathrm{smokes}_{<X,Y>}(X)$$

The following result is proven in Appendix B.

Theorem 3. *Partitioning by preemptive shattering returns count-normalized, strongly equiprobable equivalences.*

When K is small, preemptive shattering will find partitions that are close to minimal. When K is large, however, it will create large partitions, defeating the

purpose of lifted inference. In the next section, we will mention some alternative partitioning algorithms that work on a fully relaxed model. However, preemptive shattering is the only partitioning algorithm to our knowledge that works for any level of relaxation. We believe our work can motivate future work on finding more efficient general partitioning algorithms and even approximate partitioning algorithms.

5 RELATED WORK

The RCR framework has previously been used to characterize iterative belief propagation (IBP) and some of its generalizations. In the case where the simplified model is fully disconnected, the approximate marginals of RCR correspond to the approximate marginals given by IBP (Pearl, 1988; Choi and Darwiche, 2006). The approximation to the partition function further corresponds to the *Bethe free energy* approximation (Yedidia et al., 2003; Choi and Darwiche, 2008). When equivalence constraints have been recovered, RCR corresponds to a class of *generalized belief propagation* (GBP) approximations (Yedidia et al., 2003), and in particular *iterative joingraph propagation* (Aji and McEliece, 2001; Dechter et al., 2002). RCR also inspired a system that was successfully employed in a recent approximate inference competition (Elidan and Globerson, 2010; Choi and Darwiche, 2011). *Mini-buckets* can also be viewed as an instance of RCR where no compensations are used (Kask and Dechter, 2001; Dechter and Rish, 2003; Choi et al., 2007), which leads to upper bounds on the partition function (for example). Any approximate MLN found by Lifted RCR corresponds to one found by Ground RCR on the ground MLN, thus all of the above results carry over to the lifted setting.

The motivation for calling our approach *lifted* is threefold. First, in the compensation phase, we are compensating for many ground equivalences at the same time. Computing compensating weights for all of these requires inferring only a *single* pair of marginal probabilities. Second, computing marginal probabilities is done by an *exact lifted* inference algorithm. Third, we relax and recover first-order equivalence constraints, which correspond to *sets* of ground equivalences.

The work on lifted approximate inference has mainly focused on lifting the IBP algorithm. The correspondence between IBP and RCR carries over to their lifted counterparts: Lifted RCR compensations on a fully relaxed model correspond to *lifted belief propagation* (Singla and Domingos, 2008). Starting from a first-order model, Singla and Domingos (2008) proposed *lifted network construction* (LNC), which partitions atoms into so-called *supernodes*. The ground atoms represented by these supernodes send and receive the same messages when running IBP. This means that they partition the atoms into equiprobable sets and that LNC can be used for equivalence partitioning in Lifted RCR for the fully relaxed model. Kersting et al. (2009) proposed a *color-passing* (CP) algorithm that achieves similar results as LNC, only starting from a ground model, where the first-order structure is not apparent. Two other approximate lifted inference algorithms are *probabilistic theorem proving* (Gogate and Domingos, 2011), which contains a Monte-Carlo method and *bisimulation-based lifted inference* (Sen et al., 2009), which uses a mini-bucket approximation on a model that was compressed by detecting symmetries. Because of the correspondence between Ground RCR and mini-buckets mentioned above, this approach can also be seen as an instance of Lifted RCR with the compensation phase removed.

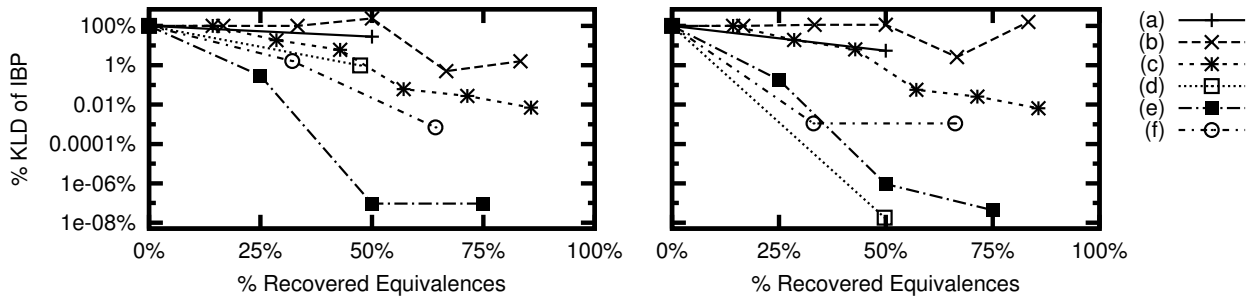
6 EXPERIMENTS

In this section, we evaluate the Lifted RCR algorithm on common benchmarks from the lifted inference literature. The experiments were set up to answer the questions: **(Q1)** To which extent does recovering first-order equivalences improve the approximations found by Lifted RCR? **(Q2)** Can IBP be improved considerably through the recovery of a small number of equivalences? **(Q3)** Is there a significant advantage to using Lifted RCR over Ground RCR?

We implemented Lifted RCR and released it as open source software.[6] To compute exact marginal probabilities in Equations 11, we use first-order knowledge compilation (Van den Broeck et al., 2011). It compiles the MLN into a logical circuit where probabilistic inference is performed by weighted model counting, which exploits context-specific independencies and determinism in the MLN. It is arguably the state of the art in exact lifted inference (Van den Broeck, 2011; Van den Broeck and Davis, 2012). In combination with preemptive shattering, we compile a first-order circuit once and re-evaluate it in each iteration of the compensation algorithm. This is possible because the structure of the compensated MLNs do not change between iterations, only their parameters change. An already compiled first-order circuit can re-evaluated very efficiently. See Appendix C for further details.

To answer **(Q1-2)** we ran Lifted RCR on MLNs from the exact lifted inference literature, where computing exact marginals is tractable. This allows us to evaluate the approximation quality of Lifted RCR for different degrees of relaxation. We used the models *p-r* and *sick-death* (de Salvo Braz et al., 2005), *work-*

[6] `http://dtai.cs.kuleuven.be/ml/systems/wfomc`



(a) Small domains - 100 random variables

(b) Large Domains - 10,000 random variables

Figure 1: Normalized approximation error of Lifted RCR for different levels of approximation on the models (a) *p-r*, (b) *sick-death*, (c) *workshop attributes*, (d) *smokers*, (e) *smokers and drinkers* and (f) *symmetric smokers*.

shop attributes (Milch et al., 2008), *smokers* (Singla and Domingos, 2008), *smokers and drinkers* (Van den Broeck et al., 2011) and *symmetric smokers* (Van den Broeck, 2011). Each of these models represents a new advance in exact lifted inference. They are incrementally more complex and challenging for lifted inference. The results are shown in Figure 1, where we ran Lifted RCR on the above models for two sets of domain sizes: a small and a large set, where the number of random variables is on the order of 100 and 10,000 respectively. We plot the symmetric KL divergence between the exact marginals and the approximations found by Lifted RCR, as a percentage of the KL divergence of the fully relaxed approximation. The horizontal axis shows the level of relaxation in terms of the percentage of recovered ground equivalences. The 0% point corresponds to the approximations found by (lifted) IBP. The 100% point corresponds to exact inference.[7]

We see that each recovered first-order equivalence tends to improve the approximation quality significantly, often by more than one order of magnitude, answering **(Q1)**. In the case of *smokers* with a large domain size, recovering a single equivalence more than the IBP approximation reduced the KL divergence by 10 orders of magnitude, giving a positive answer to **(Q2)**. The *sick-death* model is the only negative case for **(Q2)**, where recovering equivalences does not lead to approximations that are better than IBP.[8]

To answer **(Q3)**, first note that as argued in Section 5, the 0% recovery point of Lifted RCR using LNC or CP to partition equivalences corresponds to lifted IBP. For this case, the work of Singla and Domingos (2008) and Kersting et al. (2009) has extensively shown that Lifted IBP/RCR methods can significantly outperform Ground IBP/RCR. Similarly, computational gains for the 100% recovery point were shown in the exact lifted inference literature. For intermediate levels of relaxation, we ran Ground RCR on the above models with large domain sizes. On these, Ground RCR could never recover more than 5% of the relaxed equivalences before exact inference in the relaxed model becomes intractable. This answers **(Q3)** positively.

For the above experiments, Appendix D further reports on the quality of the approximations and the convergence of the compensation algorithm, both as a function of runtime and the number of iterations.

7 CONCLUSIONS

We presented Lifted RCR, a lifted approximate inference algorithm that performs exact inference in a simplified model. We showed how to obtain a simplified model by relaxing first-order equivalences, compensating for their loss, and recovering them as long as exact inference remains tractable. The algorithm can traverse an entire spectrum of approximations, from lifted iterative belief propagation to exact lifted inference. Inside this spectrum is a family of lifted join-graph propagation (and GBP) approximations. We empirically showed that recovering first-order equivalences in a relaxed model can substantially improve the quality of an approximation. We also remark that Lifted RCR relies on an exact lifted inference engine as a black box, and that any future advances in exact lifted inference have immediate impact in lifted approximate inference.

Abstract

This paper considers stochastic bandits *with side observations*, a model that accounts for both the exploration/exploitation dilemma and relationships between arms. In this setting, after pulling an arm i, the decision maker also observes the rewards for some other actions related to i. We will see that this model is suited to content recommendation in social networks, where users' reactions may be endorsed or not by their friends. We provide efficient algorithms based on upper confidence bounds (UCBs) to leverage this additional information and derive new bounds improving on standard regret guarantees. We also evaluate these policies in the context of movie recommendation in social networks: experiments on real datasets show substantial learning rate speedups ranging from 2.2× to 14× on dense networks.

1 INTRODUCTION

In the classical *stochastic multi-armed bandit* problem [4, 6], a decision maker repeatedly chooses among a finite set of K actions. At each time step t, the action i chosen yields a random reward $X_{i,t}$ drawn from a probability distribution proper to action i and unknown to the decision maker. Her goal is to maximize her cumulative expected reward over the sequence of chosen actions. This problem has received well-deserved attention from the online learning community for the simple model it provides of a tradeoff between exploration (trying out all actions) and exploitation (selecting the best action so far). It has several applications, including content recommendation, Internet advertising and clinical trials.

The decision maker's performance after n steps is typically measured in terms of the *regret* $R(n)$, defined as the difference between the reward of her strategy and that of an optimal strategy (one that would always choose actions with maximum expected reward). One of the most prominent algorithms in the stochastic bandit literature, UCB1 from Auer et al. [6], achieves a logarithmic (expected) regret

$$\mathbb{E}\left[R(n)\right] \leq A_{\mathsf{UCB1}} \ln n + B_{\mathsf{UCB1}}, \tag{1}$$

where A_{UCB1} and B_{UCB1} are two constants specific to the policy. This upper bound implies fast convergence to an optimal policy: the mean loss per decision after n rounds is only $\mathbb{E}\left[R(n)/n\right] = O(\ln n/n)$ in expectation (which scaling is known to be optimal).

This paper considers the stochastic bandit problem *with side observations* (a setting that has been considered in [16] but for adversarial bandits, see Section 2), a generalization of the standard multi-armed bandit where playing an action i at step t not only results in the reward $X_{i,t}$, but also yields information on some related actions $\{X_{j,t}\}$. We also present a direct application of this scenario is advertising in social networks: a content provider may target users with promotions (*e.g.*, "20% off if you buy this movie and post it on your wall"), get a reward if the user reacts positively, but also observe her connections' feelings toward the content (*e.g.*, friends reacting by "Liking" it or not).

Our contributions are as follows. First, we consider a generalization UCB-N of UCB1 taking side observations into account. We show that its regret can be upper bounded as in (1) with a smaller $A_{\mathsf{UCB\text{-}N}} < A_{\mathsf{UCB1}}$. Then, we provide a better algorithm UCB-MaxN achieving an improved constant term $B_{\mathsf{UCB\text{-}MaxN}} < B_{\mathsf{UCB\text{-}N}}$. We show that both improvements are significant for bandits with a large number of arms and a dense reward structure, as is for example the case of advertising in social networks. We finally evaluate our policies on real social network datasets and observe substantial learning rate speedups (from 2.2× to 14×, see Section 5).

2 RELATED WORK

Multi-armed bandit problems became popular with the seminal paper of Robbins [19] in 1952. Thirty years later, Lai and Robbins [13] provided one of the key results in this literature when they showed that, asymptotically, the expected regret for the stochastic problem has to grow at least logarithmically in the number of steps, *i.e.*,

$$\mathbb{E}\left[R(n)\right] = \Omega(\ln n).$$

They also introduced an algorithm that follows the "optimism in the face of uncertainty" principle and decides which arm to play based on *upper confidence bounds* (UCBs). Their solution asymptotically matches the logarithmic lower bound.

More recently, Auer et al. [6] considered the case of bandits with *bounded* rewards and introduced the well-known UCB1 policy, a concise strategy achieving the optimal logarithmic bound *uniformly* over time instead of asymptotically. Further work improved the constants A_{UCB1} and B_{UCB1} in their upper bound (1) using additional statistical assumptions [3].

One of the major limitations of standard bandit algorithms appears in situations where the number of arms K is large or potentially infinite; note for instance that the upper bound (1) scales linearly with K. One approach to overcome this difficulty is to add *structure* to the rewards distributions by embedding arms in a metric space and assuming that close arms share a similar reward process. This is for example the case in dependent bandits [18], where arms with close expected rewards are clustered.

$\mathcal{X}$-armed bandits [7] allow for an infinite number of arms $\mathbf{x}$ living in a measurable space $\mathcal{X}$. They assume that the mean reward function $\mu : \mathbf{x} \mapsto \mathbb{E}\left[X_{\mathbf{x}}\right]$ satisfies some Lipschitz assumptions and extend the bias term in UCBs accordingly. Bubeck et al. [7] provide a tree-based optimization algorithm that achieves, under proper assumptions, a regret independent of the dimension of the space.

Linear bandits [8, 20] are another example of structured bandit problems with infinitely many arms. In this setting, arms $\mathbf{x}$ live in a finite-dimensional vector space and mean rewards are modeled as linear functions of a system-wide parameter $\mathbf{Z} \in \mathbb{R}^r$, *i.e.*, $\mathbb{E}\left[X_{\mathbf{x}}\right] = \mathbf{Z} \cdot \mathbf{x}$. Near-optimal policies typically extend the notion of confidence intervals to *confidence ellipsoids*, estimated through empirical covariance matrices, and use the radius of these confidence regions as the bias term in their UCBs.

This last framework allows for contextual bandits and has been used as such in advertisement and content recommendation settings: [14] applied it to personalized news article recommendation, while [9] extended it to generalized linear models[1] and applied it to Internet advertisement. The approach in both these works is to reduce a large number of arms to a small set of numerical features, and then apply a linear bandit policy in the reduced space. Constructing good features is thus a crucial and challenging part of this process. In this paper, we do not make any assumption on the structure of the reward space. We handle the large number of arms in multi-armed bandits leveraging a phenomenon known as *side observations* which occurs in a variety of problems. This phenomenon has already been studied by Mannor et al. [16] in the case of *adversarial* bandits, *i.e.*, where the reward sequence $\{X_{i,t}\}$ is arbitrary and no statistical assumptions are made. They proposed two algorithms: ExpBan, a mix of experts and bandits algorithms based on a clique decomposition of the side observations graph, and ELP, an extension of the well-known EXP3 algorithm [5] taking the side observation structure into account. While the clique decomposition in ExpBan inspired our present work, our setting is that of *stochastic* bandits: statistical assumptions on the reward process allow us to derive $O(\ln n)$ regret bounds, while the best achievable bounds in the adversarial problem are $\widetilde{O}(\sqrt{n})$. It is indeed much harder to learn in an adversarial environment, and the methodology to address this family of problems is quite different from the techniques we use in our work.

Note that our side observations differ from *contextual side information*, another generalization of the standard bandit problems where some additional information is given to the decision maker *before* pulling an arm. Asymptotically optimal policies have been provided for this setting [22] in the case of two-armed bandits.

3 SIDE OBSERVATIONS

Formally, a K-armed bandit problem is defined by K distributions $\mathcal{P}_1, \ldots, \mathcal{P}_K$, one for each "arm" of the bandit, with respective means $\mu_1, \ldots, \mu_K$. When the decision maker pulls arm i at time t, she receives a reward $X_{i,t} \sim \mathcal{P}_i$. All rewards $\{X_{i,t}, i \in [\![1, K]\!], t \geq 1\}$ are assumed to be independent. We will also assume that all $\{\mathcal{P}_i\}$ have support in $[0, 1]$. The mean estimate for $\mathbb{E}\left[X_{i,\cdot}\right]$ after m observations is $\overline{X}_{i,m} := \frac{1}{m}\sum_{s=1}^{m} X_{i,s}$. The (cumulative) regret after n steps is defined by

$$R(n) := \sum_{t=1}^{n} X_{i^*,t} - \sum_{t=1}^{n} X_{I_t,t},$$

[1] in which $\mathbb{E}\left[X_{\mathbf{x}}\right] = f(\mathbf{Z} \cdot \mathbf{x})$ for some regular function f

K	# of arms
$X_{i,t}$	reward of arm i at time t
μ_i	mean reward of arm i
Δ_i	expected loss for playing arm i
i^*	index of an optimal arm
μ^*	mean reward of arm i^*
I_t	index of the arm played at time t
$T_i(n)$	# pulls to arm i after n steps
$N(i)$	neighborhood of arm i (includes i)
$O_i(n)$	# observations for arm i after n steps
$O^*(n)$	same for arm i^*

Table 1: Notations Summary

where $i^* = \arg\max\{\mu_i\}$ and I_t is the index of the arm played at time t. The gambler's goal is to minimize the *expected regret* of the policy, which one can rewrite as

$$\mathbb{E}\left[R(n)\right] = \sum_{i=1}^{K} \Delta_i \mathbb{E}\left[T_i(n)\right]$$

where $T_i(n) := \sum_{t=1}^{n} \mathbf{1}\left\{I_t = i\right\}$ denotes the number of times arm i has been pulled up to time n, and $\Delta_i := \mu^* - \mu_i$ is the expected loss incurred by playing arm i instead of an optimal arm.

In the standard multi-armed bandit problem, the only information available at time t is the sequence $(X_{I_s,s})_{s\leq t}$. We now present our setting with side observations. The *side observation (SO) graph* $G = (V, E)$ is an undirected graph over the set of arms $V = [\![1, K]\!]$, where an edge $i \leftrightarrow j$ means that pulling arm i (resp. j) at time t yields a side observation of $X_{j,t}$ (resp. $X_{i,t}$). Let $N(i)$ denote the *observation set* of arm i consisting of i and its neighbors in G. Contrary to previous work on UCB algorithms [13, 6], in our setting the number of observations made so far for arm i at time n is not $T_i(n)$ but

$$O_i(n) := \sum_{t=1}^{n} \mathbf{1}\left\{I_t \in N(i)\right\},$$

which accounts for the fact that observations come from pulling either the arm or one of its neighbors. Note that $O_i(n) \geq T_i(n)$.

A *clique* in G is a subset of vertices $C \subset V$ such that all arms in C are neighbors with each other. A *clique covering* $\mathcal{C}$ of G is a set of cliques such that $\bigcup_{C\in\mathcal{C}} C = V$. Table 1 summarizes our notations.

3.1 LOWER BOUND

Before we analyze our policies, let us note that the problem we study is at least as difficult as the standard multi-armed bandit problem in the sense that, even with additional observations, the expected regret for any strategy has to grow at least logarithmically in the number of rounds. The only exception to this would be a graph where every node is neighbor with an optimal arm, a particular and easier setting that we do not study here. This observation is stated by the following Theorem:

Theorem 1. *Let* $B^* := \arg\max\{\mu_i \,|\, i \in V\}$ *and suppose* $\bigcup_{i\in B^*} N(i) \neq V$. *Then, for any uniformly good allocation rule,*[2] $\mathbb{E}\left[R(n)\right] = \Omega(\ln n)$.

Proof. For a set of arms S, we denote $N(S) := \cup_{j\in S} N(j)$. Let $i^* \in B^*$ and $v := \arg\max\{\mu_j \,|\, j \in V\backslash N(B^*)\}$, *i.e.*, the best arm which can not be observed by pulling an optimal arm.

First assume that $N(v) \cap N(B^*) = \emptyset$. The proof follows by comparing the initial bandit problem with side observations denoted $\mathcal{A}$ with the two-armed bandit $\mathcal{B}$ *without* side observations where the reward distributions are $\mathcal{P}^*$ for the optimal arm 1 and $\mathcal{P}_v$ for the non-optimal arm 2. To any strategy for $\mathcal{A}$, we associate the following strategy for $\mathcal{B}$: if arm i is played in $\mathcal{A}$ at time t, play in $\mathcal{B}$: arm 1 if $i \in N(B^*)$ and get reward $X_{i^*,t}$; arm 2 if $i \in N(v)$ and get reward $X_{v,t}$; no arm otherwise.

Let n' denote the number of arms pulled in $\mathcal{B}$ after n steps in $\mathcal{A}$. It is clear that $n' \leq n$ and a valid strategy for $\mathcal{A}$ gives a valid strategy for $\mathcal{B}$. The expected regret incurred by arm 1 in $\mathcal{B}$ is 0, and each time arm 2 is pulled in $\mathcal{B}$, a sub-optimal arm is pulled in $\mathcal{A}$ with larger expected loss. As a consequence, $\mathbb{E}\left[R_{\mathcal{A}}(n)\right] \geq \mathbb{E}\left[R_{\mathcal{B}}(n')\right]$, where $R_{\mathcal{A}}$ (resp. $R_{\mathcal{B}}$) denotes the regret in $\mathcal{A}$ (resp. $\mathcal{B}$). By the classical result of Lai and Robbins [13], $\mathbb{E}\left[R_{\mathcal{B}}(n')\right] = \Omega(\ln n')$. Hence, if $n' = \Omega(n)$ the claim follows. If $n' = o(n)$, then sub-optimal arms are played in $\mathcal{A}$ at least $n - n'$ times so that $\mathbb{E}\left[R_{\mathcal{A}}(n)\right] = \Omega(n - n') = \Omega(n)$ and the claim follows as well.

Now assume that $N(v) \cap N(B^*) \neq \emptyset$. A valid strategy for $\mathcal{A}$ does not give a valid strategy for $\mathcal{B}$ any more, since pulling an arm in $N(v) \cap N(B^*)$ gives information on both an optimal arm and v, *i.e.*, both arms in $\mathcal{B}$. We need to modify slightly the two-armed bandit as follows. First, we define $u := \arg\max\{\mu_i \,|\, i \in N(v) \cap N(B^*)\}$ and $w := v$ if $\mu_v \geq \mu_u$ and u otherwise. The reward distribution for arm 2 in $\mathcal{B}$ is now $\mathcal{P}_w$. To any strategy for $\mathcal{A}$, we associate a strategy for $\mathcal{B}$ as follows: when arm i is played in $\mathcal{A}$ at time t, play in $\mathcal{B}$:

- $i \in N(B^*)\backslash N(v) \Rightarrow$ pull arm 1, get reward $X_{i^*,t}$;
- $i \in N(v)\backslash N(B^*) \Rightarrow$ pull arm 2, get reward $X_{w,t}$;

[2] *i.e.*, not depending on the labels of the arms, see [13]

- $i \in N(v) \cap N(B^*) \Rightarrow$ pull arms 1 and 2 in two consecutive steps, getting rewards $X_{i^*,t}$ and $X_{w,t}$;
- otherwise, do not pull any arm.

Let n' denote the number of arms pulled in $\mathcal{B}$ after n steps in $\mathcal{A}$. We now see that any valid strategy for $\mathcal{A}$ gives a valid strategy for $\mathcal{B}$. As in previous setting, the expected regret incurred by arm 1 in $\mathcal{B}$ is 0, and each time arm 2 is pulled in $\mathcal{B}$, a sub-optimal arm is pulled in $\mathcal{A}$ with larger expected loss. As a consequence, $\mathbb{E}[R_{\mathcal{A}}(n)] \geq \mathbb{E}[R_{\mathcal{B}}(n')]$, and we can conclude as above. □

3.2 UPPER CONFIDENCE BOUNDS

The UCB1 policy constructs an Upper Confidence Bound for each arm i at time t by adding a *bias term* $\sqrt{2\ln t/T_i(t-1)}$ to its sample mean. Hence, the UCB for arm i at time t is

$$\mathsf{UCB}_i(t) := \overline{X}_{i,T_i(t-1)} + \sqrt{\frac{2\ln t}{T_i(t-1)}}.$$

Auer et al. [6] have proven that the policy which picks $\arg\max_i \mathsf{UCB}_i(t)$ at every step t achieves the following upper bound after n steps:

$$\mathbb{E}[R(n)] \leq 8\left(\sum_{i=1}^{K}\frac{1}{\Delta_i}\right)\ln n + \left(1+\frac{\pi^2}{3}\right)\sum_{i=1}^{K}\Delta_i. \quad (2)$$

In the setting with side observations, we will show in Section 3.3 that a generalization of this policy yields the (improved) upper bound

$$\mathbb{E}[R(n)] \leq 8\left(\inf_{\mathcal{C}}\sum_{C\in\mathcal{C}}\frac{\max_{i\in C}\Delta_i}{\min_{i\in C}\Delta_i^2}\right)\ln n + O(K),$$

where the $O(K)$ term is the same as in (2), and the infimum is over all possible clique coverings of the SO graph. We will detail in Section 3.3 how this bound improves on the original $\sum_i 1/\Delta_i$.

We will then introduce in Section 4 an algorithm improving on the constant $O(K)$ term (remember that the number of arms K is assumed $\gg 1$). By proactively using the underlying structure of the SO graph, we will reduce it to the following finite-time upper bound:

$$\left(1+\frac{\pi^2}{3}\right)\sum_{C\in\mathcal{C}}\Delta_C + o_{n\to\infty}(1),$$

where Δ_C is the *best* individual regret in clique $C \in \mathcal{C}$. Note that, while both constant terms were linear in K in Equation (2), our improved factors are both $O(|\mathcal{C}|)$ where $|\mathcal{C}|$ is the number of cliques used to cover the SO graph. We will show that this improvement is significant for dense reward structures, as is the case with advertising in social networks (see Section 5).

3.3 UCB-N POLICY

In the multi-armed bandit problem with side observations, when the decision maker pulls an arm i after t rounds of the game, he/she gets the reward $X_{i,t}$ and observes $\{X_{j,t} \,|\, j \in N(i)\}$. We consider in this section the policy UCB-N where one always plays the arm with maximum UCB, and updates all mean estimates $\{\overline{X}_{j,t} \,|\, j \in N(i)\}$ in the observation set of the pulled arm i.

Algorithm 1 UCB-N

$\overline{\mathbf{X}}, \mathbf{O} \leftarrow \mathbf{0}, \mathbf{0}$
for $t \geq 1$ **do**
  $i \leftarrow \arg\max_i \left\{\overline{X}_i + \sqrt{\frac{2\ln t}{O_i}}\right\}$
  pull arm i
  for $k \in N(i)$ **do**
    $O_k \leftarrow O_k + 1$
    $\overline{X}_k \leftarrow X_{k,t}/O_k + (1-1/O_k)\overline{X}_k$
  end for
end for

We take the convention $\sqrt{1/0} = +\infty$ so that all arms get observed at least once. This strategy takes all the side information into account to improve the learning rate. The following Theorem quantifies this improvement as a reduction in the logarithmic factor from Equation (2).

Theorem 2. *The expected regret of policy UCB-N after n steps is upper bounded by*

$$\mathbb{E}[R(n)] \;\leq\; \inf_{\mathcal{C}}\left\{8\left(\sum_{C\in\mathcal{C}}\frac{\max_{i\in C}\Delta_i}{\Delta_C^2}\right)\ln n\right\} + \left(1+\frac{\pi^2}{3}\right)\sum_{i=1}^{K}\Delta_i,$$

where $\Delta_C = \min_{i\in C}\Delta_i$.

Proof. Consider a clique covering $\mathcal{C}$ of $G = (V, E)$, *i.e.*, a set of subgraphs such that each $C \in \mathcal{C}$ is a clique and $V = \cup_{C\in\mathcal{C}} C$. One can define the *intra-clique regret* $R_C(n)$ for any $C \in \mathcal{C}$ by

$$R_C(n) \;:=\; \sum_{t<n}\sum_{i\in C}\Delta_i \mathbf{1}\{I_t = i\}.$$

Since the set of cliques covers the whole graph, we have $R(n) \leq \sum_{C\in\mathcal{C}} R_C(n)$. From now on, we will focus on upper bounding the intra-clique regret for a given clique $C \in \mathcal{C}$.

Let $T_C(t) := \sum_{i\in C} T_i(t)$ denote the number of times (any arm in) clique C has been played up to time t.

Then, for any positive integer ℓ_C,

$$R_C(n) \leq \ell_C \max_{i\in C} \Delta_i + \sum_{\substack{i\in C\\ t\leq n}} \Delta_i \mathbf{1}\{I_t = i; T_C(t-1) \geq \ell_C\}$$

Considering that the event $\{I_t = i\}$ implies $\{\overline{X}_{i,O_i(t-1)} + c_{t-1,O_i(t-1)} \geq \overline{X}^*_{O^*(t-1)} + c_{t-1,O^*(t-1)}\}$, we can upper bound this last summation by:

$$\sum_{\substack{i\in C\\ t<n}} \Delta_i \mathbf{1}\left\{ \begin{array}{l} \overline{X}_{i,O_i(t)} + c_{t,O_i(t)} \geq \overline{X}^*_{O^*(t)} + c_{t,O^*(t)} \\ T_C(t) \geq \ell_C \end{array} \right\}$$

$$\leq \sum_{\substack{i\in C\\ t<n}} \Delta_i \mathbf{1}\left\{ \max_{\ell_C \leq s_i \leq t} \overline{X}_{i,s_i} + c_{t,s_i} \geq \min_{0\leq s\leq t} \overline{X}^*_s + c_{t,s} \right\}$$

$$\leq \sum_{\substack{i\in C\\ t<n}} \sum_{s=0}^{t} \sum_{s_i=\ell_C}^{t} \Delta_i \mathbf{1}\left\{ \overline{X}_{i,s_i} + c_{t,s_i} \geq \overline{X}^*_s + c_{t,s} \right\}$$

Now, choosing

$$\ell_C \geq \max_{i\in C} \frac{8\ln n}{\Delta_i^2} = \frac{8\ln n}{\min_{i\in C}\Delta_i^2} = \frac{8\ln n}{\Delta_C^2}$$

will ensure that $\mathbb{P}\left(\overline{X}_{i,s_i} + c_{t,s_i} \geq \overline{X}^*_s + c_{t,s}\right) \leq 2t^{-4}$ for any $i \in C$ as a consequence of the Chernoff-Hoeffding bound, and following the same argument as in [6]. Hence, the overall clique regret is bounded by:

$$\begin{aligned} R_C(n) &\leq \ell_C \max_{i\in C}\Delta_i + \sum_{i\in C}\sum_{t=1}^{\infty} 2\Delta_i t^{-2} \\ &\leq 8\frac{\max_{i\in C}\Delta_i}{\Delta_C^2}\ln n + \left(1+\frac{\pi^2}{3}\right)\sum_{i\in C}\Delta_i. \end{aligned}$$

Summing over all cliques in $\mathcal{C}$ and taking the infimum over all possible coverings $\mathcal{C}$ yields the aforementioned upper bound. □

Remark. When $\mathcal{C}$ is the trivial covering $\{\{i\}, i \in V\}$, this upper bound reduces exactly to Equation (2). Therefore, taking side observations into account systematically improves on the baseline UCB1 policy.

4 UCB-MaxN POLICY

The second term in the upper bound from Theorem 2 is still linear in the number of arms and may be large when $K \gg 1$. In this section, we introduce a new policy that makes further use of the underlying reward observations to improve performances.

Consider the two extreme scenarii that can make an arm i played at time t: it has the highest UCB, so

- either its average estimate $\overline{X}_{i,t}$ is very high, which means it is empirically the best arm to play,
- or its bias term $\sqrt{2\ln t/O_i(t-1)}$ is very high, which means one wants more information on it.

In the second case, one wants to observe a sample $X_{i,t}$ to reduce the uncertainty on arm i. But in the side observation setting, we don't have to pull this arm directly to get an observation: we may as well pull any of its neighbors, especially one with higher empirical rewards, and reduce the bias term all the same. Meanwhile, in the first case, arm i will already be the best empirical arm in its observation set.

This reasoning motivates the following policy, called UCB-MaxN, where we first pick the arm we want to *observe* according to UCBs, and then pick in its observation set the arm we want to *pull*, this time according to its empirical mean only.

Algorithm 2 UCB-MaxN

$\overline{\mathbf{X}}, \mathbf{n} \leftarrow \mathbf{0}, \mathbf{0}$
for $t \geq 1$ **do**
  $i \leftarrow \arg\max_i \left\{\overline{X}_i + \sqrt{\frac{2\ln t}{O_i}}\right\}$
  $j \leftarrow \arg\max_{j\in N(i)} \overline{X}_j$
  pull arm j
  for $k \in N(j)$ **do**
    $O_k \leftarrow O_k + 1$
    $\overline{X}_k \leftarrow X_{k,t}/O_k + (1-1/O_k)\overline{X}_k$
  end for
end for

Asymptotically, UCB-MaxN reduces the second factor in the regret upper bound (2) from $O(K)$ to $O(|\mathcal{C}|)$, where $\mathcal{C}$ is an optimal clique covering of the side observation graph G.

Theorem 3. *The expected regret of strategy UCB-MaxN after n steps is upper bounded by*

$$\begin{aligned} \mathbb{E}[R(n)] \leq \inf_{\mathcal{C}} \Bigg\{ & 8\left(\sum_{C\in\mathcal{C}} \frac{\max_{i\in C}\Delta_i}{\Delta_C^2}\right)\ln n \\ & + \left(1+\frac{\pi^2}{3}\right)\sum_{C\in\mathcal{C}}\Delta_C \Bigg\} \\ & + o_{n\to\infty}(1) \end{aligned}$$

We will make use of the following lemma to prove this theorem:

Lemma 1. *Let $X_1, \ldots, X_n$ and $Y_1, \ldots, Y_m$ denote two sets of i.i.d. random variables of respective means μ and ν such that $\mu < \nu$. Let $\Delta := \mu - \nu$. Then,*

$$\mathbb{P}\left(\overline{X}_n > \overline{Y}_m\right) \leq 2e^{-\min(n,m)\Delta^2/2}.$$

Proof. Note that either $\overline{X}_n < \frac{1}{2}(\mu+\nu) < \overline{Y}_m$ or one of the two events $\overline{X}_n > \frac{1}{2}(\mu+\nu)$ or $\overline{Y}_m < \frac{1}{2}(\mu+\nu)$ occurs. As a consequence, the probability $\mathbb{P}\left(\overline{X}_n > \overline{Y}_m\right)$ is lower than

$$\begin{aligned}
&\mathbb{P}\left(\overline{X}_n > \frac{\mu+\nu}{2}\right) + \mathbb{P}\left(\overline{Y}_m < \frac{\mu+\nu}{2}\right) \\
&\leq \mathbb{P}\left(\overline{X}_n - \mu > -\frac{\Delta}{2}\right) + \mathbb{P}\left(\overline{Y}_m - \nu < \frac{\Delta}{2}\right) \\
&\leq e^{-n\Delta^2/2} + e^{-m\Delta^2/2} \\
&\leq 2e^{-\min(n,m)\Delta^2/2}.
\end{aligned}$$

□

Proof of Theorem 3. Let $k_C := \arg\min_{i\in C} \Delta_i$ denote the best arm in clique C, and define $\delta_i := \Delta_i - \Delta_C$ for each arm $i \in C$. As in the beginning of our proof for Theorem 2, we can upper bound:

$$R_C(n) \leq \ell_C \max_{i\in C} \Delta_i + \sum_{\substack{i\in C \\ t<n}} \Delta_i \mathbf{1}\left\{I_t = i; T_C(t-1) \geq \ell_C\right\} \tag{3}$$

where this last summation is upper bounded by

$$\begin{aligned}
&\sum_{\substack{i\in C \\ t<n}} (\Delta_C + \delta_i)\mathbf{1}\left\{I_t = i; T_C(t-1) \geq \ell_C\right\} \\
&\leq \sum_{t<n} \Delta_C \mathbf{1}\left\{I_t = k_C; T_C(t-1) \geq \ell_C\right\} + \\
&\quad \sum_{\substack{i\in C \\ t<n}} \Delta_i \mathbf{1}\left\{I_t = i; T_C(t-1) \geq \ell_C\right\}
\end{aligned}$$

The first summation can be bounded using the Chernoff-Hoeffding inequality as before:

$$\begin{aligned}
&\sum_{t<n} \mathbf{1}\left\{I_t = k_C; T_C(t-1) \geq \ell_C\right\} \\
&\leq \sum_{t<n} \sum_{\substack{s\leq t \\ \ell_C \leq s_k \leq t}} \mathbf{1}\left\{\overline{X}_{k_C,s_k} + c_{t,s_k} > \overline{X}^*_s + c_{t,s}\right\} \\
&\leq 2\sum_{t<n} t^{-2} \leq 1 + \frac{\pi^2}{3}
\end{aligned}$$

with an appropriate choice of $\ell_C \geq \frac{8\ln n}{\Delta_C^2}$. As to the second summation, the fact that Algorithm 2 picks i instead of k_C at step t implies that $\overline{X}_{i,O_i(t)} > \overline{X}_{k_C,O_{k_C}(t)}$, so

$$\begin{aligned}
R'_C(n) &:= \sum_{\substack{i\in C \\ t<n}} \Delta_i \mathbf{1}\left\{I_t = i; T_C(t-1) \geq \ell_C\right\} \\
&\leq \sum_{\substack{i\in C \\ t<n}} \Delta_i \mathbf{1}\left\{ \begin{array}{l} \overline{X}_{i,O_i(t-1)} > \overline{X}_{k_C,O_{k_C}(t-1)} \\ T_C(t-1) \geq \ell_C \end{array} \right\}
\end{aligned}$$

Consider the times $\ell_C \leq \tau_1 \leq \cdots \leq \tau_{T_C(n)}$ when the clique C was played (after the first ℓ_C steps). Then, one can rewrite $R'_C(n)$ as follows:

$$\begin{aligned}
R'_C(n) &\leq \sum_{u=\ell_C}^{T_C(n)} \sum_{i\in C} \Delta_i \mathbf{1}\left\{\overline{X}_{i,O_i(\tau_u)} > \overline{X}_{k_C,O_{k_C}(\tau_u)}\right\} \\
\mathbb{E}\left[R'_C(n)\right] &\leq \sum_{u=\ell_C}^{T_C(n)} \sum_{i\in C} \Delta_i \mathbb{P}\left(\overline{X}_{i,O_i(\tau_u)} > \overline{X}_{k_C,O_{k_C}(\tau_u)}\right)
\end{aligned}$$

After the clique C has been played u times, all arms in C being neighbors in the side observation graph, we know that each estimate $\overline{X}_i, i \in C$ has at least u samples, *i.e.*, $O_i(\tau_u) \geq u$. Therefore, using Lemma 1 with "$n = O_i(\tau_u)$" and "$m = O_{k_C}(\tau_u)$" in the previous expression yields

$$\begin{aligned}
\mathbb{E}\left[R'_C(n)\right] &\leq \sum_{i\in C} \sum_{u=\ell_C}^{T_C(n)} 2\Delta_i e^{-u\delta_i^2/2} \\
&\leq 2\sum_{\substack{i\in C \\ \delta_i>0}} \Delta_i \frac{1-e^{-n\delta_i^2/2}}{1-e^{-\delta_i^2/2}} e^{-\ell_C\delta_i^2/2},
\end{aligned}$$

where $\delta_i = \mu_i - \min_{j\in C}\mu_j$. Combining all these separate upper bounds in Equation (3) leads us to

$$\begin{aligned}
\mathbb{E}\left[R_C(n)\right] \leq 8\frac{\max_{i\in C}\Delta_i}{\Delta_C^2}\ln n + \left(1+\frac{\pi^2}{3}\right)\Delta_C \\
+ 2\sum_{\substack{i\in C \\ \delta_i>0}} \Delta_i \frac{1-e^{-n\delta_i^2/2}}{1-e^{-\delta_i^2/2}} \cdot \left(\frac{1}{n}\right)^{4\delta_i^2/\Delta_C^2}
\end{aligned}$$

where this last term is $o_{n\to\infty}(1)$. □

Remark. UCB-MaxN is asymptotically better than UCB-N: again, its upper bound expression boils down to Equation (2) when applied to the trivial covering $\mathcal{C} = \{\{i\}, i \in V\}$.

Note that our bound is achieved *uniformly over time* and not only asymptotically; we only used the $o(1)$ notation in Theorem 3 to highlight that the last term vanishes when $n \to \infty$. This term may actually be large for small values of n and pathological regret distributions, *e.g.*, if some δ_i are such that $\delta_i \ll \Delta_C$. However, with distributions drawn from real datasets we observed a fast decrease: in the Flixster experiment for instance (see Section 5.3), this term was below the $(1+\pi^2/3)\Delta_C$ constant for more than 80% of the cliques after $T \sim 20K$ steps.

5 EXPERIMENTS

We have seen so far that our policies improve regret bounds compared to standard UCB strategies. Let us

evaluate how these algorithms perform on real social network datasets. In this section, we perform three experiments. First, we evaluate the UCB-N and UCB-MaxN policies on a movie recommendation problem using a dataset from Flixster [2]. The policies are compared to three baseline solutions: two UCB variants with no side observations, and an ε-greedy with side observations. Second, we investigate the impact of extending side observations to friends-of-friends, a setting inspired from average user preferences on social networks that densifies the reward structure and speeds up learning. Finally, we apply the UCB-N and UCB-MaxN algorithms in a bigger social network setup with a dataset from Facebook [1].

5.1 DATASETS

We perform empirical evaluation of our algorithms on datasets from two social networks: Flixster and Facebook. Flixster is a social networking service in which users can rate movies. This social network was crawled by Jamali *et al.* [10], yielding a dataset with 1M users, 14M friendship relations, and 8.2M movie ratings that range from 0.5 to 5 stars. We clustered the graph using Graclus [17] and obtained a strongly connected subgraph. Furthermore, we eliminated users that rated less than 30 movies and movies rated by less than 30 users. This preprocessing step helps us to learn more stable movie-rating profiles (Section 5.2). The resulting dataset involves 5K users, 5K movies, and 1.7M ratings. The subgraph from Facebook we used was collected by Viswanath *et al.* [21] from the New Orleans region. It contains 60K users and 1.5M friendship relationships. Again, we clustered the graph using Graclus and obtained a strongly connected subgraph of 14K users and 500K edges.

5.2 EXPERIMENTAL SETUP

We evaluate our policies in the context of movie recommendation in social networks. The problem is set up as a repetitive game. At each turn, a new movie is sampled from a homogeneous movie database and the policy offers it at a promotional price to one user in the social network.[3] If the user rates the movie higher than 3.5 stars, we assume that he/she accepts the promotion and our reward is 1, otherwise the reward is 0. The promotion is then posted on the user's wall and we assume that all friends of that user express their opinion, *i.e.*, whether they would accept a similar offer (*e.g.*, on Facebook by "Liking" or not the promotional message). The goal is to learn a policy that gives promotions to people who are likely to accept them.

We use standard matrix factorization techniques [12] to predict users ratings from the Flixster dataset. Since the Facebook dataset does not contain movie ratings, we generated rating profiles by matching users between the Flixster and Facebook social networks. This matching is based on structural features only, such as vertex degree, the aim of this experiment being to evaluate the performances of our policies in a bigger network with similar rating distributions across vertices.

The upper bounds we derived in the analysis of UCB-N and UCB-MaxN (Theorems 2 and 3) involve the number of cliques used to cover the side observation graph; meanwhile, bigger cliques imply more observations per step, and thus a faster convergence of estimators. These observations suggest that the minimum number of cliques required to cover the graph impacts the performances of our allocation schemes, which is why we took this factor into account in our evaluation.

Unfortunately, finding a cover with the minimum number of cliques is an NP-hard problem. We addressed it suboptimally as follows. First, for each vertex i in the graph, we computed a maximal clique C_i involving i. Second, a covering using $\{C_i\}$ is found using a greedy algorithm for the SET COVER problem [11].

For each experiment, we evaluate our policies on 3 subgraphs of the social network obtained by terminating the greedy algorithm after 3%, 15%, and 100% of the graph have been covered. This choice is motivated by the following observation: the degree distribution in social networks is heavy-tailed, and the number of cliques needed to cover the whole graph tends to be on the same scale of order as the number of vertices; meanwhile, the most active regions of the network (which are of practical interest in our content recommendation scenario) are densest and thus easier to cover with cliques. Since the greedy algorithm follows a biggest-cliques-first heuristic, looking at these 3% and 15% covers allows us to focus on these densest regions.

The quality of all policies is evaluated by the *per-step regret* $r(n) := \frac{1}{n}\mathbb{E}[R(n)]$. We also computed for each plot the improvement of each policy against UCB1 after the last round T (a $k\times$ improvement means that $r(T) \approx r_{\mathsf{UCB1}}(T)/k$). This number can be viewed as a speedup in the convergence to the optimal arm. Finally, all plots include a vertical line indicating the number of cliques in the cover, which is also the number of steps needed by any policy to pull every arm at least once. Before that line, all policies perform approximately the same.

[3]In accordance with the bandit framework, we further assume that the same movie is never sampled twice.

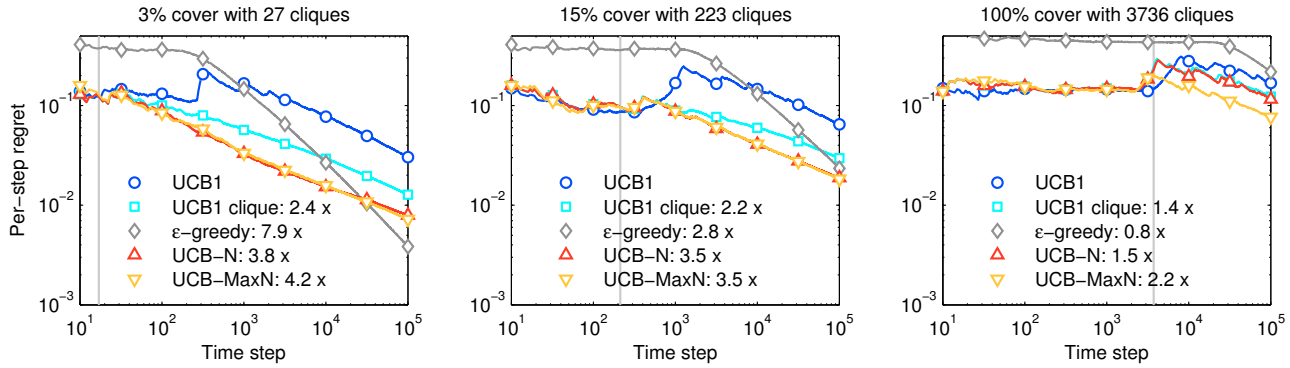

Figure 1: Per-step regret of four bandit policies on the Flixster graph.

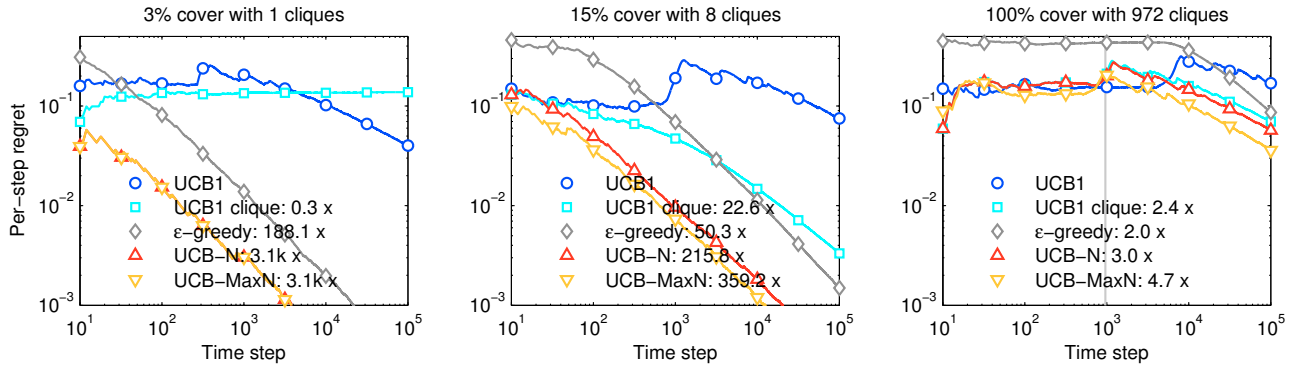

Figure 2: Per-step regret of four bandit policies on the Flixster graph with friend-of-friend side observations.

5.3 FLIXSTER

In this first experiment, we evaluate UCB-N and UCB-MaxN in the Flixster social network. These policies are compared to three baselines: UCB1 with no side observation, UCB1-on-cliques and ε-greedy. Our ε-greedy is the same as ε_n-greedy in [6] with $c = 5$, $d = 1$ and $K = |\mathcal{C}|$, which turned out to be the best empirical parametrization within our experiments. UCB1-on-cliques is similar to UCB-N, except that it updates the estimators $\{\overline{X}_k \,|\, k \in N(i)\}$ with the reward $X_{i,t}$ of the pulled arm i. This is a simple approach to make use of the network structure without access to side observations. As illustrated in Figure 1, we observe the following trends.

The regret of UCB-N and UCB-MaxN is significantly smaller than the regret of UCB1 and UCB1-on-cliques, which suggests these strategies successfully benefit from side observations to improve their learning rate. ε-greedy shows improvement as well, but its performances decrease rapidly as the size of the cover grows (*i.e.*, adding smaller cliques) compared to our strategies. Overall, the performance of all policies deteriorates with more coverage, which is consistent with the $O(K)$ and $O(|\mathcal{C}|)$ upper bounds on their regrets.

UCB-MaxN does not perform significantly better than UCB-N when the size of the cover $|\mathcal{C}|$ is small. This can be explained based on the amount of overlap between the cliques in the cover. In practice, we observed that UCB-MaxN performs better when individual arms belong to many cliques on average. For our 3%, 15%, and 100% graph cover simulations, the average number of cliques covering an arm were 1.18, 1.09, 1.76; meanwhile, the regrets of UCB-MaxN were 9%, 3%, and 33% smaller than the regrets of UCB-N, respectively.

5.3.1 FRIENDS OF FRIENDS

In the second experiment we use a denser graph where side observations come from friends and friends of friends. This setting is motivated by the observation that a majority of social network users do not restrict content sharing to their friends. For instance, more than 50% of Facebook users share all their content items with friends of friends [15].

Figure 2 shows that the gap between the baselines and our policies is even wider in this new setting. This phenomenon can be explained by larger cliques; for instance, only 8 cliques are needed to cover 15% of the graph in this instance, which is 20 times less than in Section 5.3.

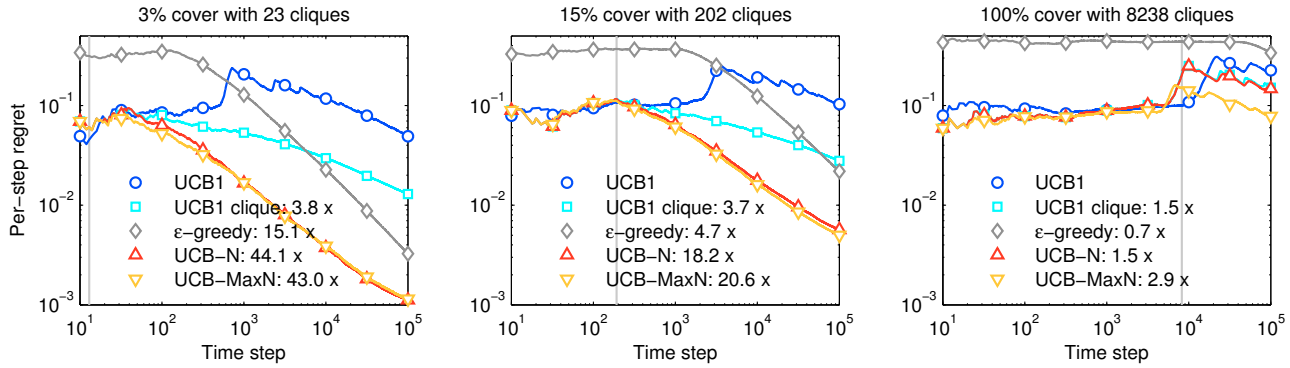

Figure 3: Per-step regret of four bandit policies on the Facebook graph.

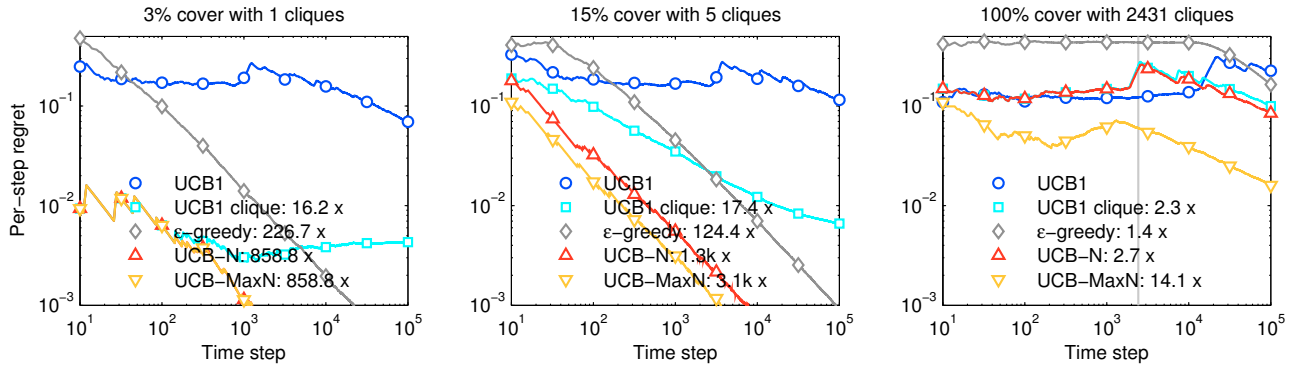

Figure 4: Per-step regret of four bandit policies on the Facebook graph with friend-of-friend side observations.

5.4 FACEBOOK

In the next experiment, we evaluate UCB-N and UCB-MaxN on a subset of the Facebook social network. This graph has three times as many vertices and twice as many edges as the Flixster graph. We experiment with both friends and friends-of-friends side observations.

As shown in Figures 3 and 4, compared to Figures 1 and 2, we observe much smaller regrets in this setting, essentially because the Facebook graph is denser. For instance, only 5 friend-of-friend cliques are needed to cover 15% of the graph. For this cover, the regret of UCB-MaxN is 10 times smaller than the regret of UCB1-on-cliques and UCB-N, respectively.

6 CONCLUSION AND FUTURE WORK

In this paper, we considered the stochastic multi-armed bandit problem with side observations. This problem generalizes the standard, independent multi-armed bandit, and has a broad set of applications including Internet advertisement and content recommendation systems. Our contribution consists in two new strategies, UCB-N and UCB-MaxN, that leverage this additional information into substantial learning rate speed-ups.

We showed that our policies reduce regret bounds from $O(K)$ to $O(|\mathcal{C}|)$, which is a significant improvement for dense reward-dependency structures. We also evaluated their performances on real datasets in the context of movie recommendation in social networks. Our experiments suggest that these strategies significantly improve the learning rate when the side observation graph is a dense social network.

So far we have focused on *cliques* as a convenient way to analyze our policies, but none of our two strategies explicitly relies on cliques (they only use the notion of neighborhood). Characterizing the most appropriate subgraph structure for this problem is still an open question that could lead to better regret bounds and inspire more efficient policies.

Abstract

We propose *interdependent defense (IDD) games*, a computational game-theoretic framework to study aspects of the interdependence of risk and security in multi-agent systems under deliberate external attacks. Our model builds upon *interdependent security (IDS) games*, a model due to Heal and Kunreuther that considers the source of the risk to be the result of *a fixed randomized-strategy*. We adapt IDS games to model *the attacker's deliberate behavior*. We define the attacker's pure-strategy space and utility function and derive appropriate cost functions for the defenders. We provide a complete characterization of mixed-strategy Nash equilibria (MSNE), and design a simple *polynomial-time* algorithm for computing *all* of them, for an important subclass of IDD games. In addition, we propose a random-instance generator of (general) IDD games based on a version of the real-world Internet-derived Autonomous Systems (AS) graph (with around $27K$ nodes and $100K$ edges), and present promising empirical results using a simple learning heuristics to compute (approximate) MSNE in such games.

1 INTRODUCTION

Attacks carried out by hackers and terrorists over the last few years have led to increased efforts by both government and the private sector to create and adopt mechanisms to prevent future attacks. This effort has yielded a more focused research attention to models, computational and otherwise, that facilitate and help to improve (homeland) security for both physical infrastructure and cyberspace. In particular, there has been quite a bit of recent research activity in the general area of game-theoretic models for terrorism settings (see, e.g., Bier and Azaiez [2009] and Cárceles-Poveda and Tauman [2011]).

Interdependent security (IDS) games are one of the earliest models resulting from a game-theoretic approach to model security in non-cooperative environments composed of free-will self-interested individual decision-makers. Originally introduced and studied by economists Kunreuther and Heal [2003], IDS games model general abstract security problems in which an individual within a population considers whether to voluntarily invest in some protection mechanisms or security against a risk they may face, knowing that the cost-effectiveness of the decision depends on the investment decisions of others in the population because of transfer risks (i.e., the "bad event" may be transferable from a compromised individual to another).

In their work, Kunreuther and Heal [2003] provided several examples based on their economics, finance and risk management expertise. (We refer the reader to their paper for more detailed descriptions.) As a canonical example of the real-world relevance of IDS settings and the applicability of IDS games, Heal and Kunreuther [2005] used this model to describe problems such as airline baggage security. In their setting, individual airlines may choose to invest in additional complementary equipment to screen passengers' bags and check for hazards such as bombs that could cause damage to their passengers, planes, buildings, or even reputations. However, mainly due to the large amount of traffic volume, it is impractical for an airline to go beyond applying security checks to bags incoming from passengers and include checks to baggage or cargo transferred from other airlines. On the other hand, if an airline invests in security, they can still experience a bad event if the bag was transferred from an airline that does not screen incoming bags, rendering their investment useless. [1] Thus, we can see how

[1]Note that even if full screening were performed, the Christmas Day 2009 episode in Detroit [O'Connor and

the cost-effectiveness of an investment can be highly dependent on others' investment decisions. Another recent application of the IDS model is on container shipping transportation [Gkonis and Psaraftis, 2010]. They use the IDS model to study the effect of investment decision on container screening of ports have on their neighboring ports.

In this work, we build on the literature in IDS games. In particular, we adapt the model to situations in which the abstract "bad event" results from the *deliberate* action of an attacker. The "internal agents" (e.g., airlines and computer network users), whom we also often refer to as "defenders" or "sites," have the voluntary choice to individually invest in security to defend themselves against a direct or indirect offensive attack, modulo, of course, the cost-effectiveness to do so. A side benefit of explicitly modeling the attacker, as we do in our model, is that the probability of an attack results directly from the equilibrium analysis. Building IDS games can be hard because it requires *a priori* knowledge of the likelihood of an attack. Attacks of this kind are considered rare events and thus notoriously difficult to statistically estimate in general.

Related Work. Johnson et al. [2010] and Fultz and Grossklags [2009] independently developed non-cooperative game models similar to ours. Johnson et al. [2010] extend IDS games by modeling uncertainty about the source of the risk (i.e., the attacker) using a Bayesian game over risk parameters. Fultz and Grossklags [2009] propose and study a non-graphical game-theoretic model for the interactions between attackers and nodes in a network. In their model, each node in the network can decide on whether to contribute (by investment) to the overall safety of the network and/or to individual safety. The attackers can attack any number of nodes, but with each attack there is an increased probability that the attacker might get caught and suffer penalties or fines. Hence, while their game has IDS characteristics, it is technically not within the standard IDS game framework introduced by Heal and Kunreuther.

Most of the previous related work explore the realm of information security and are application/network specific (see Roy et al. [2010] for a survey on game theory application to network security). Past literature has largely focused on two-person (an attacker and a defender) games where the nodes in the network are regarded as a single entity (or a central defender). For example, Lye and Wing [2002] look at the interactions between an attacker and the (system) administrator using a two-player stochastic game. Recent work uses a Stackelberg game model in which the defender (or leader) commits to a mixed strategy to allocate resources to defend a set of nodes in the network, and the follower (or attacker) optimally allocates resources to attack a set of "targets" in the network given the leader's commitment [Jain et al., 2011, Kiekintveld et al., 2009, Korzhyk et al., 2010, 2011a,b].

Other recent work strive to understand the motivation of the attackers. For example, Liu [2003] focus on understanding the attacker's intent, objectives, and strategies and derive a (two-player) game-theoretical model based on these, while Cremonini and Nizovtsev [2006] use cost-benefit analysis (of attackers) to address the issue of the optimal amount of security (of the nodes in the network).

Our Contribution. We adapt the standard non-cooperative framework of IDS games to settings in which the source of the risk is the result of a deliberate, strategic decision by an external attacker. In particular, we design and propose *interdependent defense (IDD) games*, a new class of games that, in contrast to standard IDS games, model the attacker *explicitly*, while maintaining a core component of IDS systems: the potential *transferability* of the risk resulting from an attack. We note that the explicit modeling of risk transfer is an aspect of our model that has not been a focus of previous game-theoretic attacker-defender models of security discussed earlier.

We formally define and study IDD games in depth in Section 3. We present several results that *fully* characterize their NE. [2] We also provide a *polynomial-time* algorithm to compute *all* MSNE for the important subclass of IDD games in which there is only one attack, the defender nodes are *fully transfer-vulnerable* (i.e., investing in security does nothing to reduce their external/transfer risk) and transfers are *one-hop*. [3]

We note that considering a single attacker is a typical assumption in security settings (see previous work discussed earlier). It is also reasonable: We can view many attackers as a single attacker. Allowing at most one attack prevents immediate representational and computational intractability problems because the number of the attacker's (pure) strategies grows exponentially with the number of attacks. Finally, because the attacker has no fixed target, it is ineffective for the attacker to consider or go beyond plans of attacks involving multiple (> 2) transfers: such plans are complex, time consuming and costly.

Our computational results are significant and surprising because computing all NE in general IDS games is

Schmitt, 2009] serves as a reminder that transfer risk still exists.

[2] Due to space limitation, we omit proofs of our main technical results and instead refer the reader to the supplementary document for details [Chan et al., 2012].

[3] We note that the original IDS games were also *fully transfer-vulnerable* and assume one-hop transfers.

hard (i.e., the Nash-extension problem in general IDS games is NP-complete [Kearns and Ortiz, 2003]). [4] We do not know of any other *non-trivial* game for which there exists a *polynomial-time* algorithm to compute *all* NE except ours and the algorithm for uniform-transfer IDS games of Kearns and Ortiz [2003].

In Section 4, we provide experimental results from applying learning-in-games heuristics to compute approximate NE to both fixed and randomly-generated instances of IDD games, with at most one simultaneous attack and one-hop transfers, on a very large Internet AS graph ($\approx 27K$ nodes and $\approx 100K$ edges).

2 IDS GAMES

Each player i in an IDS game has a choice to invest ($a_i = 1$) or not invest ($a_i = 0$). For each player i, C_i and L_i are the cost of investment and loss induce by the bad event, respectively. We define the ratio of the two parameters, the player's "cost-to-loss" ratio, as $\rho_i \equiv C_i/L_i$. Bad events can occur through both *direct* and *indirect* means. *Direct risk*, or *internal risk,* p_i is the probability that player i will experience a bad event because of direct contamination. The standard IDS model assumes that investing will completely protect the player from direct contamination; hence, internal risk is only possible when $a_i = 0$. *Indirect risk* q_{ji} is the probability that player j is directly "contaminated," does not experience the bad event but transfers it to player i who ends up experiencing the bad event. There is an implicit global constraint on these parameters, by the axioms of probability: $p_i + \sum_{j=1}^{n} q_{ij} \leq 1$ for all i.

We now formally define a (directed) graphical games [Kearns, 2007, Kearns et al., 2001] version of IDS games, as first introduced by Kearns and Ortiz [2003]. Denote by $[n] \equiv \{1, \ldots, n\}$ the set of n players. Note that the parameters q_{ij}'s induce a directed graph $G = ([n], E)$ such that $E \equiv \{(i,j) | q_{ij} > 0\}$. Let $\mathrm{Pa}(i) \equiv \{j \mid q_{ji} > 0\}$ be the set of players that are *parents* of player i in G (i.e., the set of players that player i is exposed to via transfers), and by $\mathrm{PF}(i) \equiv \mathrm{Pa}(i) \cup \{i\}$ the *parent family* of player i, which includes i. Denote by $k_i \equiv |\mathrm{PF}(i)|$ the size of the parent family of player i. Similarly, let $\mathrm{Ch}(i) \equiv \{j \mid q_{ij} > 0\}$ be the set of players that are *children* of player i (i.e., the set of players to whom player i can present a risk via transfer) and $\mathrm{CF}(i) \equiv \mathrm{Ch}(i) \cup \{i\}$ the *(children) family* of player i, which includes i. The *probability that player i is safe from player j*, as a function of player j's decision, is

$$e_{ij}(a_j) \equiv a_j + (1 - a_j)(1 - q_{ji}) = (1 - q_{ji})^{1-a_j},$$

because if j invests, then it is impossible for j to transfer the bad event, while if j does not invest, then j either experiences the bad event or transfers it to another player, but never both.

Denote by $\mathbf{a} \equiv (a_1, \ldots, a_n) \in \{0,1\}^n$ the *joint action* of all n players. Also denote by $\mathbf{a}_{-i}$ the joint-action of all players except i and for any subset $I \subset [n]$ of players, denote by $\mathbf{a}_I$ the sub-component of the joint action corresponding to those players in I only. We define i's *overall safety* from *all* other players as $s_i(\mathbf{a}_{\mathrm{Pa}(i)}) \equiv \prod_{j \in \mathrm{Pa}(i)} e_{ij}(a_j)$ and equivalently his *overall risk* from *some* other players is $r_i(\mathbf{a}_{\mathrm{Pa}(i)}) \equiv 1 - s_i(\mathbf{a}_{\mathrm{Pa}(i)})$. Note that each players' external safety (and risk) is a direct function of its parents only, *not* all other players. From these definitions, we obtain player i's overall cost, the cost of joint action $\mathbf{a} \in \{0,1\}^n$, corresponding to the (binary) investment decision of all players, is

$$\begin{aligned} M_i(a_i, \mathbf{a}_{\mathrm{Pa}(i)}) \equiv & a_i[C_i + r_i(\mathbf{a}_{\mathrm{Pa}(i)})L_i] + \\ & (1 - a_i)[p_i + (1 - p_i)r_i(\mathbf{a}_{\mathrm{Pa}(i)})]L_i \ . \end{aligned}$$

3 IDD GAMES

In the standard IDS game model, investment in security does not reduce transfer risks. However, in some IDS settings (e.g., vaccination and cyber-security), it is reasonable to expect that security investments would include mechanisms to reduce transfer risks. This motivates our first modification to the traditional IDS games: allowing the investment in protection to not only makes us safe from direct attack but also partially reduce (or even eliminate) the transfer risk. We incorporate this factor by introducing a new real-valued parameter $\alpha_i \in [0,1]$ representing the probability that a transfer of a potentially bad event will go *unblocked* by i's security, assuming i has invested. Thus, we redefine player *i's* overall cost as [5]

$$\begin{aligned} M_i(a_i, \mathbf{a}_{\mathrm{Pa}(i)}) \equiv & a_i[C_i + \alpha_i r_i(\mathbf{a}_{\mathrm{Pa}(i)})L_i] + \\ & (1 - a_i)[p_i + (1 - p_i)r_i(\mathbf{a}_{\mathrm{Pa}(i)})]L_i \ . \end{aligned}$$

Next, we introduce an additional player, the *attacker*, who *deliberately* initiates bad events. (So that now bad events are no longer "chance occurrences" without any strategic deliberation.) The attacker has a *target decision* for each player - a choice of attack ($b_i = 1$) or not attack ($b_i = 0$) player i. Hence,

[4] To put our computational contributions in context, note that deciding whether a game has a PSNE is in general NP-complete (see, e.g., Gilboa and Zemel [1989], Gottlob et al. [2005]), and computing an MSNE is PPAD-complete, even in two-player games (see, e.g., Chen et al. [2009] and Daskalakis et al. [2009]). Also, computing *all* MSNE is rarely achieved and counting-related problems are often #P-complete (see, e.g., [Conitzer and Sandholm, 2008]).

[5] A similar extension was also proposed independently by Heal and Kunreuther [2007].

the attacker's pure strategy is denoted by the vector $\mathbf{b} \in \{0,1\}^n$. The game parameter p_i implicitly "encodes" b_i because $b_i = 0$ implies $p_i = 0$. Thus, we redefine $p_i \equiv p_i(b_i) \equiv b_i\widehat{p}_i$ so that player i has *intrinsic risk* $\widehat{p}_i$, and only has *internal risk* if targeted (i.e, $b_i = 1$). The new parameter $\widehat{p}_i$ represents the (*conditional*) probability that an attack is successful at player i *given* that player i was directly targeted and did not invest in protection. The game parameter q_{ij} "encodes" $b_i = 1$, because a prerequisite is that i is targeted before it can transfer the bad event to j. We redefine $q_{ij} \equiv q_{ij}(b_i) \equiv b_i\widehat{q}_{ij}$ so that $\widehat{q}_{ij}$ is the intrinsic transfer probability from player i to player j, independent of b_i. The new parameter $\widehat{q}_{ij}$ represents the (*conditional*) probability that an attack is successful at player j *given* that it originated at player i, did not occur at i but was transferred undetected to j. Note that just as it was the case with traditional IDS games, there is an implicit constraint on the risk-related parameters: $\widehat{p}_i + \sum_{j\in \mathrm{Ch}(i)} \widehat{q}_{ij} \leq 1$, for all i. Because the p_i's and q_{ij}'s depend on the attacker's action $\mathbf{b}$, so does the safety and risk functions. In particular, we now have

$$e_{ij}(a_j, b_j) \equiv a_j + (1-a_j)(1-b_j\widehat{q}_{ji}) = (1-\widehat{q}_{ji})^{b_j(1-a_j)},$$

$s_i(\mathbf{a}_{\mathrm{Pa}(i)}, \mathbf{b}_{\mathrm{Pa}(i)}) \equiv \prod_{j\in\mathrm{Pa}(i)} e_{ij}(a_j, b_j) \equiv 1 - r_i(\mathbf{a}_{\mathrm{Pa}(i)}, \mathbf{b}_{\mathrm{Pa}(i)})$. Hence, for each player i, the *cost* function becomes

$$M_i(a_i, \mathbf{a}_{\mathrm{Pa}(i)}, b_i, \mathbf{b}_{\mathrm{Pa}(i)}) \equiv a_i[C_i + \alpha_i r_i(\mathbf{a}_{\mathrm{Pa}(i)}, \mathbf{b}_{\mathrm{Pa}(i)})L_i] + (1-a_i)[b_i\widehat{p}_i + (1-b_i\widehat{p}_i)r_i(\mathbf{a}_{\mathrm{Pa}(i)}, \mathbf{b}_{\mathrm{Pa}(i)})]L_i.$$

We assume the attacker wants to cause as much damage as possible. One possible *utility/payoff* function U quantifying the objective of the attacker is

$$U(\mathbf{a}, \mathbf{b}) \equiv \textstyle\sum_{i=1}^n M_i(\mathbf{a}_{\mathrm{PF}(i)}, \mathbf{b}_{\mathrm{PF}(i)}) - a_i C_i - b_i C_i^0.$$

which adds the expected players costs (for targeted and transferred bad events) over all players, minus C_i^0, the attacker's own *"cost" to target player i*.

3.1 MIXED STRATEGIES IN IDD GAMES

For all player i, denote by x_i the *mixed strategy of player i*: the probability that player i invests. Similarly, y denotes the joint probability mass function (PMF) corresponding to the *attacker's mixed strategy* so that for all $\mathbf{b} \in \{0,1\}^n$, $y(\mathbf{b})$ is the probability that the attacker executes joint-attack vector $\mathbf{b}$.

Denote the marginal PMF over a subset $I \subset [n]$ of the internal players by y_I such that for all $\mathbf{b}_I$, $y_I(\mathbf{b}_I) \equiv \sum_{\mathbf{b}_{-I}} y(\mathbf{b}_I, \mathbf{b}_{-I})$ is the (marginal) probability that the attacker chooses a joint-attack vector in which the subcomponent decisions corresponding to players in I are as in $\mathbf{b}_I$. Denote simply by $y_i \equiv y_{\{i\}}(1)$ the marginal probability that the attacker chooses an attack vector in which player i is directly targeted. Slightly abusing notation, we redefine the function e_{ij} (i.e., how safe i is from j), s_i and r_i (i.e., the overall transfer safety and risk, respectively) as $e_{ij}(x_j, b_j) \equiv x_j + (1-x_j)(1-b_j\widehat{q}_{ji})$, $s_i(\mathbf{x}_{\mathrm{Pa}(i)}, \mathbf{b}_{\mathrm{Pa}(i)}) \equiv \prod_{j\in\mathrm{Pa}(i)} e_{ij}(x_j, b_j)$,

$$s_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{Pa}(i)}) \equiv \sum_{\mathbf{b}_{\mathrm{Pa}(i)}} y_{\mathrm{Pa}(i)}(\mathbf{b}_{\mathrm{Pa}(i)}) s_i(\mathbf{x}_{\mathrm{Pa}(i)}, \mathbf{b}_{\mathrm{Pa}(i)}) \,,$$

and $r_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{Pa}(i)}) \equiv 1 - s_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{Pa}(i)})$.

In general, the *expected* cost of protection to site i, with respect to a joint mixed-strategy $(\mathbf{x}, y)$, can be expressed as

$$M_i(x_i, \mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) \equiv x_i[C_i + \alpha_i r_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{Pa}(i)})L_i] + (1-x_i)[\widehat{p}_i f_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) + r_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{Pa}(i)})]L_i \,,$$

where $f_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) \equiv \sum_{\mathbf{b}_{\mathrm{PF}(i)}} y_{\mathrm{PF}(i)}(\mathbf{b}_{\mathrm{PF}(i)})\, b_i s_i(\mathbf{x}_{\mathrm{Pa}(i)}, \mathbf{b}_{\mathrm{Pa}(i)})$.

The expected payoff of the attacker is

$$U(\mathbf{x}, y) \equiv \textstyle\sum_{i=1}^n M_i(\mathbf{x}_{\mathrm{PF}(i)}, y_{\mathrm{PF}(i)}) - x_i C_i - y_i C_i^0.$$

Let $\widehat{\Delta}_i \equiv \rho_i/\widehat{p}_i \equiv \frac{C_i}{L_i\widehat{p}_i}$ and $\widehat{s}_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) \equiv f_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) + \frac{1-\alpha_i}{\widehat{p}_i} r_i(x_{\mathrm{Pa}(i)}, y_{\mathrm{Pa}(i)})$. The best-response correspondence of defender i is then

$$\mathcal{BR}_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) \equiv \begin{cases} \{1\}, & \text{if } \widehat{s}_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) > \widehat{\Delta}_i, \\ \{0\}, & \text{if } \widehat{s}_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) < \widehat{\Delta}_i, \\ [0,1], & \text{if } \widehat{s}_i(\mathbf{x}_{\mathrm{Pa}(i)}, y_{\mathrm{PF}(i)}) = \widehat{\Delta}_i. \end{cases}$$

The best-response correspondence for the attacker is simply $\mathcal{BR}_0(\mathbf{x}) \equiv \arg\max_y U(\mathbf{x}, y)$.

Definition 1 *A joint mixed-strategy* $(\mathbf{x}^*, y^*)$ *is a* mixed-strategy Nash equilibrium (MSNE) *of an IDD game if (1) for all* $i \in [n]$, $x_i^* \in \mathcal{BR}_i(\mathbf{x}^*_{Pa(i)}, y^*_{\mathrm{PF}(i)})$ *and (2)* $y^* \in \mathcal{BR}_0(\mathbf{x}^*)$. *If* $(\mathbf{x}^*, y^*)$ *corresponds to a (deterministic)* joint action *then we call the MSNE a* pure-strategy Nash equilibrium (PSNE).

3.2 MODEL ASSUMPTIONS

Note that the attacker has in principle an *exponential* number of pure strategies! This affords the attacker unrealistic amount of power. Hence, we need restriction on the attacker's power. The simplest way is to allow at most a single simultaneous attack. We can weaken this assumption to allow the attacker at most K simultaneous attacks. Even then, the number of pure strategies will grow *exponentially* in the number of potential attacks, which still renders the attacker's pure-strategy space unrealistic, especially on a very large network with twenty-thousand nodes. Worst-case, we need to consider up to 2^n number of pure strategies for K attacks as K goes to n.

Assumption 1 *The set of pure strategies of the attacker is* $\mathcal{B} = \{\mathbf{b} \in \{0,1\}^n \mid \sum_{i=1}^n b_i \leq 1\}$.

The following assumptions are on the game *parameters*. The next assumption states that every site's investment cost is positive and (strictly) smaller than the *conditional* expected *direct* loss if the site were to be attacked directly ($b_i = 1$); that is, if a site knows that an attack is directed against it, the site will prefer to invest in security, unless the *external risk* is too high. This assumption is reasonable because otherwise the player will never invest regardless of what other players do (i.e., not investing would be a dominant strategy).

Assumption 2 *For all sites* $i \in [n]$, $0 < C_i < \widehat{p}_i L_i$.

The next assumption states that, for all sites i, the attacker's cost to attack i is positive and (strictly) smaller than the expected loss (i.e., gains from the perspective of the attacker) achieved if an attack initiated at site i is successful, either directly at i or at one of its children (after transfer); that is, if an attacker knows that an attack is rewarding (or able to obtain a positive utility), it will prefer to attack some nodes in the network. This assumption is reasonable; otherwise the attacker will never attack regardless of what other players do (i.e., not attacking would be a dominant strategy, leading to an easy problem to solve).

Assumption 3 *For all sites* $i \in [n]$, $0 < C_i^0 < \widehat{p}_i L_i + \sum_{j \in Ch(i)} \widehat{q}_{ij} \alpha_j L_j$.

PSNE of IDD Games. It turns out that under these three assumptions, there is no PSNE in IDD games. This is typical of attacker-defender settings. The following proposition eliminates PSNE as a universal solution concept for natural IDD games in which at most one attack is possible. The main significance of this result is that it allows us to concentrate our efforts on the much harder problem of computing MSNE.

Proposition 1 *No IDD game in which Assumptions 1, 2 and 3 hold has a PSNE.*

3.3 MSNE OF IDD GAMES

We first consider the IDD games under the assumption that no protection from transfer risk, which is used in the original IDS games. Note that, throughout this subsection, we will be using the assumptions we made earlier (in additional to the following assumption).

Assumption 4 *For all internal players* $i \in N$, *the probability that player* i*'s investment in security does not protect the player from transfers,* α_i, *is* 1.

Definition 2 *We say an IDD game is* transfer-vulnerable *if Assumption 4 holds. We say an IDD game is a* single simultaneous attack *game if Assumption 1 holds (i.e., at most one attack is possible).*

Assumption 1, in the context of mixed strategies, implies the probability of no attack $y_0 \equiv 1 - \sum_i^n y_i$. Assumptions 1 and 4 greatly simplify the best-response condition of the internal players because now $\widehat{s}_i(\mathbf{x}_{\text{Pa}(i)}, y_{\text{PF}(i)}) = y_i$. Let $L_i^0(x_i) \equiv (1 - x_i)(\widehat{p}_i L_i + \sum_{j \in \text{Ch}(i)} \widehat{q}_{ij} L_j)$. It will also be convenient to denote by $\overline{L}_i^0 \equiv L_i^0(0) = \widehat{p}_i L_i + \sum_{j \in \text{Ch}(i)} \widehat{q}_{ij} L_j$, so that we can express $L_i^0(x_i) = (1 - x_i)\overline{L}_i^0$, to highlight that L_i^0 is a linear function of x_i. Similarly, it will also be convenient to let $M_i^0(x_i) \equiv L_i^0(x_i) - C_i^0$, and denote $\overline{M}_i^0 \equiv M_i^0(0) = \overline{L}_i^0 - C_i^0$. Let $\eta_i^0 \equiv C_i^0 / \overline{L}_i^0$. The best-response condition of the attacker also simplifies under the same assumptions because now $U(\mathbf{x}, y) = \sum_{i=1}^n y_i M_i^0(x_i)$. Assumption 3 is reasonable in our new context because, under Assumption 4, if there were a player i with $\eta_i^0 > 1$, the attacker would never attack i, and as a result player i would never invest. In that case, we can safely remove j from the game, without any loss of generality.

We now characterize the space of MSNE in IDD games, which will immediately lead to a polynomial-time algorithm for computing *all* MSNE.

Characterization. The characterization starts by partitioning the space of games into three, based on whether $\sum_{i=1}^n \widehat{\Delta}_i$ is (1) $<$, (2) $=$, or (3) $>$ than 1. The rationale behind this is that now the players are indifferent between investing or not investing when $y_i = \widehat{\Delta}_i$, by the best-response correspondence the attacker's mixed strategy is restricted. The following result fully characterizes the set of MSNE in single simultaneous attack transfer-vulnerable IDD games.

Proposition 2 *The joint mixed-strategy* $(\mathbf{x}^*, y^*)$ *is an MSNE of a single simultaneous attack transfer-vulnerable IDD game in which*

1. $\sum_{i=1}^n \widehat{\Delta}_i < 1$ *if and only if (1)* $1 > y_0^* = 1 - \sum_{i=1}^n \widehat{\Delta}_i > 0$, *and (2) for all* i, $y_i^* = \widehat{\Delta}_i > 0$ *and* $0 < x_i^* = 1 - \eta_i^0 < 1$.

2. $\sum_{i=1}^n \widehat{\Delta}_i = 1$ *if and only if (1)* $y_0^* = 0$, *and (2) for all* i, $y_i^* = \widehat{\Delta}_i > 0$ *and* $x_i^* = 1 - \frac{v + C_i^0}{\overline{L}_i^0}$ *with* $0 \leq v \leq \min_{i \in [n]} \overline{M}_i^0$.

3. $\sum_{i=1}^n \widehat{\Delta}_i > 1$ *if and only if (1)* $y_0^* = 0$, *and (2) there exists a non-singleton, non-empty subset* $I \subset [n]$, *such that* $\min_{i \in I} \overline{M}_i^0 \geq \max_{k \notin I} \overline{M}_k^0$ *if* $I \neq [n]$, *and the following holds: (a) for all* $k \notin I$, $x_k^* = 0$ *and* $y_k^* = 0$, *(b) for all* $i \in J \equiv \arg\min_{i \in I} \overline{M}_i^0$, $x_i^* = 0$ *and* $0 \leq y_i^* \leq \widehat{\Delta}_i$,

and in addition, $\sum_{i\in J} y_i^* = 1 - \sum_{t\in I-J} \widehat{\Delta}_i$*; and (c) for all* $i \in I - J$*,* $y_i^* = \widehat{\Delta}_i$ *and* $0 < x_i^* = 1 - \frac{\min_{t\in I} \overline{M}_t^0 + C_i^0}{\overline{L}_i^0} < 1$.

As proof sketch, we briefly state that the proposition follows from the restrictions imposed by the model parameters and their implication to indifference and monotonicity conditions. We also mention that the third case in the proposition implies that if the $\overline{M}_l^0$'s form a complete order, then the last condition stated in that case allows us to search for a MSNE by exploring only $n-2$ sets, vs. 2^{n-2} if done naively. [6]

We now discuss properties of the characterization.

Security investment characteristics of MSNE. At equilibrium $\mathbf{x}^*$, if $x_i^* > 0$, the probability of *not* investing is proportional to C_i^0 and *inversely* proportional to $\widehat{p}_i\overline{L} + \sum_{j\in \mathrm{Ch}(i)} \widehat{q}_{ij} L_j$. It is kind of reassuring the at equilibrium, which is the (almost-surely) unique stable outcome of the system, the probability of investing increases with the potential loss a player's non-investment decision could cause to the system. Hence, behavior in a stable system implicitly "forces" all players to indirectly account for or take care of their own children. This may sound a bit paradoxical at first given that we are working within "noncooperative" setting and each player's cost function is only dependent on the investment decision of the player's *parents*. Interestingly, the existence of the attacker in the system is inducing an (almost-surely) unique stable outcome in which an implicit form of "cooperation" occurs. A defenders's best response is independent of their parents, the source of transfer risk, if investment in security does nothing to protect that player from transfers (i.e., $\alpha_i = 1$). This makes sense because the player cannot control the transfer risk.

Relation to network structure. How does the network structure and the equilibrium relate? As seen above, the values of the equilibrium strategy of each player depend on information from the attacker, the player and the player's children. From the discussion in the last paragraph, a player's probability of investing at the equilibrium increases with the expected loss sustained from a "bad event" occurring as a result of a transfer from a player to the player's children.

Let us explore this last point further by considering the case of uniform-transfer probabilities (also studied by Kunreuther and Heal [2003] and Kearns and Ortiz [2003]). In that case, transfer probabilities are only a function of the source, not the destination: $\widehat{q}_{ij} \equiv \widehat{\delta}_i$. The expression for the equilibrium probabilities of those players who have a positive probability of investing would simplify to $x_i^* = 1 - \frac{v + C_i^0}{\widehat{p}_i L_i + \delta_i \sum_{j\in \mathrm{Ch}(i)} L_j}$, for some constant v. The last expression suggests that $\sum_{j\in \mathrm{Ch}(i)} L_j$ differentiates the probability of investing between players. That would suggests the larger the number of children the larger the probability of investing. A scenario that seems to further lead us to that conclusion is when we make further assumptions (homogeneous system: first studied in the original IDS paper): $L_i \equiv L$, $\widehat{p}_i \equiv \widehat{p}$, $\delta_i \equiv \delta$, and $C_i^0 \equiv C^0$ [7] for all players. Then, we would get $x_i^* = 1 - \frac{v + C^0}{L(\widehat{p} + \delta|\mathrm{Ch}(i)|)}$. So the probability of *not* investing is inversely proportional to the *number* of children the player has.

On the attacker's equilibrium strategy. The support of the attacker, $I^* \equiv \{i \mid y_i^* > 0\}$, at equilibrium has the following properties: (1) players for which the attacker's cost-to-expected-loss is higher are "selected" first in the algorithm; (2) if the size of that set is t, and there is a lower bound on $\widehat{\Delta}_i > \widehat{\Delta}$, and $\sum_{i=1}^n \widehat{\Delta}_i > 1$, then $t < 1/\widehat{\Delta}$ is an upper-bound on the number of players that could potentially be attacked; (3) if we have a game with homogeneous parameters, then the probability of an attack will be uniform over that set I^*; and (4) all but one of the players in that set I^* invest in security with some non-zero probability (almost surely).

3.4 COMPUTING MSNE EFFICIENTLY

We now describe an algorithm to compute *all* MSNE in single simultaneous attack transfer-vulnerable IDD games that falls off the Proposition 2. We begin by noting that the equilibrium in the case of IDD games with $\sum_{i=1}^n \widehat{\Delta}_i \leq 1$, corresponding to cases 1 and 2 of the proposition, has essentially an analytic closed-form. Hence, we concentrate on the remaining and most realistic case in large-population games of $\sum_{i=1}^n \widehat{\Delta}_i > 1$. We start by sorting the indices of the internal players in descending order based on the $\overline{M}_i^0$'s. Let $\mathrm{Val}(l)$ and $\mathrm{Idx}(l)$ be the lth value and index in the resulting sorted list, respectively. Find t such that $1 - \widehat{\Delta}_{\mathrm{Idx}(t)} \leq \sum_{l=1}^{t-1} \widehat{\Delta}_{\mathrm{Idx}(l)} < 1$. Let $k = \arg\max\{l \geq t \mid \mathrm{Val}(l) = \mathrm{Val}(t)\}$ (i.e., continue down the sorted list of values until a change occurs). For $i = 1, \ldots, t-1$, let $l = \mathrm{Idx}(i)$ and set $x_l^* = 1 - \frac{\mathrm{Val}(t) + C_l^0}{\overline{L}_l^0}$ and $y_l^* = \widehat{\Delta}_l$. For $i = k+1, \ldots, n$, let $l = \mathrm{Idx}(i)$ and set $x_l^* = 0$ and $y_l^* = 0$. For $i = t, \ldots, k$, let $l = \mathrm{Idx}(i)$ and set $x_l^* = 0$. Finally, represent the simplex defined by the following constraints: for $i = t, \ldots, k$, let $l = \mathrm{Idx}(i)$ and $0 \leq y_l^* \leq \widehat{\Delta}_l$;

[6] In fact, it turns out a complete order is not actually necessary because we can safely move all defenders with the same value of $\overline{M}_i^0$ in a group as a whole inside or outside the set I referred to in that case of the proposition.

[7] Note that this does not mean that the expected loss caused by a player that does not invest but is attacked, $L(\widehat{p} + \delta|\mathrm{Ch}(i)|)$, is the same for all players.

$\sum_{i=t}^{k} y^*_{\mathrm{Idx}(i)} = 1 - \sum_{i=1}^{t-1} \widehat{\Delta}_{\mathrm{Idx}(i)}$. The running time of the algorithm is $O(n \log n)$ (because of sorting). As mentioned earlier, the theorem is significant because we do not know of any other non-trivial class of games that have algorithms to compute all Nash equilibria in polynomial time, except ours and the uniform IDS games [Kearns and Ortiz, 2003].

Theorem 1 *There exists a polynomial-time algorithm to compute all MSNE of a single simultaneous attack transfer-vulnerable IDD game.*

Note that the case in which $\sum_{i=1}^{n} \widehat{\Delta}_i = 1$ has (Borel) measure zero and is quite brittle (i.e., adding or removing a player breaks the equality). For the case in which $\sum_{i=1}^{n} \widehat{\Delta}_i > 1$, if the value of the $\overline{M}_i^0$'s are distinct, [8] then there is a unique MSNE!

4 EXPERIMENTS

In the previous section, we established the theoretical characteristics and computational tractability of single simultaneous attack IDD games with the highest transfer vulnerability parameter: $\alpha_i = 1$. In this section, partly motivated by security problems in cyberspace, we concentrate instead on empirically evaluating the other extreme of transfer vulnerability: games with low α_i values (i.e., near 0), so that investing in security considerably reduces the transfer risk.

Our main objectives for the experiments presented here are (1) to demonstrate that a simple heuristic, *best-response-gradient dynamics (BRGD)*, is practically effective in computing an (approximate) MSNE in a very large class of IDD games with realistic Internet-scale network graphs in a reasonable amount of time for cases in which the transfer vulnerabilities α_i's are low; and (2) to explore the general structural and computational characteristics of (approximate) MSNE in such IDD games, including their dependence on the underlying network structure of the game (and approximation quality).

BRGD is a well-known technique from the work on learning in games [Fudenberg and Levine, 1999, Singh et al., 2000, Kearns and Ortiz, 2003, Heal and Kunreuther, 2005, Kearns, 2005]. Here, we use BRGD as a tool to *compute* an ϵ-approximate MSNE, which is a joint mixed strategy with the property that the gain in utility (or reduction in cost) of any individual from unilaterally deviating from their prescribed mixed-strategy is no larger than ϵ; a 0-approximate MSNE is an exact MSNE.

[8] Distinct $\overline{M}_i^0$'s for the set of defenders at which the sum goes over one is sufficient to guarantee unique MSNE.

Table 1: Internet Games' Model Parameters

Model Parameters	Fixed: U = 0.5 Random: U ∼ Uniform([0,1])
α_i	$U/20$
L_i	$10^8 + (10^9) * U$
C_i	$10^5 + (10^6) * U$
$\widehat{p}_i$	$0.9 * \frac{\widetilde{p}_i}{\widetilde{p}_i + \sum_{k \in \mathrm{Ch}(i)} \widetilde{q}_{ik}}$
$\widehat{q}_{ij}$	$0.9 * \frac{\widetilde{q}_{ij}}{\widetilde{p}_i + \sum_{k \in \mathrm{Ch}(i)} \widetilde{q}_{ik}}$
z_i	$0.2 + U/5$
$\widetilde{p}_i$	$0.8 + U/10$
$\widetilde{q}_{ij}$	$z_i \frac{\lvert\mathrm{Ch}(j)\rvert + \lvert\mathrm{Pa}(j)\rvert}{\sum_{k \in \mathrm{Ch}(i)} \lvert\mathrm{Ch}(k)\rvert + \lvert\mathrm{Pa}(k)\rvert}$
C_i^0	10^6

We obtained the latest version (March 2010 at the time) of the real structure and topology of the Autonomous Systems (AS) in the Internet from DIMES (netdimes.org) [Shavitt and Shir, 2005]. The AS-level network has 27,106 nodes (683 isolated) and 100,402 directed edges; the graph length (diameter) is 6,253, the density (number of edges divided by number of possible edges) is 1.9920×10^{-5}, and the average (in and out) degree is 3.70, with $\approx$ 76.93% and 2.59% of the nodes having zero indegree and outdegree, respectively. *All the IDD games in the experiments presented in this section have this network structure.*

For simplicity, we call *Internet games* the class of IDD games with the AS-level network graph and low α_i values. We considered various settings for model parameters of Internet games: a single instance with specific fixed values; and several instances generated at random (see Table 1 for details). The attacker's cost-to-attack parameter for each node i is always held constant: $C_i^0 = 10^6$. For each run of each experiment, we ran BRGD with randomly-generated initial conditions (i.e., random initializations of the players' mixed strategies): $x_i \sim \mathrm{Uniform}([0,1])$, i.i.d. for all i, and y is a probability distribution generated uniformly at random, and independent of $\mathbf{x}$, from the set of all probability mass functions over $n+1$ events. [9] The initialization of the transfer-probability parameters of a node essentially gives higher transfer probability to children with high (total) degree (because they are potentially "more popular"). The initialization also enforces $\widehat{p}_i + \sum_{j \in \mathrm{Ch}(i)} \widehat{q}_{ij} = 0.9$. Other initializations are possible but we did not explore then here.

4.1 COMPUTING ϵ-MSNE USING BRGD

Given the lack of theoretical guarantees on the convergence rate of BRGD, we began our empirical study by evaluating the convergence and computation/running-time behavior of BRGD on Internet games. We ran

[9] Recall the probability of no attack $y_0 = 1 - \sum_{i=1}^{n} y_i$.

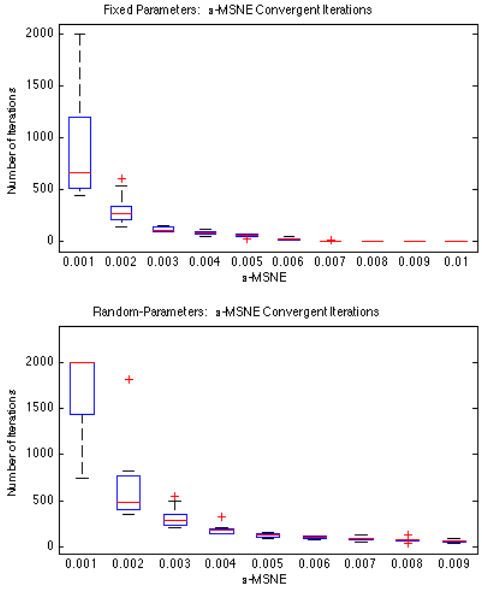

Figure 1: **Convergence Rate of Learning Dynamics:** The plots above present the number of iterations of BRGD as a function of ϵ under the two experimental conditions: Internet games with fixed (top) and randomly-generated parameters (bottom). Applying MSE regression to the top and bottom graphs, we obtain a functional expression for the number of iterations $N^F(\epsilon) = 0.00003\epsilon^{-2.547}$ ($R^2 = 0.90415$) and $N^R(\epsilon) = 0.0291\epsilon^{-1.589}$ ($R^2 = 0.9395$), respectively (i.e., low-degree polynomials of $1/\epsilon$).

ten simulations for each ϵ value and recorded the number of iterations until convergence (up to $2,000$ iterations). Figure 1 presents the number of iterations taken by BRGD to compute an ϵ-MSNE as a function of ϵ. All simulations in this experiment converged (except for $\epsilon = 0.001$: 2 and all of the runs for single and randomly-generated instances, respectively, did not). Each iteration took roughly 1-2 sec. (wall clock). Hence, we can use BRGD to consistently compute an ϵ-MSNE of a 27K-players Internet game in a few seconds!

4.2 CHARACTERISTICS OF THE ϵ-MSNE

We now concentrate on the empirical study of the *structural* characteristics of the ϵ-MSNE found by BRGD. We experimented on both the single and randomly-generated Internet game instances. We discuss the typical behavior of the attacker and the sites in an ϵ-MSNE, and the typical relationship between ϵ-MSNE and network structure.

4.2.1 A Single Internet Game

We first studied the characteristics of the ϵ-MSNE of a single Internet game instance. The only source of randomness in these experiments comes from BRGD's

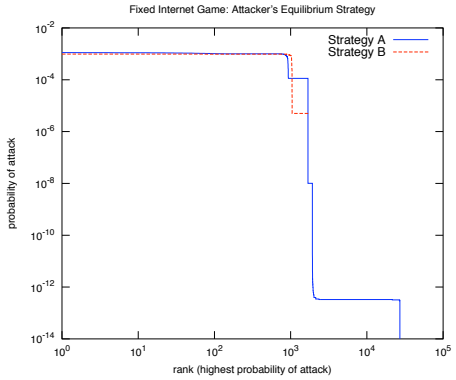

Figure 2: **Attacker's Equilibrium Strategy on an Internet Game Instance (Fixed):** The graph shows the values of $y_i^* > 0$ for each node i, sorted in decreasing order (in log-log scale), for attacker's Strategy A (blue/denser-dots line) and Strategy B (red/sparser-dots line) at an MSNE of the single instance of the Internet game.

initial conditions (i.e., the initialization of the mixed strategies $\mathbf{x}$ and $\mathbf{y}$). BRGD consistently found *exact* MSNE (i.e., $\epsilon = 0$) in *all* runs.

Players' equilibrium behavior. In fact, we consistently found that the attacker always displays only two types of "extreme" equilibrium behavior, corresponding to the two kinds of MSNE BRGD found for the single Internet game: place positive probability of a direct attack to either *almost all* nodes (Strategy A) or a *small subset* (Strategy B). Figure 2 shows a plot of the typical probability of direct attack for those two equilibrium strategies for the attacker when BRGD stops. In both strategies, a relatively small number of nodes (about 1K out of 27K) have a reasonably *high* (and near *uniform*) probability of direct attack. In Strategy A, however, *every* node has a positive probability of being the target of a direct attack, albeit relatively very low for most; this is contrast to Strategy B where *most* nodes are fully immune from a direct attack. Interestingly, *none* of the nodes invest in either MSNE: $x_i^* = 0$ for all nodes i. Thus, in this particular Internet game instance, *all* site nodes are willing to risk an attack!

Relation to network structure. We found that the nodes with (relatively) high probability of direct attack are at the "fringe" of the graph (i.e., have low or no degree). In Strategy A, fringe nodes (with mostly 0 or 1 outdegree) have relatively higher probability of direct attack than nodes with higher outdegree. Similarly, in Strategy B, the small subset of nodes that are potential target of a direct attack have relatively low outdegree (mostly 0, and 0.0067 on average; this is in contrast to the average outdegree of 3.9639 for the nodes immune from direct attack). In short, we consistently found that the nodes with low outdegree

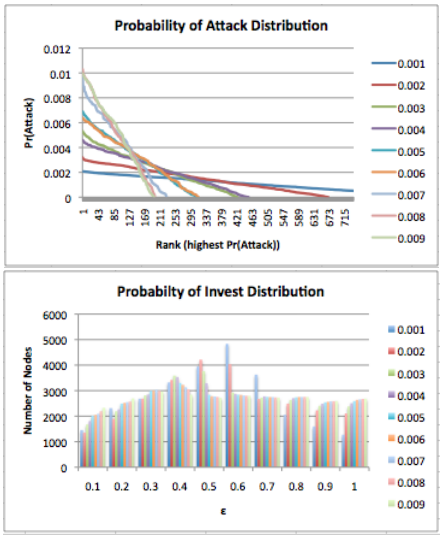

Figure 3: **Attacker's and Site's ϵ-MSNE Strategies for Randomly-Generated Internet Games:** The graphs show the empirical distributions of the probability of attack (top) and histograms of the probability of investment (bottom), for different ϵ-value conditions encoded in the right-hand side of the plots (i.e., from 0.001 to 0.009). In both graphs, the distributions and histograms found for each ϵ value considered are drawn in the same corresponding graph superimposed. The top graph plots the distribution of y_i where the nodes are ordered decreasingly based on the y_i value. The bottom bar graph shows histograms of the probability of investing in defense/security measures based on the following sequence of 10 ranges partitioning the unit interval: $([0, 0.1], (0.1, 0.2], ..., (0.9, 1])$.

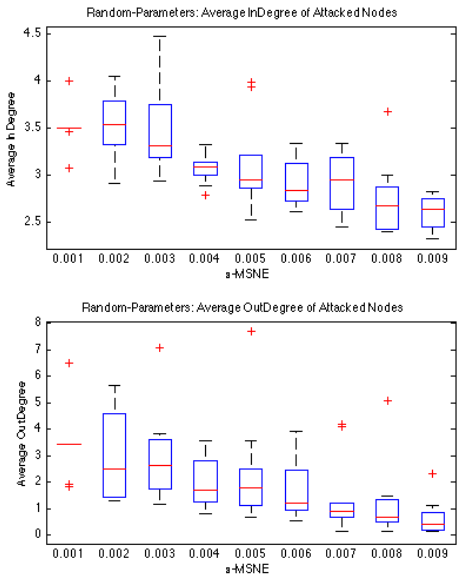

Figure 4: **Attacker's ϵ-MSNE Strategy vs. Node Degree:** Average indegree (top) and outdegree (bottom) of nodes potentially attacked in terms of the ϵ-MSNE.

are more likely to get attacked directly in the single Internet game instance.

4.2.2 Randomly-Generated Internet Games

We now present results from experiments on randomly-generated instances of the Internet game, a single instance for each $\epsilon \in \{0.001, 0.002, \ldots, 0.009\}$. For simplicity, we present the result of a single BRGD run on each instance. [10]

Behavior of the players. Figure 3 shows plots of the attacker's probability of direct attack and histograms of the nodes's probability of investment in a typical run of BRDG on each Internet game instance randomly-generated for each ϵ value. The plots suggest that approximate MSNE found by BRGD is quite sensitive to the ϵ value: as ϵ decreases, the attacker tends to "spread the risk" by selecting a larger set of nodes as potential targets for a direct attack, thus lowering the probability of a direct attack on any individual node; the nodes, on the other hand, tend to deviate from (almost) fully investing and (almost) not investing to a more uniform mixed strategy (i.e., investing or not investing with roughly equal probability). A possible reason for this is that as more nodes become potential targets of a direct attack, more nodes with initial mixed strategies close to the "extreme" (i.e., very high or very low probabilities of investing) will move closer to a more uniform (and thus less "predictable") investment distribution.

Relation to network structure. Figure 4 presents some experimental results on the relationship between network structure and the attacker's equilibrium behavior. The graphs show, for each ϵ value, the average indegree and outdegree, across the ten BRGD runs, of those nodes that are potential targets of a direct attack at an ϵ-MSNE. In general, both the average indegree and outdegree of the nodes that are potential targets of a direct attack tend to increase as ϵ decreases. One possible reason for this finding could be the fact that the values of α_i generated for each player are relatively low (i.e., uniformly distributed over $\left[0, \frac{1}{40}\right]$); yet, interestingly, such behavior and pattern, is exact opposite of the theory for the case $\alpha_i = 1$.

[10] While the results presented here are for a single instance of the Internet game for each ϵ, the results are typical of multiple instances. Our observations are robust to the experimental randomness in both the Internet game parameters and the initialization of BRGD. For the sake of simplicity of presentation, we discuss results based on a single instance of the Internet game, and in some cases based on a single BRGD run. Note that, for each ϵ value we considered, the Internet game parameters remain constant within different BRGD runs. BRGD always converged within $2,000$ iterations (except 6 runs for $\epsilon = 0.001$).

Abstract

The problem of modeling and predicting spatiotemporal traffic phenomena over an urban road network is important to many traffic applications such as detecting and forecasting congestion hotspots. This paper presents a decentralized data fusion and active sensing (D^2FAS) algorithm for mobile sensors to actively explore the road network to gather and assimilate the most informative data for predicting the traffic phenomenon. We analyze the time and communication complexity of D^2FAS and demonstrate that it can scale well with a large number of observations and sensors. We provide a theoretical guarantee on its predictive performance to be equivalent to that of a sophisticated centralized sparse approximation for the Gaussian process (GP) model: The computation of such a sparse approximate GP model can thus be parallelized and distributed among the mobile sensors (in a Google-like MapReduce paradigm), thereby achieving efficient and scalable prediction. We also theoretically guarantee its active sensing performance that improves under various practical environmental conditions. Empirical evaluation on real-world urban road network data shows that our D^2FAS algorithm is significantly more time-efficient and scalable than state-of-the-art centralized algorithms while achieving comparable predictive performance.

1 Introduction

Knowing and understanding the traffic conditions and phenomena over road networks has become increasingly important to the goal of achieving smooth-flowing, congestion-free traffic, especially in densely-populated urban cities. According to a 2011 urban mobility report (Schrank *et al.*, 2011), traffic congestion in the USA has caused 1.9 billion gallons of extra fuel, 4.8 billion hours of travel delay, and \$101 billion of delay and fuel cost. Such huge resource wastage can potentially be mitigated if the spatiotemporally varying traffic phenomena (e.g., speeds and travel times along road segments) are predicted accurately enough in real time to detect and forecast the congestion hotspots; network-level (e.g., ramp metering, road pricing) and user-level (e.g., route replanning) measures can then be taken to relieve this congestion, so as to improve the overall efficiency of road networks.

In practice, it is non-trivial to achieve real-time, accurate prediction of a spatiotemporally varying traffic phenomenon because the quantity of sensors that can be deployed to observe an entire road network is cost-constrained. Traditionally, static sensors such as loop detectors (Krause *et al.*, 2008a; Wang and Papageorgiou, 2005) are placed at designated locations in a road network to collect data for predicting the traffic phenomenon. However, they provide sparse coverage (i.e., many road segments are not observed, thus leading to data sparsity), incur high installation and maintenance costs, and cannot reposition by themselves in response to changes in the traffic phenomenon. Low-cost GPS technology allows the collection of traffic data using passive mobile probes (Work *et al.*, 2010) (e.g., taxis/cabs). Unlike static sensors, they can directly measure the travel times along road segments. But, they provide fairly sparse coverage due to low GPS sampling frequency (i.e., often imposed by taxi/cab companies) and no control over their routes, incur high initial implementation cost, pose privacy issues, and produce highly-varying speeds and travel times while traversing the same road segment due to inconsistent driving behaviors. A critical mass of probes is needed on each road segment to ease the severity of the last drawback (Srinivasan and Jovanis, 1996) but is often hard to achieve on non-highway segments due to sparse coverage. In contrast, we propose the use of active mobile probes (Turner *et al.*, 1998) to overcome the limitations of static and passive mobile probes. In particular, they can be directed to explore any segments of a road network to gather traffic data at a desired GPS sampling rate while enforcing consistent driving behavior.

How then do the mobile probes/sensors actively explore a road network to gather and assimilate the most informative

observations for predicting the traffic phenomenon? There are three key issues surrounding this problem, which will be discussed together with the related works:

Models for predicting spatiotemporal traffic phenomena. The spatiotemporal correlation structure of a traffic phenomenon can be exploited to predict the traffic conditions of any unobserved road segment at any time using the observations taken along the sensors' paths. To achieve this, existing Bayesian filtering frameworks (Chen *et al.*, 2011; Wang and Papageorgiou, 2005; Work *et al.*, 2010) utilize various handcrafted parametric models predicting traffic flow along a highway stretch that only correlate adjacent segments of the highway. So, their predictive performance will be compromised when the current observations are sparse and/or the actual spatial correlation spans multiple segments. Their strong Markov assumption further exacerbates this problem. It is also not shown how these models can be generalized to work for arbitrary road network topologies and more complex correlation structure. Existing multivariate parametric traffic prediction models (Kamarianakis and Prastacos, 2003; Min and Wynter, 2011) do not quantify uncertainty estimates of the predictions and impose rigid spatial locality assumptions that do not adapt to the true underlying correlation structure.

In contrast, we assume the traffic phenomenon over an urban road network (i.e., comprising the full range of road types like highways, arterials, slip roads) to be realized from a rich class of Bayesian non-parametric models called the *Gaussian process* (GP) (Section 2) that can formally characterize its spatiotemporal correlation structure and be refined with growing number of observations. More importantly, GP can provide formal measures of predictive uncertainty (e.g., based on variance or entropy criterion) for directing the sensors to explore highly uncertain areas of the road network. Krause *et al.* (2008a) used GP to represent the traffic phenomenon over a network of only highways and defined the correlation of speeds between highway segments to depend only on the geodesic (i.e., shortest path) distance of these segments with respect to the network topology; their features are not considered. Neumann *et al.* (2009) maintained a mixture of two independent GPs for flow prediction such that the correlation structure of one GP utilized road segment features while that of the other GP depended on manually specified relations (instead of geodesic distance) between segments with respect to an undirected network topology. Different from the above works, we propose a relational GP whose correlation structure exploits the geodesic distance between segments based on the topology of a directed road network with vertices denoting road segments and edges indicating adjacent segments weighted by dissimilarity of their features, hence tightly integrating the features and relational information.

Data fusion. The observations are gathered distributedly by each sensor along its path in the road network and have to be assimilated in order to predict the traffic phenomenon. Since a large number of observations are expected to be collected, a centralized approach to GP prediction cannot be performed in real time due to its cubic time complexity.

To resolve this, we propose a decentralized data fusion approach to efficient and scalable approximate GP prediction (Section 3). Existing decentralized and distributed Bayesian filtering frameworks for addressing non-traffic related problems (Chung *et al.*, 2004; Coates, 2004; Olfati-Saber, 2005; Rosencrantz *et al.*, 2003; Sukkarieh *et al.*, 2003) will face the same difficulties as their centralized counterparts described above if applied to predicting traffic phenomena, thus resulting in loss of predictive performance. Distributed regression algorithms (Guestrin *et al.*, 2004; Paskin and Guestrin, 2004) for static sensor networks gain efficiency from spatial locality assumptions, which cannot be exploited by mobile sensors whose paths are not constrained by locality. Cortes (2009) proposed a distributed data fusion approach to approximate GP prediction based on an iterative Jacobi overrelaxation algorithm, which incurs some critical limitations: (a) the past observations taken along the sensors' paths are assumed to be uncorrelated, which greatly undermines its predictive performance when they are in fact correlated and/or the current observations are sparse; (b) when the number of sensors grows large, it converges very slowly; (c) it assumes that the range of positive correlation has to be bounded by some factor of the communication range. Our proposed decentralized algorithm does not suffer from these limitations and can be computed exactly with efficient time bounds.

Active sensing. The sensors have to coordinate to actively gather the most informative observations for minimizing the uncertainty of modeling and predicting the traffic phenomenon. Existing centralized (Low *et al.*, 2008, 2009a, 2011) and decentralized (Low *et al.*, 2012; Stranders *et al.*, 2009) active sensing algorithms scale poorly with a large number of observations and sensors. We propose a partially decentralized active sensing algorithm that overcomes these issues of scalability (Section 4).

This paper presents a novel *Decentralized Data Fusion and Active Sensing* (D^2FAS) algorithm (Sections 3 and 4) for sampling spatiotemporally varying environmental phenomena with mobile sensors. Note that the decentralized data fusion component of D^2FAS can also be used for static and passive mobile sensors. The practical applicability of D^2FAS is not restricted to traffic monitoring; it can be used in other environmental sensing applications such as mineral prospecting (Low *et al.*, 2007), monitoring of ocean and freshwater phenomena (Dolan *et al.*, 2009; Podnar *et al.*, 2010; Low *et al.*, 2009b, 2011, 2012) (e.g., plankton bloom, anoxic zones), forest ecosystems, pollution (e.g., oil spill), or contamination (e.g., radiation leak). The specific contributions of this paper include:

- Analyzing the time and communication overheads of

D^{2}FAS (Section 5): We prove that D^{2}FAS can scale better than existing state-of-the-art centralized algorithms with a large number of observations and sensors;
- Theoretically guaranteeing the predictive performance of the decentralized data fusion component of D^{2}FAS to be equivalent to that of a sophisticated centralized sparse approximation for the GP model (Section 3): The computation of such a sparse approximate GP model can thus be parallelized and distributed among the mobile sensors (in a Google-like MapReduce paradigm), thereby achieving efficient and scalable prediction;
- Theoretically guaranteeing the performance of the partially decentralized active sensing component of D^{2}FAS, from which various practical environmental conditions can be established to improve its performance;
- Developing a relational GP model whose correlation structure can exploit both the road segment features and road network topology information (Section 2.1);
- Empirically evaluating the predictive performance, time efficiency, and scalability of the D^{2}FAS algorithm on a real-world traffic phenomenon (i.e., speeds of road segments) dataset over an urban road network (Section 6): D^{2}FAS is more time-efficient and scales significantly better with increasing number of observations and sensors while achieving predictive performance close to that of existing state-of-the-art centralized algorithms.

2 Relational Gaussian Process Regression

The *Gaussian process* (GP) can be used to model a spatiotemporal traffic phenomenon over a road network as follows: The traffic phenomenon is defined to vary as a realization of a GP. Let V be a set of road segments representing the domain of the road network such that each road segment $s \in V$ is specified by a p-dimensional vector of features and is associated with a realized (random) measurement z_s (Z_s) of the traffic condition such as speed if s is observed (unobserved). Let $\{Z_s\}_{s\in V}$ denote a GP, that is, every finite subset of $\{Z_s\}_{s\in V}$ follows a multivariate Gaussian distribution (Rasmussen and Williams, 2006). Then, the GP is fully specified by its *prior* mean $\mu_s \triangleq \mathbb{E}[Z_s]$ and covariance $\sigma_{ss'} \triangleq \mathrm{cov}[Z_s, Z_{s'}]$ for all $s, s' \in V$. In particular, we will describe in Section 2.1 how the covariance $\sigma_{ss'}$ for modeling the correlation of measurements between all pairs of segments $s, s' \in V$ can be designed to exploit the road segment features and the road network topology.

A chief capability of the GP model is that of performing probabilistic regression: Given a set $D \subset V$ of observed road segments and a column vector z_D of corresponding measurements, the joint distribution of the measurements at any set $Y \subseteq V \setminus D$ of unobserved road segments remains Gaussian with the following *posterior* mean vector and covariance matrix

$$\mu_{Y|D} \triangleq \mu_Y + \Sigma_{YD}\Sigma_{DD}^{-1}(z_D - \mu_D) \quad (1)$$

$$\Sigma_{YY|D} \triangleq \Sigma_{YY} - \Sigma_{YD}\Sigma_{DD}^{-1}\Sigma_{DY} \quad (2)$$

where μ_Y (μ_D) is a column vector with mean components μ_s for all $s \in Y$ ($s \in D$), Σ_{YD} (Σ_{DD}) is a covariance matrix with covariance components $\sigma_{ss'}$ for all $s \in Y, s' \in D$ ($s, s' \in D$), and Σ_{DY} is the transpose of Σ_{YD}. The posterior mean vector $\mu_{Y|D}$ (1) is used to predict the measurements at any set Y of unobserved road segments. The posterior covariance matrix $\Sigma_{YY|D}$ (2), which is independent of the measurements z_D, can be processed in two ways to quantify the uncertainty of these predictions: (a) the trace of $\Sigma_{YY|D}$ yields the sum of posterior variances $\Sigma_{ss|D}$ over all $s \in Y$; (b) the determinant of $\Sigma_{YY|D}$ is used in calculating the Gaussian posterior joint entropy

$$\mathbb{H}[Z_Y|Z_D] \triangleq \frac{1}{2}\log(2\pi e)^{|Y|}\left|\Sigma_{YY|D}\right| . \quad (3)$$

In contrast to the first measure of uncertainty that assumes conditional independence between measurements in the set Y of unobserved road segments, the entropy-based measure (3) accounts for their correlation, thereby not overestimating their uncertainty. Hence, we will focus on using the entropy-based measure of uncertainty in this paper.

2.1 Graph-Based Kernel

If the observations are noisy (i.e., by assuming additive independent identically distributed Gaussian noise with variance σ_n^2), then their prior covariance $\sigma_{ss'}$ can be expressed as $\sigma_{ss'} = k(s, s') + \sigma_n^2\delta_{ss'}$ where $\delta_{ss'}$ is a Kronecker delta that is 1 if $s = s'$ and 0 otherwise, and k is a kernel function measuring the pairwise "similarity" of road segments. For a traffic phenomenon (e.g., road speeds), the correlation of measurements between pairs of road segments depends not only on their features (e.g., length, number of lanes, speed limit, direction) but also the road network topology. So, the kernel function is defined to exploit both the features and topology information, which will be described next.

Definition 1 (Road Network) *Let the road network be represented as a weighted directed graph $G \triangleq (V, E, m)$ that consists of*

- *a set V of vertices denoting the domain of all possible road segments,*
- *a set $E \subseteq V \times V$ of edges where there is an edge (s, s') from $s \in V$ to $s' \in V$ iff the end of segment s connects to the start of segment s' in the road network, and*
- *a weight function $m : E \to \mathbb{R}^+$ measuring the standardized Manhattan distance (Borg and Groenen, 2005) $m((s, s')) \triangleq \sum_{i=1}^{p} |[s]_i - [s']_i|/r_i$ of each edge (s, s') where $[s]_i$ ($[s']_i$) is the i-th component of the feature vector specifying road segment s (s'), and r_i is the range of the i-th feature. The weight function m serves as a dissimilarity measure between adjacent road segments.*

The next step is to compute the shortest path distance $d(s, s')$ between all pairs of road segments $s, s' \in V$ (i.e., using Floyd-Warshall or Johnson's algorithm) with respect to the topology of the weighted directed graph G. Such a distance function is again a measure of dissimilarity, rather than one of similarity, as required by a kernel function. Fur-

thermore, a valid GP kernel needs to be positive semidefinite and symmetric (Schölkopf and Smola, 2002), which are clearly violated by d.

To construct a valid GP kernel from d, multi-dimensional scaling (Borg and Groenen, 2005) is applied to embed the domain of road segments into the p'-dimensional Euclidean space $\mathbb{R}^{p'}$. Specifically, a mapping $g : V \rightarrow \mathbb{R}^{p'}$ is determined by minimizing the squared loss $g^* = \arg\min_g \sum_{s,s' \in V} (d(s,s') - \|g(s) - g(s')\|)^2$. With a small squared loss, the Euclidean distance $\|g^*(s) - g^*(s')\|$ between $g^*(s)$ and $g^*(s')$ is expected to closely approximate the shortest path distance $d(s,s')$ between any pair of road segments s and s'. After embedding into Euclidean space, a conventional kernel function such as the squared exponential one (Rasmussen and Williams, 2006) can be used:

$$k(s,s') = \sigma_s^2 \exp\left(-\frac{1}{2}\sum_{i=1}^{p'}\left(\frac{[g^*(s)]_i - [g^*(s')]_i}{\ell_i}\right)^2\right)$$

where $[g^*(s)]_i$ ($[g^*(s')]_i$) is the i-th component of the p'-dimensional vector $g^*(s)$ ($g^*(s')$), and the hyperparameters $\sigma_s, \ell_1, \ldots, \ell_{p'}$ are, respectively, signal variance and length-scales that can be learned using maximum likelihood estimation (Rasmussen and Williams, 2006). The resulting kernel function k[1] is guaranteed to be valid.

2.2 Subset of Data Approximation

Although the GP is an effective predictive model, it faces a practical limitation of cubic time complexity in the number $|D|$ of observations; this can be observed from computing the posterior distribution (i.e., (1) and (2)), which requires inverting covariance matrix Σ_{DD} and incurs $\mathcal{O}(|D|^3)$ time. If $|D|$ is expected to be large, GP prediction cannot be performed in real time. For practical usage, we have to resort to computationally cheaper approximate GP prediction.

A simple method of approximation is to select only a subset U of the entire set D of observed road segments (i.e., $U \subset D$) to compute the posterior distribution of the measurements at any set $Y \subseteq V \setminus D$ of unobserved road segments. Such a *subset of data* (SoD) approximation method produces the following predictive Gaussian distribution, which closely resembles that of the full GP model (i.e., by simply replacing D in (1) and (2) with U):

$$\mu_{Y|U} = \mu_Y + \Sigma_{YU}\Sigma_{UU}^{-1}(z_U - \mu_U) \quad (4)$$

$$\Sigma_{YY|U} = \Sigma_{YY} - \Sigma_{YU}\Sigma_{UU}^{-1}\Sigma_{UY} \; . \quad (5)$$

Notice that the covariance matrix Σ_{UU} to be inverted only incurs $\mathcal{O}(|U|^3)$ time, which is independent of $|D|$.

The predictive performance of SoD approximation is sensitive to the selection of subset U. In practice, random subset selection often yields poor performance. This issue can be resolved by actively selecting an informative subset U in an iterative greedy manner: Firstly, U is initialized to be an empty set. Then, all road segments in $D \setminus U$ are scored based on a criterion that can be chosen from, for example, the works of (Krause *et al.*, 2008b; Lawrence *et al.*, 2003; Seeger and Williams, 2003). The highest-scored segment is selected for inclusion in U and removed from D. This greedy selection procedure is iterated until U reaches a predefined size. Among the various criteria introduced earlier, the differential entropy score (Lawrence *et al.*, 2003) is reported to perform well (Oh *et al.*, 2010); it is a monotonic function of the posterior variance $\Sigma_{ss|U}$ (5), thus resulting in the greedy selection of a segment $s \in D \setminus U$ with the largest variance in each iteration.

[1]For spatiotemporal traffic modeling, the kernel function k can be extended to account for the temporal dimension.

3 Decentralized Data Fusion

In the previous section, two centralized data fusion approaches to exact (i.e., (1) and (2)) and approximate (i.e., (4) and (5)) GP prediction are introduced. In this section, we will discuss the decentralized data fusion component of our D^{2}FAS algorithm, which distributes the computational load among the mobile sensors to achieve efficient and scalable approximate GP prediction.

The intuition of our decentralized data fusion algorithm is as follows: Each of the K mobile sensors constructs a local summary of the observations taken along its own path in the road network and communicates its local summary to every other sensor. Then, it assimilates the local summaries received from the other sensors into a globally consistent summary, which is exploited for predicting the traffic phenomenon as well as active sensing. This intuition will be formally realized and described in the paragraphs below.

While exploring the road network, each mobile sensor summarizes its local observations taken along its path based on a common support set $U \subset V$ known to all the other sensors. Its local summary is defined as follows:

Definition 2 (Local Summary) *Given a common support set $U \subset V$ known to all K mobile sensors, a set $D_k \subset V$ of observed road segments and a column vector z_{D_k} of corresponding measurements local to mobile sensor k, its local summary is defined as a tuple $(\dot{z}_U^k, \dot{\Sigma}_{UU}^k)$ where*

$$\dot{z}_U^k \triangleq \Sigma_{UD_k}\Sigma_{D_kD_k|U}^{-1}(z_{D_k} - \mu_{D_k}) \quad (6)$$

$$\dot{\Sigma}_{UU}^k \triangleq \Sigma_{UD_k}\Sigma_{D_kD_k|U}^{-1}\Sigma_{D_kU} \quad (7)$$

such that $\Sigma_{D_kD_k|U}$ is defined in a similar manner to (5).

Remark. Unlike SoD (Section 2.2), the support set U of road segments does not have to be observed, since the local summary (i.e., (6) and (7)) is independent of the corresponding measurements z_U. So, U does not need to be a subset of $D = \bigcup_{k=1}^K D_k$. To select an informative support set U from the set V of all possible segments in the road network, an offline active selection procedure similar to that in the last paragraph of Section 2.2 can be performed just once prior to observing data to determine U. In contrast, SoD has to perform online active selection every time new road segments are being observed.

By communicating its local summary to every other sensor, each mobile sensor can then construct a globally consistent summary from the received local summaries:

Definition 3 (Global Summary) *Given a common support set $U \subset V$ known to all K mobile sensors and the local summary $(\dot{z}_U^k, \dot{\Sigma}_{UU}^k)$ of every mobile sensor $k = 1, \ldots, K$, the global summary is defined as a tuple $(\ddot{z}_U, \ddot{\Sigma}_{UU})$ where*

$$\ddot{z}_U \triangleq \sum_{k=1}^{K} \dot{z}_U^k \tag{8}$$

$$\ddot{\Sigma}_{UU} \triangleq \Sigma_{UU} + \sum_{k=1}^{K} \dot{\Sigma}_{UU}^k \ . \tag{9}$$

Remark. In this paper, we assume all-to-all communication between the K mobile sensors. Supposing this is not possible and each sensor can only communicate locally with its neighbors, the summation structure of the global summary (specifically, (8) and (9)) makes it amenable to be constructed using distributed consensus filters (Olfati-Saber, 2005). We omit these details since they are beyond the scope of this paper.

Finally, the global summary is exploited by each mobile sensor to compute a globally consistent predictive Gaussian distribution, as detailed in Theorem 1A below, as well as to perform decentralized active sensing (Section 4):

Theorem 1 *Let a common support set $U \subset V$ be known to all K mobile sensors.*

A. *Given the global summary $(\ddot{z}_U, \ddot{\Sigma}_{UU})$, each mobile sensor computes a globally consistent predictive Gaussian distribution $\mathcal{N}(\overline{\mu}_Y, \overline{\Sigma}_{YY})$ of the measurements at any set Y of unobserved road segments where*

$$\overline{\mu}_Y \triangleq \mu_Y + \Sigma_{YU} \ddot{\Sigma}_{UU}^{-1} \ddot{z}_U \tag{10}$$

$$\overline{\Sigma}_{YY} \triangleq \Sigma_{YY} - \Sigma_{YU}(\Sigma_{UU}^{-1} - \ddot{\Sigma}_{UU}^{-1})\Sigma_{UY} \ . \tag{11}$$

B. *Let $\mathcal{N}(\mu_{Y|D}^{\text{PITC}}, \Sigma_{YY|D}^{\text{PITC}})$ be the predictive Gaussian distribution computed by the centralized sparse partially independent training conditional (PITC) approximation of GP model (Quiñonero-Candela and Rasmussen, 2005) where*

$$\mu_{Y|D}^{\text{PITC}} \triangleq \mu_Y + \Gamma_{YD}\left(\Gamma_{DD} + \Lambda\right)^{-1}(z_D - \mu_D) \tag{12}$$

$$\Sigma_{YY|D}^{\text{PITC}} \triangleq \Sigma_{YY} - \Gamma_{YD}\left(\Gamma_{DD} + \Lambda\right)^{-1}\Gamma_{DY} \tag{13}$$

such that

$$\Gamma_{BB'} \triangleq \Sigma_{BU}\Sigma_{UU}^{-1}\Sigma_{UB'} \tag{14}$$

and Λ is a block-diagonal matrix constructed from the K diagonal blocks of $\Sigma_{DD|U}$, each of which is a matrix $\Sigma_{D_k D_k|U}$ for $k = 1, \ldots, K$ where $D = \bigcup_{k=1}^{K} D_k$. Then, $\overline{\mu}_Y = \mu_{Y|D}^{\text{PITC}}$ and $\overline{\Sigma}_{YY} = \Sigma_{YY|D}^{\text{PITC}}$.

Its proof is given in (Chen *et al.*, 2012). The equivalence result of Theorem 1B bears two implications:

Remark 1. The computation of PITC can be parallelized and distributed among the mobile sensors in a Google-like MapReduce paradigm (Chu *et al.*, 2007), thereby improving the time efficiency of prediction: Each of the K mappers (sensors) is tasked to compute its local summary while the reducer (any sensor) sums these local summaries into a global summary, which is then used to compute the predictive Gaussian distribution. Supposing $|Y| \leq |U|$ for simplicity, the $\mathcal{O}\big(|D|((|D|/K)^2 + |U|^2)\big)$ time incurred by PITC can be reduced to $\mathcal{O}\big((|D|/K)^3 + |U|^3 + |U|^2 K\big)$ time of running our decentralized algorithm on each of the K sensors, the latter of which scales better with increasing number $|D|$ of observations.

Remark 2. We can draw insights from PITC to elucidate an underlying property of our decentralized algorithm: It is assumed that $Z_{D_1}, \ldots, Z_{D_K}, Z_Y$ are conditionally independent given the measurements at the support set U of road segments. To potentially reduce the degree of violation of this assumption, an informative support set U is actively selected, as described earlier in this section. Furthermore, the experimental results on real-world urban road network data[2] (Section 6) show that D^{2}FAS can achieve predictive performance comparable to that of the full GP model while enjoying significantly lower computational cost, thus demonstrating the practicality of such an assumption for predicting traffic phenomena. The predictive performance of D^{2}FAS can be improved by increasing the size of U at the expense of greater time and communication overhead.

4 Decentralized Active Sensing

The problem of active sensing with K mobile sensors is formulated as follows: Given the set $D_k \subset V$ of observed road segments and the currently traversed road segment $s_k \in V$ of every mobile sensor $k = 1, \ldots, K$, the mobile sensors have to coordinate to select the most informative walks $w_1^*, \ldots, w_K^*$ of length (i.e., number of road segments) L each and with respective origins $s_1, \ldots, s_K$ in the road network G:

$$(w_1^*, \ldots, w_K^*) = \underset{(w_1, \ldots, w_K)}{\arg\max}\ \mathbb{H}\Big[Z_{\bigcup_{k=1}^{K} Y_{w_k}} \Big| Z_{\bigcup_{k=1}^{K} D_k}\Big] \tag{15}$$

where Y_{w_k} denotes the set of unobserved road segments induced by the walk w_k. To simplify notation, let a joint walk be denoted by $w \triangleq (w_1, \ldots, w_K)$ (similarly, for w^*) and its induced set of unobserved road segments be $Y_w \triangleq \bigcup_{k=1}^{K} Y_{w_k}$ from now on. Interestingly, it can be shown using the chain rule for entropy that these maximum-entropy walks w^* minimize the posterior joint entropy (i.e., $\mathbb{H}[Z_{V \setminus (D \bigcup Y_{w^*})} | Z_{D \bigcup Y_{w^*}}]$) of the measurements at the remaining unobserved segments (i.e., $V \setminus (D \bigcup Y_{w^*})$) in the road network. After executing the walk w_k^*, each mobile sensor k observes the set $Y_{w_k^*}$ of road segments and updates its local information:

$$D_k \leftarrow D_k \bigcup Y_{w_k^*}, z_{D_k} \leftarrow z_{D_k \bigcup Y_{w_k^*}}, s_k \leftarrow \text{terminus of } w_k^* \ . \tag{16}$$

[2] Quiñonero-Candela and Rasmussen (2005) only illustrated the predictive performance of PITC on a simulated toy example.

Evaluating the Gaussian posterior entropy term in (15) involves computing a posterior covariance matrix (3) using one of the data fusion methods described earlier: If (2) of full GP model (Section 2) or (5) of SoD (Section 2.2) is to be used, then the observations that are gathered distributedly by the sensors have to be fully communicated to a central data fusion center. In contrast, our decentralized data fusion algorithm (Section 3) only requires communicating local summaries (Definition 2) to compute (11) for solving the active sensing problem (15):

$$w^* = \arg\max_{w} \overline{\mathbb{H}}[Z_{Y_w}] \ , \tag{17}$$

$$\overline{\mathbb{H}}[Z_{Y_w}] \triangleq \frac{1}{2}\log(2\pi e)^{|Y_w|}\left|\overline{\Sigma}_{Y_w Y_w}\right| \ . \tag{18}$$

Without imposing any structural assumption, solving the active sensing problem (17) will be prohibitively expensive due to the space of possible joint walks w that grows exponentially in the number K of mobile sensors. To overcome this scalability issue for D^{2}FAS, our key idea is to construct a block-diagonal matrix whose log-determinant closely approximates that of $\overline{\Sigma}_{Y_w Y_w}$ (11) and exploit the property that the log-determinant of such a block-diagonal matrix can be decomposed into a sum of log-determinants of its diagonal blocks, each of which depends only on the walks of a disjoint subset of the K mobile sensors. Consequently, the active sensing problem can be partially decentralized, leading to a reduced space of possible joint walks to be searched, as detailed in the rest of this section.

Firstly, we extend an earlier assumption in Section 3: $Z_{D_1},\ldots,Z_{D_K},Z_{Y_{w_1}},\ldots,Z_{Y_{w_K}}$ are conditionally independent given the measurements at the support set U of road segments. Then, it can be shown via the equivalence to PITC (Theorem 1B) that $\overline{\Sigma}_{Y_w Y_w}$ (11) comprises diagonal blocks of the form $\overline{\Sigma}_{Y_{w_k} Y_{w_k}}$ for $k=1,\ldots,K$ and off-diagonal blocks of the form $\Sigma_{Y_{w_k}U}\ddot{\Sigma}^{-1}_{UU}\Sigma_{UY_{w_{k'}}}$ for $k,k'=1,\ldots,K$ and $k\neq k'$. In particular, each off-diagonal block of $\overline{\Sigma}_{Y_w Y_w}$ represents the correlation of measurements between the unobserved road segments Y_{w_k} and $Y_{w_{k'}}$ along the respective walks w_k of sensor k and $w_{k'}$ of sensor k'. If the correlation between some pair of their possible walks is high enough, then their walks have to be coordinated. This is formally realized by the following coordination graph over the K sensors:

Definition 4 (Coordination Graph) *Define the coordination graph to be an undirected graph $\mathcal{G}\triangleq(\mathcal{V},\mathcal{E})$ that comprises*

- *a set $\mathcal{V}$ of vertices denoting the K mobile sensors, and*
- *a set $\mathcal{E}$ of edges denoting coordination dependencies between sensors such that there exists an edge $\{k,k'\}$ incident with sensors $k\in\mathcal{V}$ and $k'\in\mathcal{V}\setminus\{k\}$ iff*

$$\max_{s\in Y_{W_k},s'\in Y_{W_{k'}}}\left|\Sigma_{sU}\ddot{\Sigma}^{-1}_{UU}\Sigma_{Us'}\right|>\varepsilon \tag{19}$$

for a predefined constant $\varepsilon>0$ where W_k denotes the set of possible walks of length L of mobile sensor k from origin s_k in the road network G and $Y_{W_k}\triangleq\bigcup_{w_k\in W_k}Y_{w_k}$.

Remark. The construction of $\mathcal{G}$ can be decentralized as follows: Since $\ddot{\Sigma}_{UU}$ is symmetric and positive definite, it can be decomposed by Cholesky factorization into $\ddot{\Sigma}_{UU}=\Psi\Psi^\top$ where Ψ is a lower triangular matrix and $\Psi^\top$ is the transpose of Ψ. Then, $\Sigma_{sU}\ddot{\Sigma}^{-1}_{UU}\Sigma_{Us'}=(\Psi\backslash\Sigma_{Us})^\top\Psi\backslash\Sigma_{Us'}$ where $\Psi\backslash B$ denotes the column vector ϕ solving $\Psi\phi=B$. That is, $\Sigma_{sU}\ddot{\Sigma}^{-1}_{UU}\Sigma_{Us'}$ (19) can be expressed as a dot product of two vectors $\Psi\backslash\Sigma_{Us}$ and $\Psi\backslash\Sigma_{Us'}$; this property is exploited to determine adjacency between sensors in a decentralized manner:

Definition 5 (Adjacency) *Let*

$$\Phi_k\triangleq\{\Psi\backslash\Sigma_{Us}\}_{s\in Y_{W_k}} \tag{20}$$

for $k=1,\ldots,K$. A sensor $k\in\mathcal{V}$ is adjacent to sensor $k'\in\mathcal{V}\setminus\{k\}$ in coordination graph $\mathcal{G}$ iff

$$\max_{\phi\in\Phi_k,\phi'\in\Phi_{k'}}\left|\phi^\top\phi'\right|>\varepsilon \ . \tag{21}$$

It follows from the above definition that if each sensor k constructs Φ_k and exchanges it with every other sensor, then it can determine its adjacency to all the other sensors and store this information in a column vector a_k of length K with its k'-th component being defined as follows:

$$[a_k]_{k'}=\begin{cases}1 & \text{if sensor } k \text{ is adjacent to sensor } k',\\ 0 & \text{otherwise.}\end{cases} \tag{22}$$

By exchanging its adjacency vector a_k with every other sensor, each sensor can construct a globally consistent adjacency matrix $A_{\mathcal{G}}\triangleq(a_1\ldots a_K)$ to represent coordination graph $\mathcal{G}$.

Next, by computing the connected components (say, $\mathcal{K}$ of them) of coordination graph $\mathcal{G}$, their resulting vertex sets partition the set $\mathcal{V}$ of K sensors into $\mathcal{K}$ disjoint subsets $\mathcal{V}_1,\ldots,\mathcal{V}_{\mathcal{K}}$ such that the sensors within each subset have to coordinate their walks. Each sensor can determine its residing connected component in a decentralized way by performing a depth-first search in $\mathcal{G}$ starting from it as root.

Finally, construct a block-diagonal matrix $\widehat{\Sigma}_{Y_w Y_w}$ to comprise diagonal blocks of the form $\overline{\Sigma}_{Y_{w_{\mathcal{V}_n}}Y_{w_{\mathcal{V}_n}}}$ for $n=1,\ldots,\mathcal{K}$ where $w_{\mathcal{V}_n}\triangleq(w_k)_{k\in\mathcal{V}_n}$ and $Y_{w_{\mathcal{V}_n}}\triangleq\bigcup_{k\in\mathcal{V}_n}Y_{w_k}$. The active sensing problem (17) is then approximated by

$$\begin{aligned}&\max_{w}\ \frac{1}{2}\log(2\pi e)^{|Y_w|}\left|\widehat{\Sigma}_{Y_w Y_w}\right|\\ &\equiv\max_{(w_{\mathcal{V}_1},\ldots,w_{\mathcal{V}_{\mathcal{K}}})}\sum_{n=1}^{\mathcal{K}}\log(2\pi e)^{|Y_{w_{\mathcal{V}_n}}|}\left|\overline{\Sigma}_{Y_{w_{\mathcal{V}_n}}Y_{w_{\mathcal{V}_n}}}\right| \qquad (23)\\ &=\sum_{n=1}^{\mathcal{K}}\max_{w_{\mathcal{V}_n}}\log(2\pi e)^{|Y_{w_{\mathcal{V}_n}}|}\left|\overline{\Sigma}_{Y_{w_{\mathcal{V}_n}}Y_{w_{\mathcal{V}_n}}}\right|,\end{aligned}$$

which can be solved in a partially decentralized manner by each disjoint subset $\mathcal{V}_n$ of mobile sensors:

$$\widehat{w}_{\mathcal{V}_n}=\arg\max_{w_{\mathcal{V}_n}}\log(2\pi e)^{|Y_{w_{\mathcal{V}_n}}|}\left|\overline{\Sigma}_{Y_{w_{\mathcal{V}_n}}Y_{w_{\mathcal{V}_n}}}\right|. \tag{24}$$

Our active sensing algorithm becomes fully decentralized if ε is set to be sufficiently large: more sensors become isolated in $\mathcal{G}$, consequently decreasing the size $\kappa\triangleq\max_n|\mathcal{V}_n|$

of its largest connected component to 1. As shown in Section 5.1, decreasing κ improves its time efficiency. On the other hand, it tends to a centralized behavior (17) by setting $\varepsilon \to 0^+$: $\mathcal{G}$ becomes near-complete, thus resulting in $\kappa \to K$.

Let
$$\xi \triangleq \max_{n, w_{\mathcal{V}_n}, i, i'} \left| \left[\left(\overline{\Sigma}_{Y_{w_{\mathcal{V}_n}} Y_{w_{\mathcal{V}_n}}} \right)^{-1} \right]_{ii'} \right| \quad (25)$$

and $\epsilon \triangleq 0.5 \log 1 \Big/ \left(1 - \left(K^{1.5} L^{2.5} \kappa \xi \varepsilon\right)^2\right)$. In the result below, we prove that the joint walk $\widehat{w} \triangleq (\widehat{w}_{\mathcal{V}_1}, \ldots, \widehat{w}_{\mathcal{V}_\mathcal{K}})$ is guaranteed to achieve an entropy $\overline{\mathbb{H}}[Z_{Y_{\widehat{w}}}]$ (i.e., by plugging $\widehat{w}$ into (18)) that is not more than ϵ from the maximum entropy $\overline{\mathbb{H}}[Z_{Y_{w^*}}]$ achieved by joint walk w^* (17):

Theorem 2 (Performance Guarantee) *If* $K^{1.5} L^{2.5} \kappa \xi \varepsilon < 1$, *then* $\overline{\mathbb{H}}[Z_{Y_{w^*}}] - \overline{\mathbb{H}}[Z_{Y_{\widehat{w}}}] \leq \epsilon$.

Its proof is given in (Chen *et al.*, 2012). The implication of Theorem 2 is that our partially decentralized active sensing algorithm can perform comparatively well (i.e., small ϵ) under the following favorable environmental conditions: (a) the network of K sensors is not large, (b) length L of each sensor's walk to be optimized is not long, (c) the largest subset of κ sensors being formed to coordinate their walks (i.e., largest connected component in $\mathcal{G}$) is reasonably small, and (d) the minimum required correlation ε between walks of adjacent sensors is kept low.

Algorithm 1 below outlines the key operations of our D^{2}FAS algorithm to be run on each mobile sensor k, as detailed previously in Sections 3 and 4:

Algorithm 1: D^{2}FAS$(U, K, L, k, D_k, z_{D_k}, s_k)$

while *true* **do**
- /* Data fusion (Section 3) */
- Construct local summary by (6) & (7)
- Exchange local summary with every sensor $i \neq k$
- Construct global summary by (8) & (9)
- Predict measurements at unobserved road segments by (10) & (11)
- /* Active Sensing (Section 4) */
- Construct Φ_k by (20)
- Exchange Φ_k with every sensor $i \neq k$
- Compute adjacency vector a_k by (21) & (22)
- Exchange adjacency vector with every sensor $i \neq k$
- Construct adjacency matrix of coordination graph
- Find vertex set $\mathcal{V}_n$ of its residing connected component
- Compute maximum-entropy joint walk $\widehat{w}_{\mathcal{V}_n}$ by (24)
- Execute walk $\widehat{w}_k$ and observe its road segments $Y_{\widehat{w}_k}$
- Update local information D_k, z_{D_k}, and s_k by (16)

5 Time and Communication Overheads

In this section, the time and communication overheads of our D^{2}FAS algorithm are analyzed and compared to that of centralized active sensing (17) coupled with the data fusion methods: Full GP (FGP) and SoD (Section 2).

5.1 Time Complexity

The data fusion component of D^{2}FAS involves computing the local and global summaries and the predictive Gaussian distribution. To construct the local summary using (6) and (7), each sensor has to evaluate $\Sigma_{D_k D_k|U}$ in $\mathcal{O}\big(|U|^3 + |U|(|D|/K)^2\big)$ time and invert it in $\mathcal{O}\big((|D|/K)^3\big)$ time, after which the local summary is obtained in $\mathcal{O}\big(|U|^2|D|/K + |U|(|D|/K)^2\big)$ time. The global summary is computed in $\mathcal{O}\big(|U|^2 K\big)$ by (8) and (9). Finally, the predictive Gaussian distribution is derived in $\mathcal{O}\big(|U|^3 + |U||Y|^2\big)$ time using (10) and (11). Supposing $|Y| \leq |U|$ for simplicity, the time complexity of data fusion is then $\mathcal{O}\big((|D|/K)^3 + |U|^3 + |U|^2 K\big)$.

Let the maximum out-degree of G be denoted by δ. Then, each sensor has to consider $\Delta \triangleq \delta^L$ possible walks of length L. The active sensing component of D^{2}FAS involves computing Φ_k in $\mathcal{O}\big(\Delta L |U|^2\big)$ time, a_k in $\mathcal{O}\big(\Delta^2 L^2 |U| K\big)$ time, its residing connected component in $\mathcal{O}\big(\kappa^2\big)$ time, and the maximum-entropy joint walk by (11) and (24) with the following incurred time: The largest connected component of κ sensors in $\mathcal{G}$ has to consider Δ^κ possible joint walks. Note that $\overline{\Sigma}_{Y_{w_{\mathcal{V}_n}} Y_{w_{\mathcal{V}_n}}} = \mathrm{diag}\Big((\Sigma_{Y_{w_k} Y_{w_k}|U})_{k \in \mathcal{V}_n}\Big) + \Sigma_{Y_{w_{\mathcal{V}_n}} U} \ddot{\Sigma}_{UU}^{-1} \Sigma_{U Y_{w_{\mathcal{V}_n}}}$ where $\mathrm{diag}(B)$ constructs a diagonal matrix by placing vector B on its diagonal. By exploiting Φ_k, the diagonal and latter matrix terms for all possible joint walks can be computed in $\mathcal{O}\big(\kappa\Delta(L|U|^2 + L^2|U|)\big)$ and $\mathcal{O}\big(\kappa^2\Delta^2 L^2 |U|\big)$ time, respectively. For each joint walk $w_{\mathcal{V}_n}$, evaluating the determinant of $\overline{\Sigma}_{Y_{w_{\mathcal{V}_n}} Y_{w_{\mathcal{V}_n}}}$ incurs $\mathcal{O}\big((\kappa L)^3\big)$ time. Therefore, the time complexity of active sensing is $\mathcal{O}\big(\kappa\Delta L|U|^2 + \Delta^2 L^2 |U|(K + \kappa^2) + \Delta^\kappa (\kappa L)^3\big)$.

Hence, the time complexity of our D^{2}FAS algorithm is $\mathcal{O}((|D|/K)^3 + |U|^2(|U| + K + \kappa\Delta L) + \Delta^2 L^2 |U|(K + \kappa^2) + \Delta^\kappa (\kappa L)^3)$. In contrast, the time incurred by centralized active sensing coupled with FGP and SoD are, respectively, $\mathcal{O}\big(|D|^3 + \Delta^K KL(|D|^2 + (KL)^2)\big)$ and $\mathcal{O}\big(|U|^3|D| + \Delta^K KL(|U|^2 + (KL)^2)\big)$. It can be observed that D^{2}FAS can scale better with large $|D|$ (i.e., number of observations) and K (i.e., number of sensors). The scalability of D^{2}FAS vs. FGP and SoD will be further evaluated empirically in Section 6.

5.2 Communication Complexity

Let the communication overhead be defined as the size of each broadcast message. Recall from the data fusion component of D^{2}FAS in Algorithm 1 that, in each iteration, each sensor broadcasts a $\mathcal{O}\big(|U|^2\big)$-sized summary encapsulating its local observations, which is robust against communication failure. In contrast, FGP and SoD require each sensor to broadcast, in each iteration, a $\mathcal{O}(|D|/K)$-sized message comprising exactly its local observations to handle communication failure. If the number of local observations grows to be larger in size than a local summary of predefined size, then the data fusion component of D^{2}FAS is more scalable than FGP and SoD in terms of communication overhead. For the partially decentralized active sensing component of D^{2}FAS, each sensor broadcasts $\mathcal{O}(\Delta L|U|)$-sized Φ_k and $\mathcal{O}(K)$-sized a_k messages.

6 Experiments and Discussion

This section evaluates the predictive performance, time efficiency, and scalability of our D^{2}FAS algorithm on a real-world traffic phenomenon (i.e., speeds (km/h) of road segments) over an urban road network (top figure) in Tampines area, Singapore during evening peak hours on April 20, 2011. It comprises 775 road segments including highways, arterials, slip roads, etc. The mean speed is 48.8 km/h and the standard deviation is 20.5 km/h.

The performance of D^{2}FAS is compared to that of centralized active sensing (17) coupled with the state-of-the-art data fusion methods: full GP (FGP) and SoD (Section 2). A network of K mobile sensors is tasked to explore the road network to gather a total of up to 960 observations. To reduce computational time, each sensor repeatedly computes and executes maximum-entropy walks of length $L = 2$ (instead of computing a very long walk), unless otherwise stated. For D^{2}FAS and SoD, $|U|$ is set to 64 . For the active sensing component of D^{2}FAS, ε is set to 0.1, unless otherwise stated. The experiments are run on a Linux PC with Intel® Core™2 Quad CPU Q9550 at 2.83 GHz.

6.1 Performance Metrics

The first metric evaluates the predictive performance of a tested algorithm: It measures the *root mean squared error* (RMSE) $\sqrt{|V|^{-1}\sum_{s\in V}\left(z_s-\widehat{\mu}_s\right)^2}$ over the entire domain V of the road network that is incurred by the predictive mean $\widehat{\mu}_s$ of the tested algorithm, specifically, using (1) of FGP, (4) of SoD, or (10) of D^{2}FAS. The second metric evaluates the time efficiency and scalability of a tested algorithm by measuring its incurred time; for D^{2}FAS, the maximum of the time incurred by all subsets $\mathcal{V}_1,\ldots,\mathcal{V}_K$ of sensors is recorded.

6.2 Results and Analysis

Predictive performance and time efficiency. Fig. 1 shows results of the performance of the tested algorithms averaged over 40 randomly generated starting sensor locations with varying number $K = 4, 6, 8$ of sensors. It can be observed that D^{2}FAS is significantly more time-efficient and scales better with increasing number $|D|$ of observations (Figs. 1d to 1f) while achieving predictive performance close to that of centralized active sensing coupled with FGP and SoD (Figs. 1a to 1c). Specifically, D^{2}FAS is about $1, 2, 4$ orders of magnitude faster than centralized active sensing coupled with FGP and SoD for $K = 4, 6, 8$ sensors, respectively.

Scalability of D^{2}FAS. Using the same results as that in Fig. 1, Fig. 2 plots them differently to reveal the scalability of the tested algorithms with increasing number K of sensors. Additionally, we provide results of the performance of D^{2}FAS for $K = 10, 20, 30$ sensors; such results are not available for centralized active sensing coupled with FGP and SoD due to extremely long incurred time. It can be observed from Figs. 2a to 2c that the predictive performance of all tested algorithms improve with a larger number of sensors because each sensor needs to execute fewer walks and its performance is therefore less adversely affected by its myopic selection (i.e., $L = 2$) of maximum-entropy walks. As a result, more informative unobserved road segments are explored.

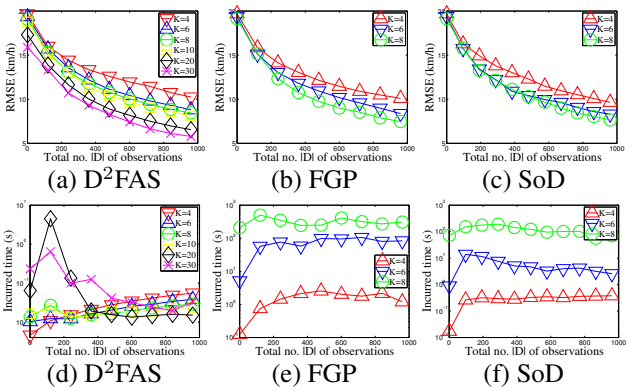
(d) $K = 4$ (e) $K = 6$ (f) $K = 8$

Figure 1: Graphs of (a-c) predictive performance and (d-f) time efficiency vs. total no. $|D|$ of observations gathered by varying number K of mobile sensors.

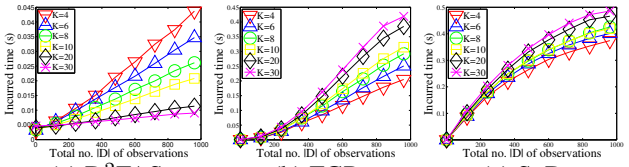


(a) D^{2}FAS (b) FGP (c) SoD

(d) D^{2}FAS (e) FGP (f) SoD

Figure 2: Graphs of (a-c) predictive performance and (d-f) time efficiency vs. total no. $|D|$ of observations gathered by varying number K of mobile sensors.

As shown in Fig. 2d, when the randomly placed sensors gather their initial observations (i.e., $|D| < 400$), the time incurred by D^{2}FAS is higher for greater K due to larger subsets of sensors being formed to coordinate their walks (i.e., larger κ). As more observations are gathered (i.e., $|D| \geq 400$), its partially decentralized active sensing component directs the sensors to explore further apart from each other in order to maximize the entropy of their walks. This consequently decreases κ, leading to a reduction in incurred time. Furthermore, as K increases from 4 to 20, the incurred time decreases due to its decentralized data fusion component that can distribute the computational load



(a) D^{2}FAS (b) FGP (c) SoD

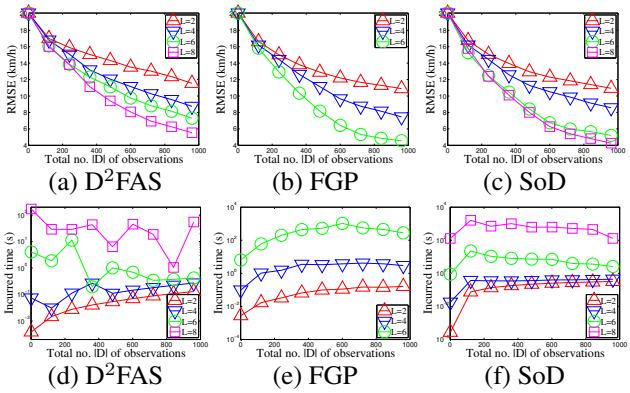
Figure 3: Graphs of time efficiency vs. total no. $|D|$ of observations gathered by varying number K of sensors.

among a greater number of sensors. When the road network becomes more crowded from $K = 20$ to $K = 30$ sensors, the incurred time increases slightly due to slightly larger κ. In contrast, Figs. 2e and 2f show that the time taken by FGP and SoD increases significantly primarily due to their centralized active sensing incurring exponential time in K. Hence, the scalability of our D^{2}FAS algorithm in the number of sensors allows the deployment of a larger-scale mobile sensor network (i.e., $K \geq 10$) to achieve more accurate traffic modeling and prediction (Figs. 2a to 2c).

Scalability of data fusion. Fig. 3 shows results of the scalability of the tested data fusion methods with increasing number K of sensors. In order to produce meaningful results for fair comparison, the same active sensing component has to be coupled with the data fusion methods and its incurred time kept to a minimum. As such, we impose the use of a fully decentralized active sensing component to be performed by each mobile sensor k: $w_k^* = \arg\max_{w_k} \mathbb{H}[Z_{Y_{w_k}}|Z_D]$. For D^{2}FAS, this corresponds exactly to (24) by setting a large enough ε (in our experiments, $\varepsilon = 2$) to yield $\kappa = 1$; consequently, computational and communicational operations pertaining to the coordination graph can be omitted.

It can be seen from Fig. 3a that the time incurred by the decentralized data fusion component of D^{2}FAS decreases with increasing K, as explained previously. In contrast, the time incurred by FGP and SoD increases (Fig. 3b and 3c): As discussed above, a larger number of sensors results in a greater quantity of more informative unique observations to be gathered (i.e., fewer repeated observations), which increases the time needed for data fusion. When $K \geq 10$, D^{2}FAS is at least 1 order of magnitude faster than FGP and SoD. It can also be observed that D^{2}FAS scales better with increasing number of observations. So, the real-time performance and scalability of D^{2}FAS's decentralized data fusion enable it to be used for persistent large-scale traffic modeling and prediction where a large number of observations and sensors (including static and passive ones) are expected to be available.

Varying length L of walk. Fig. 4 shows results of the performance of the tested algorithms with varying length $L = 2, 4, 6, 8$ of maximum-entropy joint walks; we choose to experiment with just 2 sensors since Figs. 2 and 3 reveal that a smaller number of sensors produce poorer predictive performance and higher incurred time with large number of



(a) D^{2}FAS (b) FGP (c) SoD

(d) D^{2}FAS (e) FGP (f) SoD

Figure 4: Graphs of (a-c) predictive performance and (d-f) time efficiency vs. total no. $|D|$ of observations gathered by 2 mobile sensors with varying length L of maximum-entropy joint walks.

observations for D^{2}FAS. It can be observed that the predictive performance of all tested algorithms improve with increasing walk length L because the selection of maximum-entropy joint walks is less myopic. The time incurred by D^{2}FAS increases due to larger κ but grows more slowly and is lower than that incurred by centralized active sensing coupled with FGP and SoD. Specifically, when $L = 8$, D^{2}FAS is at least 1 order of magnitude faster (i.e., average of 60 s) than centralized active sensing coupled with SoD (i.e., average of > 732 s) and FGP (i.e., not available due to excessive incurred time). Also, notice from Figs. 2a and 2d that if a large number of sensors (i.e., $K = 30$) is available, D^{2}FAS can select shorter walks of $L = 2$ to be significantly more time-efficient (i.e., average of > 3 orders of magnitude faster) while achieving predictive performance comparable to that of SoD with $L = 8$ and FGP with $L = 6$.

7 Conclusion

This paper describes a decentralized data fusion and active sensing algorithm for modeling and predicting spatiotemporal traffic phenomena with mobile sensors. Analytical and empirical results have shown that our D^{2}FAS algorithm is significantly more time-efficient and scales better with increasing number of observations and sensors while achieving predictive performance close to that of state-of-the-art centralized active sensing coupled with FGP and SoD. Hence, D^{2}FAS is practical for deployment in a large-scale mobile sensor network to achieve persistent and accurate traffic modeling and prediction. For our future work, we will assume that each sensor can only communicate locally with its neighbors (instead of assuming all-to-all communication) and develop a *distributed* data fusion approach to efficient and scalable approximate GP prediction based on D^{2}FAS and consensus filters (Olfati-Saber, 2005).

Abstract

In recent years a number of methods have been developed for automatically learning the (sparse) connectivity structure of Markov Random Fields. These methods are mostly based on L_1-regularized optimization which has a number of disadvantages such as the inability to assess model uncertainty and expensive cross-validation to find the optimal regularization parameter. Moreover, the model's predictive performance may degrade dramatically with a sub-optimal value of the regularization parameter (which is sometimes desirable to induce sparseness). We propose a fully Bayesian approach based on a "spike and slab" prior (similar to L_0 regularization) that does not suffer from these shortcomings. We develop an approximate MCMC method combining Langevin dynamics and reversible jump MCMC to conduct inference in this model. Experiments show that the proposed model learns a good combination of the structure and parameter values without the need for separate hyper-parameter tuning. Moreover, the model's predictive performance is much more robust than L_1-based methods with hyper-parameter settings that induce highly sparse model structures.

1 Introduction

Undirected probabilistic graphical models, also known as Markov Random Fields (MRFs), have been widely used in a large variety of domains including computer vision (Li, 2009), natural language processing (Sha and Pereira, 2003), and social networks (Robins et al., 2007). The structure of the model is defined through a set of features defined on subsets of random variables. Automated methods to select relevant features are becoming increasingly important in a time where the proliferation of sensors make it possible to measure a multitude of data-attributes. There is also an increasing interest in *sparse* model structures because they help against overfitting and are computationally more tractable than dense model structures.

In this paper we focus on a particular type of MRF, called a log-linear model, where structure learning or feature selection is integrated with parameter estimation. Although structure learning has been extensively studied for directed graphical models, it is typically more difficult for undirected models due to the intractable normalization term of the probability distribution, known as the partition function. Traditional algorithms apply only to restricted types of structures with low tree-width (Andrew and Gao, 2007; Tsuruoka et al., 2009; Hu et al., 2009) or special models such as Gaussian graphical models (Jones et al., 2005) so that accurate inference can be conducted efficiently.

For an arbitrary structure, various methods have been proposed in the literature, generally categorized into two approaches. One approach is based on separate tests on an edge or the neighbourhood of a node so that there is no need to compute the joint distribution (Wainwright et al., 2007; Bresler et al., 2008; Ravikumar et al., 2010). The other approach is based on maximum likelihood estimation (MLE) with a sparsity inducing criterion. These methods require approximate inference algorithms in order to estimate the log-likelihood such as Gibbs sampling (Della Pietra et al., 1997), loopy belief propagation (Lee et al., 2006; Zhu et al., 2010), or pseudo-likelihood (Höfling and Tibshirani, 2009). A popular choice of such a criterion is L_1 regularization (Riezler and Vasserman, 2004; Dudik et al., 2004) which enjoys several good properties such as a convex objective function and a consistency guarantee. However, L_1-regularized MLE is usually sensitive to the choice the regularization strength, and these optimization-based methods cannot provide a credible interval for the learned structure. Also, in order to learn a sparse structure, a strong penalty has to be imposed on all the edges which usually results in suboptimal parameter values.

We will follow a third approach to MRF structure learning in a fully Bayesian framework which has not been ex-

plored yet. The Bayesian approach considers the structure of a graphical model as random. Inference in a Bayesian model provides inherent regularization, and offers a fully probabilistic characterization of the underlying structure. It was shown in Park and Casella (2008) that Bayesian models with a Gaussian or Laplace prior distribution (corresponding to L_2 or L_1 regularization) do not exhibit sparse structure. Mohamed et al. (2011) proposes to use a "spike and slab" prior for learning *directed* graphical models which corresponds to the ideal L_0 regularization. This model exhibits better robustness against over-fitting than the related L_1 approaches. Unlike the Laplace/Gaussian prior, the posterior distribution over parameters for a "spike and slab" prior is no longer guaranteed to be unimodal. However, approximate inference methods have been successfully applied in the context of directed models using MCMC (Mohamed et al., 2011) and expectation propagation (Hernández-Lobato et al., 2010).

Unfortunately, Bayesian inference for MRFs is much harder than for directed networks due to the partition function. This feature renders even MCMC sampling intractable which caused some people to dub these problems "double intractability" (Murray et al., 2006). Nevertheless, variational methods (Parise and Welling, 2006; Qi et al., 2005) and MCMC methods (Murray and Ghahramani, 2004) have been successfully explored for approximate inference when the model structure is fixed.

We propose a Bayesian structure learning method with a spike and slab prior for MRFs and devise an approximate MCMC method to draw samples of both the model structure and the model parameters by combining a modified Langevin sampler with a reversible jump MCMC method. Experiments show that the posterior distribution estimated by our inference method matches the actual distribution very well. Moreover, our method offers better robustness to both under-fitting and over-fitting than L_1-regularized methods. A related but different application of the spike and slab distribution in MRFs is shown in Courville et al. (2011) for modelling hidden random variables.

This paper is organized as follows: we first introduce a hierarchical Bayesian model for MRF structure learning in section 2 and then describe an approximate MCMC method in section 3, 4, and 5 to draw samples for the model parameters, structure, and other hyper-parameters respectively. Experiments are conducted in section 6 on two simulated data sets and a real-world dataset, followed by a discussion section.

2 Learning the Structure of MRFs as Bayesian Inference

The probability distribution of a MRF is defined by a set of potential functions. Consider a widely used family of MRFs with log-linear parametrization:

$$P(\mathbf{x}|\boldsymbol{\theta}) = \frac{1}{Z(\boldsymbol{\theta})} \exp\left(\sum_{\alpha} \theta_\alpha f_\alpha(\mathbf{x}_\alpha)\right) \tag{1}$$

where each potential function is defined as the exponential of the product between a feature function f_α of a set of variables $\mathbf{x}_\alpha$ and an associated parameter θ_α. Z is called the partition function. All the variables in the scope of a potential function form a clique in their graphical representation. When a parameter θ_α has a value of zero, we could equivalently remove feature f_α and all the edges between variables in $\mathbf{x}_\alpha$ (if these variables are not also in the scope of other features) without changing the distribution of $\mathbf{x}$. Therefore, by learning the parameters of this MRF model we can simultaneously learn the structure of a model if we allow some parameters to go to zero.

The Bayesian learning approach to graphical models considers parameters as a random variable subject to a prior. Given observed data, we can infer the posterior distribution of the parameters and their connectivity structure. Two commonly used priors, the Laplace and the Gaussian distribution, correspond to the L_1 and L_2 penalties respectively in the associated optimization-based approach. Although a model learned by L_1-penalized MLE is able to obtain a sparse structure, the full Bayesian treatment usually results in a fully connected model with many weak edges as observed in Park and Casella (2008), without special approximate assumptions like the ones in Lin and Lee (2006). We propose to use the "spike and slab" prior to learn a sparse structure for MRFs in a fully Bayesian approach. The spike and slab prior (Mitchell and Beauchamp, 1988; Ishwaran and Rao, 2005) is a mixture distribution which consists of a point mass at zero (spike) and a widely spread distribution (slab):

$$P(\theta_\alpha) = (1 - p_0)\delta(\theta_\alpha) + p_0 \mathcal{N}(\theta_\alpha; 0, \sigma_0^2) \tag{2}$$

where $p_0 \in [0, 1]$, δ is the Dirac delta function, and σ_0 is usually large enough to be uninformative. The spike component controls the sparsity of the structure in the posterior distribution while the slab component usually applies a mild shrinkage effect on the parameters of the existing edges even in a highly sparse model. This type of *selective* shrinkage is different from the global shrinkage imposed by L_1/L_2 regularization, and enjoys benefits in parameter estimation as demonstrated in the experiment section.

The Bayesian MRF with the spike and slab prior is formulated as follows:

$$\begin{aligned} P(\mathbf{x}|\boldsymbol{\theta}) &= \frac{1}{Z(\boldsymbol{\theta})} \exp\left(\sum_{\alpha} \theta_\alpha f_\alpha(\mathbf{x}_\alpha)\right) \\ \theta_\alpha &= Y_\alpha A_\alpha \\ Y_\alpha &\sim \mathrm{Bern}(p_0) \quad p_0 \sim \mathrm{Beta}(a, b) \\ A_\alpha &\sim \mathcal{N}(0, \sigma_0^2) \quad \sigma_0^{-2} \sim \Gamma(c, d) \end{aligned} \tag{3}$$

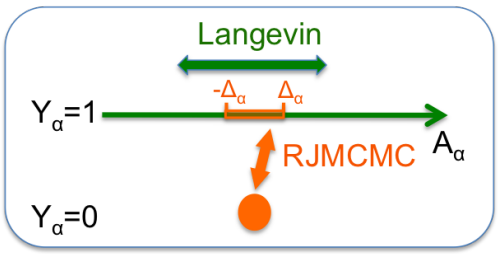

Figure 1: Illustration of the MCMC for A_α and Y_α.

where $\mathbf{x}$ is a set of state variables and a, b, c, and d are hyper-parameters. In the experiments we will use pairwise features in which case $\alpha = (i, j)$ plus bias terms given by $\sum_i \theta_i f_i(x_i)$ in the expression for the log-probability. We will use a normal prior $\theta_i \sim \mathcal{N}(0, \sigma_b^2)$ for these bias terms. σ_b is chosen to be large enough to act as an uninformative prior. Y_α is a binary random variable representing the existence of the edges in the clique $\mathbf{x}_\alpha$, and A_α is the actual value of the parameter θ_α when the edges are instantiated. It is easy to observe that given p_0 and σ_0, θ_α has the same distribution as in equation 2. We use a hierarchical model for $\boldsymbol{\theta}$ so that the inference will be insensitive to the choice of the hyper-parameters. In fact, experiments show that with a simple setting of the hyper-parameters, proper values of the sparsity parameter p_0 and the variance σ_0 are learned automatically by our model for all the data sets without the necessity of cross-validation.

Unlike the optimization-based methods which estimate a single structure, the Bayesian approach expresses uncertainty about the existence of edges through its posterior distribution, $P(\mathbf{Y}|\mathcal{D})$. We have applied a simple thresholding on $P(Y_\alpha|\mathcal{D})$ for edge detection in the experiments although more sophisticated methods can conceivably give better results.

Standard approaches to posterior inference do not work for Bayesian MRFs because it is intractable to compute the probability of a state $\mathbf{x}$ (due to the intractability of the partition function). We devised an approximate MCMC algorithm for inference, where we draw samples of the continuous variable A_α by a modified Langevin dynamics algorithm, and samples of the discrete variable Y_α jointly with A_α by a reversible jump MCMC method, as illustrated in Figure 1 and explained in the following sections.

3 Sampling Parameter Values by Langevin Dynamics

Given $\mathbf{Y}$, p_0, σ_0, and an observed data set $\mathcal{D} = \{\mathbf{x}^{(m)}\}, m = 1 \ldots N$, the conditional distribution of parameters $\{A_\alpha : Y_\alpha = 1\}$ is the posterior distribution of an MRF with a fixed edge set induced by $\{\alpha : Y_\alpha = 1\}$ and an independent Gaussian prior $\mathcal{N}(0, \sigma_0^2)$. We consider drawing samples of A_α with fixed $\mathbf{Y}$ in this section and will use θ_α and A_α interchangeably to refer to a nonzero parameter. Even for an MRF model with a fixed structure, MCMC is still intractable. Approximate MCMC methods have been discussed in Murray and Ghahramani (2004) among which Langevin Monte Carlo (LMC) with "brief sampling" to compute the required expectations in the gradients, shows good performance. (Welling and Teh, 2011) further shows that LMC with a noisy gradient can draw samples from the exact posterior distribution when the step size approaches zero.

Langevin dynamics is described as the hybrid Monte Carlo (HMC) method with one leapfrog step in section 5.5.2 of Neal (2010):

$$\begin{aligned} \boldsymbol{p}_{t+\varepsilon/2} &= \boldsymbol{p}_t + \frac{\varepsilon C}{2}\boldsymbol{g}(\boldsymbol{\theta}_t) \\ \boldsymbol{\theta}_{t+\varepsilon} &= \boldsymbol{\theta}_t + \varepsilon C \boldsymbol{p}_{t+\varepsilon/2} \\ \boldsymbol{p}_{t+\varepsilon} &= \boldsymbol{p}_{t+\varepsilon/2} + \frac{\varepsilon C}{2}\boldsymbol{g}(\boldsymbol{\theta}_{t+\varepsilon}) \end{aligned} \tag{4}$$

where $\boldsymbol{p}$ is the auxiliary momentum, ε is the step size, C is a positive definite preconditioning matrix, and $\boldsymbol{g}$ is the gradient of the log-posterior probability $\log P(\boldsymbol{\theta}|\mathcal{D})$ [1]. A new value of $\boldsymbol{p}$ is drawn at every iteration from an isotropic Gaussian distribution $\mathcal{N}(\mathbf{0}, \mathbb{I})$ and then discarded after $\boldsymbol{\theta}$ is updated. The leapfrog step is usually followed by a Metropolis-Hastings accept/reject step to ensure detailed balance. But since the rejection rate decays as ε^3, that step can be skipped for small step sizes without incurring much error.

In a MRF, the gradient term $\boldsymbol{g}$ involves computing an expectation over exponentially many states as

$$g_\alpha(\theta) = \sum_{m=1}^{N} f_\alpha(\mathbf{x}_\alpha^{(m)}) - N\mathbb{E}_{P(\mathbf{x}|\boldsymbol{\theta})} f_\alpha(\mathbf{x}_\alpha) - \frac{\theta_\alpha}{\sigma_0^2} \tag{5}$$

The expectation is estimated by a set of state samples $\{\tilde{\mathbf{x}}^{(s)}\}$ in the "brief Langevin" algorithm of Murray and Ghahramani (2004), where these samples are drawn by running a few steps of Gibbs sampling initialized from a subset of the training data. We adopt the "brief Langevin" algorithm with three modifications for faster mixing.

3.1 Persistent Gibbs Sampling

We maintain a set of persistent Markov chains for the state samples $\{\tilde{\mathbf{x}}^{(s)}\}$ by initializing Gibbs sampling at the last states of the previous iteration instead of the data. This is motivated by the persistent contrastive divergence algorithm of Tieleman (2008). When $\boldsymbol{\theta}$ changes slowly enough, the Gibbs sampler will approximately sample from the stationary distribution, even when allowed a few steps at every iteration.

[1] We omit all the other random variables that $\boldsymbol{\theta}$ is conditioned on in this section for ease of notation.

3.2 Preconditioning

When the posterior distribution of $\{\theta_\alpha\}$ has different scales along different variables, the original LMC with a common step size for all θ_α's will traverse the parameter space slowly. We adopt a preconditioning matrix C to speed up the mixing, where C satisfies $CC^T = H$ with H is the Hessian matrix of $\log P(\boldsymbol{\theta}_{\text{MAP}}|\mathcal{D})$, computed as:

$$H(\boldsymbol{\theta}_{\text{MAP}}) = \text{Cov}_{P(\mathbf{x}|\boldsymbol{\theta}_{\text{MAP}})}\boldsymbol{f}(\mathbf{x}) + \sigma_0^{-2} \tag{6}$$

This is reminiscent of the observed Fisher information matrix in Girolami and Calderhead (2011) except that we use the MAP estimate with the prior. We approximate $H(\boldsymbol{\theta}_{\text{MAP}})$ by averaging over $H(\boldsymbol{\theta}_t)$ during a burn-in period and estimate $\text{Cov}_{P(\mathbf{x}|\boldsymbol{\theta}_t)}\boldsymbol{f}$ with the set of state samples from the persistent Markov chains. The adoption of a preconditioning matrix also helps us pick a common step size parameter ε suitable for different training sets.

3.3 Partial Momentum Refreshment

The momentum term $\mathbf{p}$ in the leapfrog step represents the update direction of the parameter. Langevin dynamics is known to explore the parameter space through inefficient random walk behavior because it draws an independent sample for $\mathbf{p}$ at every iteration. We can achieve a better mixing rate with the partial momentum refreshment method proposed in Horowitz (1991). When $\mathbf{p}$ is updated at every step by:

$$\boldsymbol{p}_t \leftarrow \alpha \boldsymbol{p}_t + \beta \mathbf{n}_t \tag{7}$$

where $n_t \sim \mathcal{N}(\mathbf{0}, \mathbb{I})$, and α, β satisfy $\alpha^2 + \beta^2 = 1$, the momentum is partially preserved from the previous iteration and thereby suppresses the random-walk behavior in a similar fashion as HMC with multiple leapfrog steps.

α controls how much momentum to be carried over from the previous iteration. With a large value of α, LMC reduces the auto-correlation between samples significantly relative to LMC without partial momentum refreshment. The improved mixing rate is illustrated in Figure 2. We also show that the mean and standard deviation of the posterior distribution does not change. However, caution should be exercised especially when the step size η is large because a value of α that is too large would increase the error in the update equation which we do not correct with a Metropolis-Hastings step because that is intractable.

4 Sampling Edges by Reversible Jump MCMC

Langevin dynamics handles the continuous change in the parameter value A_α. As for discrete changes in the model structure, Y_α, we propose an approximate reversible jump MCMC (RJMCMC) step (Green, 1995) to

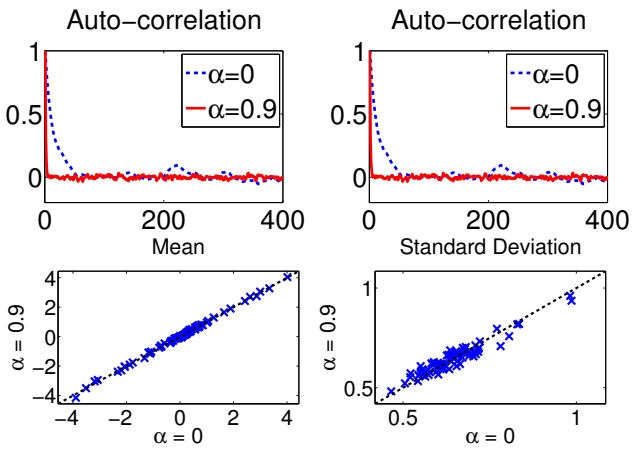

Figure 2: Comparison of Langevin dynamics on the block model in section 6.1 with partial momentum refreshment $\alpha = 0.9$ against $\alpha = 0$. Step size $\eta = 10^{-3}$. Top: the auto-correlation of two typical parameters. Bottom: the posterior mean and standard deviation of all parameters estimated with 10K samples.

sample Y_α and A_α jointly from the conditional distribution $P(\mathbf{A}, \mathbf{Y}|p_0, \sigma_0, \mathcal{D})$. The proposed Markov chain adds/deletes one clique (or simply one edge when $\alpha = (i, j)$) at a time. When an edge does not exist, i.e., $Y_\alpha = 0$, the variable A_α can be excluded from the model, and therefore we consider the jump between a full model with $Y_\alpha \neq 0$, $A_\alpha = a$ and a degenerate model with $Y_\alpha = 0$.

The proposed RJMCMC is as follows: when $Y_\alpha = 0$, propose adding an edge with probability P_{add} and sample $A_\alpha = a$ from a proposal distribution $q(A)$ with support on $[-\Delta_\alpha, \Delta_\alpha]$; when $Y_\alpha = 1$ and $|A_\alpha| \leq \Delta_\alpha$, propose deleting an edge with P_{del}. The reason of restricting the proposed move within $[-\Delta_\alpha, \Delta_\alpha]$ will be explained later. It is easy to see that the Jacobian is 1. The jump is then accepted by the Metropolis-Hastings algorithm with a probability:

$$\begin{aligned} Q_{add} &= \min\{1, Q^*(a)\}, \quad Q_{del} = \min\{1, 1/Q^*(a)\} \\ Q^*(a) &= \exp(a \sum_m f_\alpha(\mathbf{x}_\alpha^{(m)})) \left(\frac{Z(Y_\alpha = 0)}{Z(Y_\alpha = 1, A_\alpha = a)}\right)^N \\ &\quad \frac{p_0 \mathcal{N}(A_\alpha = a|0, \sigma_0^2)}{(1 - p_0)} \frac{P_{del}}{P_{add} q(A_\alpha = a)} \end{aligned} \tag{8}$$

The factors in the first line of Q^* represent the ratio of the model likelihoods while the other two are respectively the ratio of the prior distributions and the ratio of the proposal distributions.

4.1 Unbiased Estimate to Q^* and $1/Q^*$

Computing the partition functions in equation 8 is generally intractable. However, noticing that $Z(Y_\alpha = 1, A_\alpha = a) \to Z(Y_\alpha = 0)$, as $a \to 0$, the log-ratio of the two partition functions should be well approximated by a quadratic approximation at the origin when a is small. In this way

we reduce the problem of estimating the partition function to computing the first and second order derivatives of the log-partition function. We employ a second order Taylor expansion for the ratio of partition functions in Q^* as follows:

$$\left(\frac{Z(Y_\alpha=0)}{Z(Y_\alpha=1,A_\alpha=a)}\right)^N \stackrel{\text{def}}{=} R_{add}$$
$$\approx \exp\left(-Na\frac{\partial \log(Z)}{\partial A_\alpha}\mid_{A_\alpha=0} -\frac{Na^2}{2}\frac{\partial^2 \log(Z)}{\partial A_\alpha^2}\mid_{A_\alpha=0}\right) \tag{9}$$

We know that the kth order derivatives of the log-partition function of an MRF correspond to the kth order centralized moments (or cumulants) of the features, that is,

$$\frac{\partial \log(Z)}{\partial A_\alpha} = \mathbb{E}f_\alpha, \quad \frac{\partial^2 \log(Z)}{\partial A_\alpha^2} = \mathrm{Var}f_\alpha \tag{10}$$

Given a set of n state samples $\tilde{\mathbf{x}}^{(s)} \sim P(\mathbf{x}|Y_\alpha=0)$ from the persistent Markov chains, we can compute an unbiased estimate of the mean and variance of f_α as the sample mean $\bar{f}_\alpha$ and sample variance $S_\alpha^2 = \sum_s (f_\alpha(\tilde{\mathbf{x}}^{(s)}) - \bar{f}_\alpha)^2/(n-1)$ respectively. Consequently we obtain an estimate of R_{add} by plugging $\bar{f}_\alpha$ and S_α^2 into equation 9, which is unbiased in the logarithmic domain, denoted as $\hat{R}_{add}$.

An unbiased estimate in the logarithmic domain, unfortunately, is no longer unbiased once transformed to the linear domain. To correct the bias induced by the transformation, we take another Taylor expansion of $\hat{R}_{add}/R_{add}$ around $a=0$. After some derivation, we obtain an unbiased estimate of R_{add} upto the second order of a given by

$$\tilde{R}_{add}(a) = \exp\left(-Na\bar{f}_\alpha - \frac{Na^2}{2}S_\alpha^2\right)\left(1+\frac{N^2a^2}{2n}S_\alpha^2\right)^{-1}$$

with variance:

$$\mathrm{Var}(\tilde{R}_{add}/R_{add}) = \frac{N^2a^2}{n}\mathrm{Var}(f_\alpha) + o(a^3) \tag{11}$$

Similarly, we can also obtain an unbiased estimate, $\tilde{R}_{del}$, in $1/Q^*$ when considering deleting an edge, with the same formula as $\tilde{R}_{add}$ except that a is replaced by $-a$ and the sample mean and variance are now estimated with respect to $P(\mathbf{x}|Y_\alpha=1,A_\alpha=a)$. If we plug in $\tilde{R}_{add}$ (or $\tilde{R}_{del}$) into Q_{add} (or Q_{del}) we get an unbiased estimate of the acceptance probability except when Q^* (or $1/Q^*$) is close to 1 in which case the $\min$ operation causes extra bias. Since the variance can be computed as a function of a in equation 11, we can estimate how large a jump range Δ can be used in order to keep the error in the acceptance probability negligible. A larger data set requires a smaller jump range or alternatively a larger sample set that grows quadratically with the size of the data set.

4.2 Optimal Proposal Distribution q

After plugging equations 9, 10 and 5 into equation 8, we obtain the acceptance probability as a function of a:

$$Q_{add} = \min\left\{1, \frac{h(a)}{q(A_\alpha=a)}\mathrm{const}\right\}$$
$$h(a) = \exp\left(-\frac{a^2}{2}\left(\frac{1}{\sigma_0^2}+\mathrm{Var}f_\alpha\right)+aNg_\alpha\right) \tag{12}$$

where g_α and $\mathrm{Var}f_\alpha$ are defined at $\theta_\alpha=0$. Clearly, the optimal proposal distribution in terms of minimal variance is given by the following truncated Gaussian distribution

$$q_{opt}(A_\alpha=a|\boldsymbol{\theta}) \propto h(a), \quad a\in[-\Delta_\alpha,\Delta_\alpha] \tag{13}$$

When adding an edge, we have state samples $\tilde{\mathbf{x}}^{(s)} \sim P(\mathbf{x}|Y_\alpha=0)$. The expectation $\mathbb{E}f_\alpha$ in g_α can be estimated by $\bar{f}_\alpha(\{\tilde{\mathbf{x}}^{(s)}\})$ and $\mathrm{Var}f_\alpha$ by $S_\alpha^2(\{\tilde{\mathbf{x}}^{(s)}\})$. When deleting an edge, the samples are from $P(\mathbf{x}|Y_\alpha=1,A_\alpha=a)$. We apply a quadratic approximation for $\log Z(\theta_\alpha)$, use equation 10, and estimate $\mathrm{Var}f_\alpha \approx S_\alpha^2$ and $\mathbb{E}f_\alpha \approx \bar{f}_\alpha - aS_\alpha^2$.

4.3 Parallel Proposals

Since the most computationally demanding step is to obtain a set of state samples $\{\tilde{\mathbf{x}}^{(s)}\}$, we want to reuse the samples whenever possible. Given that Δ_α is small enough, the parameter value does not change much when we accept an "add or delete edge" move. We can thus assume that the distribution of A_α on an edge is not affected much by an accepted move on other edges. As a result we do not have to rerun the Gibbs sampler after every edge operation, and we can propose jumps for all $\{\alpha : |A_\alpha| < \Delta_\alpha\}$ in parallel, using the same set of samples. This reduces the computation time significantly.

5 Sampling for Hyper-parameters

Given $\mathbf{A}$ and $\mathbf{Y}$, the hyper-parameters are easy to sample when using conjugate priors:

$$p_0|\mathbf{Y} \sim \mathrm{Beta}(a+\sum_\alpha I(Y_\alpha=1), b+\sum_\alpha I(Y_\alpha=0))$$
$$\sigma_0^{-2}|\mathbf{Y},\mathbf{A} \sim \Gamma(c+\frac{1}{2}\sum_\alpha I(Y_\alpha=1), d+\frac{1}{2}\sum_{\alpha:Y_\alpha=1} A_\alpha^2) \tag{14}$$

where I is the indicator function.

The whole inference algorithm is summarized in Alg 1.

6 Experiments

6.1 Datasets

We assess the performance of our proposed method on two simulated data sets and one real-world data set. For the

Algorithm 1 MCMC for Bayesian MRFs with Langevin Dynamics and RJMCMC

(Parameters: number of iterations $ITER$, number of Gibbs sampling steps N_{Gibbs}, sample size n, step size ε, partial momentum refreshment α, RJMCMC proposal width Δ_α.)
Initialize $\mathbf{A}$, $\mathbf{Y}$, and momentum $\mathbf{p}$ randomly
for $iter = 1 \to ITER$ **do**
  Sample p_0 and σ_0 given $\mathbf{A}$ and $\mathbf{Y}$
  Run Gibbs sampling for N_{Gibbs} steps to draw $\{\mathbf{x}^{(s)}\}_{s=1}^n$.
  Run LMC to draw $\{A_\alpha : Y_\alpha \neq 0\}$.
  Run RJMCMC to propose adding an edge for $\{\alpha : Y_\alpha = 0\}$, and deleting an edge for $\{\alpha : Y_\alpha = 1, |A_\alpha| < \Delta_\alpha\}$
end for

simulated data, we randomly generate sparse Ising models with binary ± 1 states and with parameters sampled from a Gaussian distribution $\mathcal{N}(0, \sigma^2)$ where $\sigma = 0.5$ for edges and 0.1 for node biases. These models are then converted to their equivalent Boltzmann machines with binary $\{0, 1\}$ states from which we draw exact samples. Two structures are considered: (1) a block model with 12 nodes equally divided into 3 groups. Edges are added randomly within a group with a probability of 0.8, and across groups with 0.1. Edges within a group are strong and positively coupled. There are 66 candidate edges with 20 edges in the ground truth model. (2) a 10×10 lattice with 4950 candidate edges and with 180 edges in the ground truth model.

For the real data, we use the MNIST digits image data. We convert the gray scale pixel values to binary values by thresholding at a value of 50, resize the images to a 14×14 scale, and then pick a 9×12 patch centered in each image where the average value of each pixel is in the range of $[10^{-4}, 1 - 10^{-4}]$. The last step is necessary because the other competing models do not have regularization on their biases, which will result in divergent parameter estimates for pixels that are always 0 or 1.

6.2 Model Specification

We compare our Bayesian structure learning algorithm with two other approaches. One is proposed in Wainwright et al. (2007) which recovers the neighbourhood of nodes by training separate L_1-regularized logistic regressions on each variable. While its goal is edge detection, we can also use it as a parameter estimation method with two output models, "Wain Max" and "Wain Min", as defined in Höfling and Tibshirani (2009). We implement the "Wain Max/Min" methods with the Lasso regularized generalized linear model package of Friedman et al. (2010) [2]. The other approach is one of the several variants of L_1-regularized MLE methods which use a pseudo-likelihood approximation (Höfling and Tibshirani, 2009), denoted as "MLE" [3].

For our Bayesian model, we consider two schemes to specify a model for prediction. One is the fully Bayesian approach, referred as "Bayes", in which we random pick 100 model samples in the Markov chain and approximate the Bayesian model by a mixture model of these 100 components. The other one is to obtain a single model by applying a threshold of 0.5 to $P(Y_{i,j}|\mathcal{D})$ and estimate the posterior mean of the included edges, referred to as "Bayes PM".

The performance of the Bayesian model is insensitive to the choice of hyper-parameters. We simply set $a = b = c = d = 5$ for p_0 and σ_0, and $\sigma_b = 10$ across all experiments. For the parameters of the MCMC method, we also use a common setting. We use a diagonal approximation to the feature covariance $\mathrm{Cov}\boldsymbol{f}$ and thereby the preconditioning matrix C. We set the sample size $n = 100$, number of Gibbs sampling steps $N_{Gibbs} = 1$, LMC step size $\varepsilon = 10^{-3}$, and momentum refreshment rate $\alpha = 0.9$. The RJMCMC proposal width is set as $\Delta_\alpha = 0.01/\sqrt{N \mathrm{Var} f}$ to achieve a small estimation error as in equation 11. For each experiment, we run the MCMC algorithm to collect $10K$ samples with a subsampling interval of 1000. Since the exact partition function can be computed on the small block model, we also run an exact MCMC, "Bayes Exact", with an exact gradient and accept/reject decision as well as larger values in ε, α, and Δ than the approximate MCMC.

Different levels of sparsity have to be considered in L_1-based methods for an optimal regularization strength. For the Bayesian method, we learn a single sparsity level. However, for the sake of comparison, we also consider a method with p_0 as a parameter and vary it between $(0, 1)$ to induce different sparsity, referred to with a suffix "p_0".

6.3 Accuracy of Inference

We first evaluate the validity of the proposed MCMC method on the block data where exact inference can be carried out. The marginal posterior distribution of an edge parameter, $\theta_{i,j}$, is a mixture of a point mass at zero and a continuous component with a single mode. Figure 3 shows the histogram of samples in the continuous component of four randomly picked $\theta_{i,j}$'s. The title above each plot is the posterior probability of the edge (i, j) being present in the model, i.e. $\theta_{i,j} \neq 0$ or $Y_{i,j} = 1$. In this figure, the marginal distribution estimated from the approximate MCMC method matches the distribution from "Bayes Exact" very well. For a more comprehensive comparison, we run "Bayes p_0" and "Bayes Exact p_0" methods, and vary the value of p_0 from 10^{-4} to 0.99 to achieve different levels of sparsity. We estimate and collect across different p_0

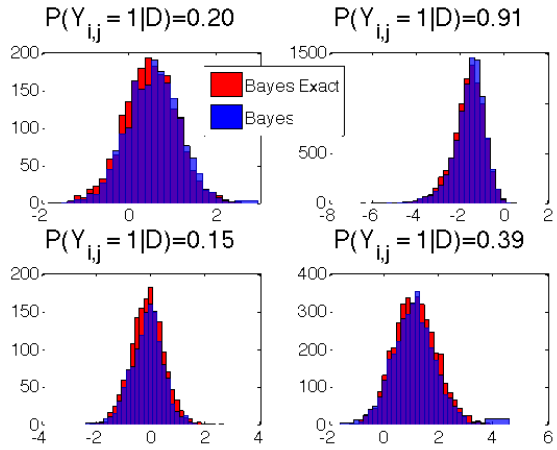

Figure 3: Histogram of the parameter samples of four randomly picked edges from "Bayes" and "Bayes Exact" when $Y_{i,j} = 1$. The training data is from the block model with $N = 100$.

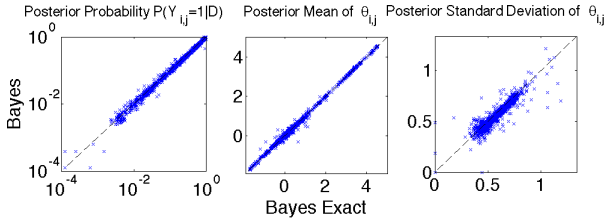

Figure 4: Comparison of "Bayes p_0" and "Bayes Exact p_0" on posterior probability of $Y_{i,j} = 1$, and the posterior mean and standard deviation of $\theta_{i,j}$ when $Y_{i,j} = 1$. The training data is from the block model with $N = 100$.

values the posterior probability of $\theta_{i,j} \neq 0$, posterior mean and standard deviation of $\theta_{i,j}$ in the continuous component, as shown in Figure 4. Each point represents a parameter under some value of p_0. We find the approximate MCMC procedure produces about the same values for these three statistics as the exact MCMC method.

6.4 Simulated Data

We then compare the performance of various methods on simulated data sets for two tasks: structure recovery and model estimation. The accuracy of recovering the true structure is measured by the precision and recall of the true edges. The quality of the estimated models is evaluated by the predictive performance on a held-out validation set. Since computing the log-likelihood of a MRF is in general intractable, we use the conditional log-likelihood (CLL) on a group of variables instead, which is a generalization of the conditional marginal log-likelihood in Lee et al. (2006). For each data case in the validation set, we randomly choose a group of variables, which is all the variables in the block model and a 3×3 grid in the lattice and MNIST models, and compute $\log P(\{x_i\}_{i \in group} | \{x_j\}_{j \notin group})$.

We train models on the simulated data ranging between 50 and 1000 items. For the Bayesian models, we remove an edge if the posterior probability $P(Y_{i,j} = 1|\mathcal{D}) < 0.5$.

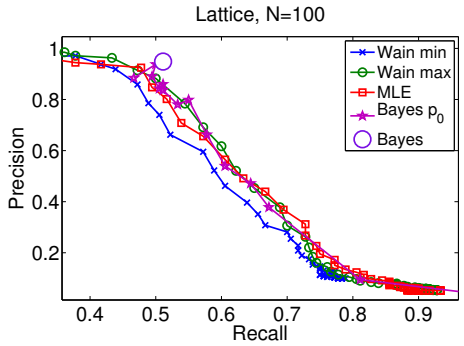

Figure 5: Precision-Recall Curves for the lattice data with 100 data cases.

Figure 5 shows typical precision-recall curves for different methods. It turns out that all the models with a sparsity tuning parameter perform similarly across all the training sets. The "Bayes" model tends to find a structure with high precision.

We then consider the average CLL as a function of the edge density of a model. The edge density is defined as the percentage of edges present in a model, i.e., $1 - sparsity$. For the fully Bayesian model, we measure the average density in the Markov chain. In fact, the variance of the edge density is usually small, suggesting that most model samples have about the same number of edges. We show the average CLL of different models trained with 100 data cases in Figure 6. The results on other data sizes are omitted because they have the same tendency. All the Bayesian models give robust prediction performance in the sparse and dense model ranges and "Bayes p_0" outperforms all the other methods with a tunable sparsity parameter for almost all settings of p_0. Moreover, the curve of "Bayes p_0" peaks at the true density level. In contrast, L_1 methods would underfit to the data for sparse models or overfit for dense models. "MLE" performs better than "Wain" models. This makes sense as the "Wain" models were not designed for MRF parameter estimation. Figure 7 compares the Bayesian models with exact and approximate inference. Again, the approximate MCMC method generates about the same posterior distribution as the "exact" method.

The difference between Bayesian models and L_1-based models could be partially explained by the different prior/regularization. As shown in Figure 8, to achieve a sparse structure, we have to use strong regularization in the L_1 models which causes global shrinkage for all parameters, resulting in under-fitting. On the other hand, to obtain a dense structure, weak regularization must be applied globally which leads to over-fitting. In contrast, with a spike and slab prior, the parameter value of existing edges is not affected directly by p_0. Instead, their variance is controlled by another random variable σ_0 which fits the data automatically with a weak hierarchical prior. The behavior of selective shrinkage in the spike and slab prior is also discussed in Mohamed et al. (2011); Ishwaran and Rao (2005).

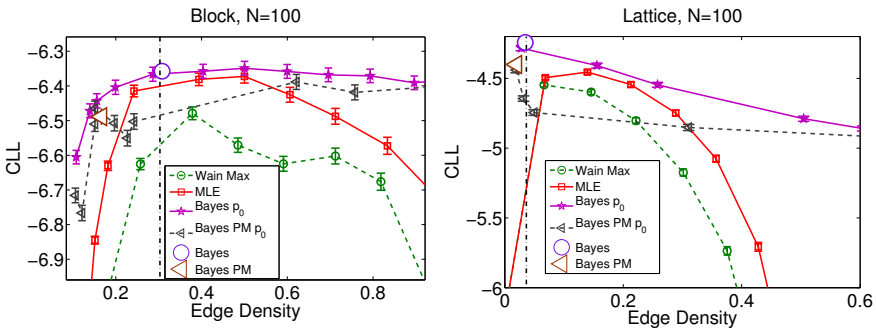

Figure 6: Mean and standard deviation of average CLL at different density levels for block (left) and lattice (right) model with 100 training data cases. "Wain Min" is not plotted as it is always inferior to "Wain Max". Vertical line: true edge density.

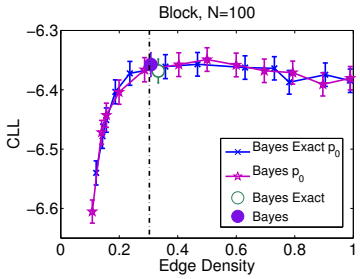

Figure 7: Average CLL at different density levels for the block model with 100 training cases.

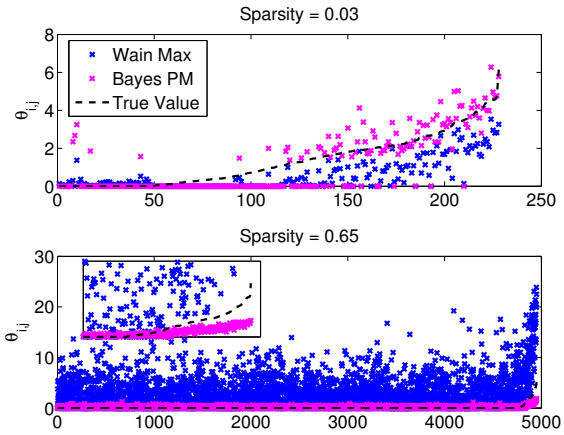

Figure 8: Absolute value of edge parameters in the true model, "Wain Max", and "Bayes PM" for lattice data with 100 samples. Parameters are plotted only if they are not zero in at least one model and sorted along the x-axis by the absolute value in the true model. The parameters in "Wain Max" are too small in sparse models (top, edge density $\approx 3\%$) and too large in dense models (bottom, 65%). Inset: zoom-in at the right-hand side. "Wain Min" and "MLE" are similar to "Wain Max".

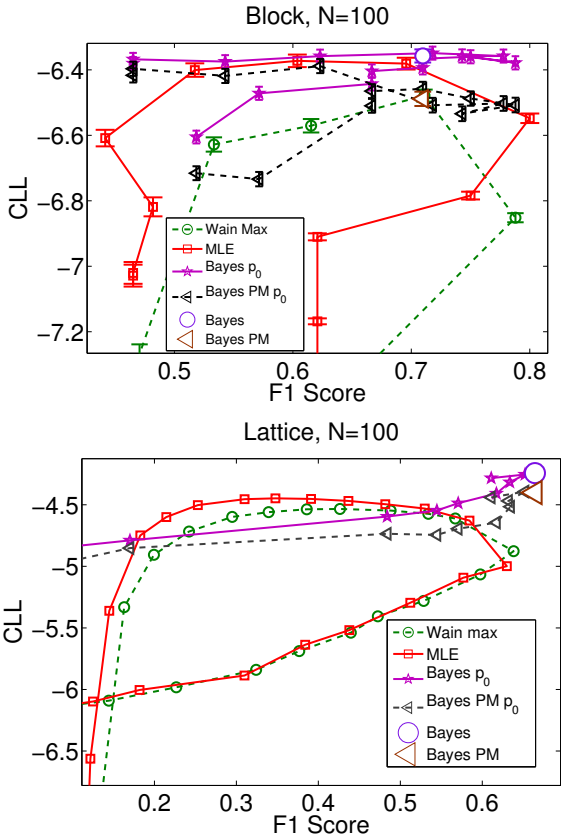

Figure 9: CLL vs F1 score for block and lattice model with 100 data cases. A good model is at the upper right corner.

The Bayesian models, "Bayes p_0" and "Bayes PM p_0" do however show an interesting "under-fitting" phenomenon at a large density levels. This is due to a misspecified value for p_0. Since the standard deviation σ_0 is shared by all the $A_{i,j}$'s whose $Y_{i,j} = 1$, when we fix p_0 at an improperly large value, it forces a lot of non-existing edges to be included in the model, which consequently brings down the posterior distribution of σ_0. This results in too small values on real edges as shown in the inset of Figure 8 and thereby a decrease in the model predictive accuracy.

However, this "misbehavior" in return just suggests the ability of our Bayesian model to learn the true structure. Once we release p_0 through a hierarchical prior, the model will abandon these improper values in p_0 and automatically find a good structure and parameters. The vertical line in Figure 6 indicates the sparsity of the true model. Both "Bayes" and "Bayes PM" find sparsity levels very close to the true value, while L_1-based methods are under-fitted at that same level as shown in the upper panel of Figure 8. We show the joint performance of edge detection and parameter learning in Figure 9 where the performance of edge detection is summarized by the F1 score (the harmonic mean of the precision and recall). The Bayesian models with a hierarchical p_0 prior achieve both a high F-1 score and CLL value near the upper right corner.

6.5 MNIST Data

Since there does not exist ground truth in the model structure of the MIST data set, we evaluate how well we can learn a sparse model for prediction. Figure 10 shows the average CLL on $10K$ test images with a model trained on

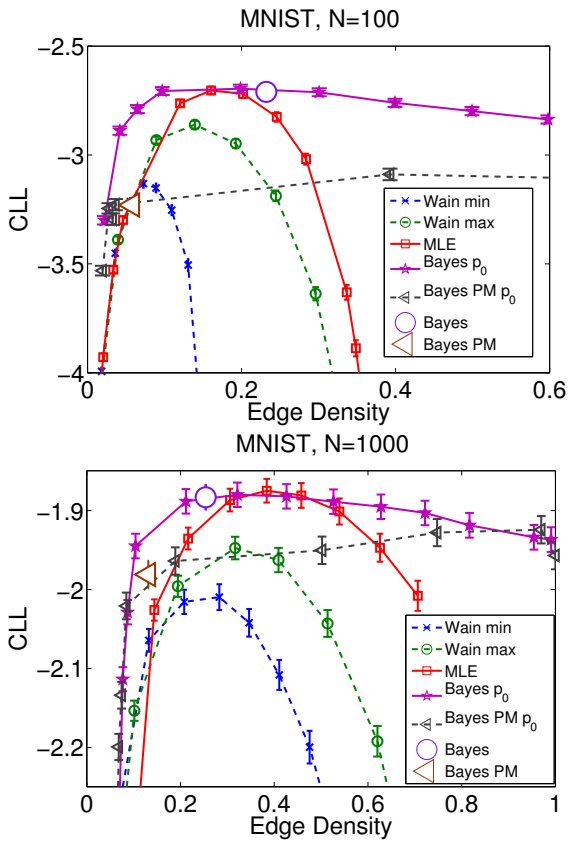

Figure 10: Mean and standard deviation of average CLL versus edge density on MNIST with 100 and 1000 data cases.

100 and 1000 images respectively. In the sparse and dense model ranges, we observe again a better performance of "Bayes" than L_1-based methods. "Bayes PM" also shows robustness to under/over-fitting although it seems that simply computing the posterior mean does not provide sufficiently good model parameters in the median density range.

To get a more intuitive comparison about the quality of learned sparse models, we train models on 1000 images by different methods with a density of 0.2 and then run Gibbs sampling to draw 36 samples from each model. The images are shown in Figure 11. While it is hard to get good reconstruction using a model without hidden variables, the Bayesian methods produce qualitatively better images than competing methods, even though "Bayes PM" does not have higher CLL than "MLE" at this level.

A common limitation of learning Bayesian models with the MCMC inference method is that it is much slower than training a model with a point estimate. However, as shown in the experiments, the Bayesian methods are able to learn a good combination of parameters and a structure without the need to tune hyper-parameters through cross validation. Also, the Bayesian methods learn sparser models than L_1-based methods without sacrificing predictive performance significantly. Because the computational complexity of inference grows exponentially with the maximum clique size of MRFs, L_1-based models at their optimal (not so

Figure 11: Samples from learned models at an edge density level of 0.2.

sparse) regularization level can in fact become significantly more computationally expensive than their Bayesian counterparts at prediction time. Turning up the regularization will result in sparser models but at the cost of under-fitting the data and thus sacrificing predictive accuracy.

7 Discussion

We propose Bayesian structure learning for MRFs with a spike and slab prior. An approximate MCMC method is proposed to achieve effective inference based on Langevin dynamics and reversible jump MCMC. As far as we known this is the first attempt to learn MRF structures in the fully Bayesian approach using spike and slab priors. Related work was presented in Parise and Welling (2006) with a variational method for Bayesian MRF model selection. However this method can only compare a given list of candidate models instead of searching in the exponentially large structure space.

The proposed MCMC method is shown to provide accurate posterior distributions at small step sizes. The selective shrinkage property of the spike and slab prior enables us to learn an MRF at different sparsity levels without noticeably suffering from under-fitting or over-fitting even for a small data set. Experiments with simulated data and real-world data show that the Bayesian method can learn both an accurate structure and a set of parameter values with strong predictive performance. In contrast the L_1-based methods could fail to accomplish both tasks with a single choice of the regularization strength. Also, the performance of our Bayesian model is largely insensitive to the choice of hyper-parameters. It provides an automated way to choose a proper sparsity level, while L_1 methods usually rely on cross-validation to find their optimal regularization setting.

Designing Informative Securities*

Abstract

We create a formal framework for the design of informative securities in prediction markets. These securities allow a market organizer to infer the likelihood of events of interest as well as if he knew all of the traders' private signals. We consider the design of markets that are always informative, markets that are informative for a particular signal structure of the participants, and informative markets constructed from a restricted selection of securities. We find that to achieve informativeness, it can be necessary to allow participants to express information that may not be directly of interest to the market organizer, and that understanding the participants' signal structure is important for designing informative prediction markets.

1 INTRODUCTION

Prediction markets are often used to better understand the likelihood of future events. Consider, for example, a market that predicts whether a particular candidate will become the U.S. President. Traders in the market may have diverse private information, like whether the candidate will win a particular state or receive millions of dollars in donations. Pooling this information could lead to an accurate forecast of the likelihood that the candidate will be elected, but may or may not be possible depending on how well the market is designed.

A typical prediction market offers securities with payoffs associated with future events. For example, a prediction market might offer a security worth \$1 if the candidate is elected and \$0 otherwise. A risk neutral trader who believes that the probability of election is p would be willing to buy this security at any price less than \$$p$, and (short) sell the security at any price above \$$p$. For this reason, the market price of a security of this form is frequently interpreted as the traders' collective belief about the likelihood of election.

Prediction markets have been shown to produce forecasts at least as accurate as other alternatives in a wide variety of settings, including politics [6], business [11, 42], disease surveillance [38], and entertainment [34]. The New York Times has cited prices from the popular Dublin-based market Intrade in discussions of upcoming elections,[1] and the North American Derivatives Exchange has proposed running real-money prediction markets for political events.[2] Extensive prior work has studied markets' abilities to aggregate information relevant to the value of a given security in both lab and field experiments [35–37] and at theoretical equilibria such as rational expectations equilibria [39], competitive equilibria [32, 43], and game-theoretic equilibria [10, 24, 31]. However, there has been little research studying the problem of designing securities to aggregate information relevant to externally specified events.

We develop a formal framework in which to study the design of *informative* securities for predicting the likelihood of events of interest. Loosely speaking, we consider a set of securities informative if, given their prices, it is possible to calculate the posterior probabilities of the events as if we were given the traders' private information. This suggests two requirements:

1. The price of each security offered should converge to the expected value of the security conditioned on the traders' pooled information.

[2] http://www.freakonomics.com/2012/02/02/the-politics-of-political-prediction-markets/

2. It should be possible to uniquely map the final security prices to estimates of the likelihood of each event of interest.

Prior work [31] has described when a given security meets the first condition in perfect Bayesian equilibria. We focus on the design of securities that meet both conditions with respect to a specified set of events. This theoretical investigation offers insight on how to design prediction markets in practice to produce more accurate forecasts.

Poor security design can stop participants from aggregating their information, as the following example derived from Geanakoplos and Polemarchakis [18] shows.

Example 1. *Consider a market offering a single security worth \$1 if a particular candidate wins the presidential election and \$0 otherwise. The market has two participants: a political analyst in Washington and an Iowa caucus-goer who is well-informed on local politics. The analyst understands the importance of Iowa on the campaign and knows whether a win or loss there will mean the candidate is elected. The caucus-goer, on the other hand, knows whether the candidate will win or lose the caucus, but not its broader effect.*

This situation can be described by defining four states of the world, ω_1, ω_2, ω_3, and ω_4:

		Iowa	
		Wins	Loses
General Election	Wins	ω_1	ω_2
	Loses	ω_3	ω_4

The analyst knows if the true state of the world is on the diagonal or not (the effect of the caucus) and the caucus-goer knows which column the true state is in (the results of the caucus). If they could reveal their private information they would learn the true state of the world, ω^*. But with a uniform prior over the state space, both think the likelihood of election is $1/2$ and value the security at \$0.50 no matter what their private information is, since every signal contains a state where the candidate wins the election and another where the candidate loses. This prevents either from inferring the other's signal, and no aggregation occurs.

The traders in Example 1 are unable to effectively express their private information and determine the correct value for the security, even though they have between them the knowledge to do so. But even when a market determines the correct value for its securities nothing may be learned. A constant-valued security worth \$1 regardless of the outcome is, for example, always priced correctly, but tells us nothing about the likelihood of future events.

In practice many prediction markets offer multiple securities, like a security that pays \$1 if and only if a candidate wins Iowa and another that pays \$1 if and only if the candidate wins the general election. These two securities together would allow the analyst and caucus-goer to aggregate their information. The caucus-goer could first participate in the Iowa market. Then, having observed the price change in the Iowa market, the analyst would have the information he needs to participate in the general election market, revealing his own private information. Furthermore, the market organizer would be able to infer the probability of election by observing their trades. In short, these securities together are what we call *informative* on the candidate's election. We show that multiple securities are necessary for informativeness in some cases. Using too many securities, however, is bad design.

The design questions we examine are also relevant for *combinatorial prediction markets* over exponentially large outcome spaces, like the 9.2 quintillion outcomes for the NCAA tournament [44], the over 2^{50} ways for states to vote in the U.S. presidential election, and the $n!$ rankings for a competition with n candidates. Offering a security for each state would be technically informative but practically unmanageable. Prior work has frequently considered markets with securities that correspond to natural events of interest, such as horse A beating horse B in a race [3, 9], but these securities may or may not be informative.

This paper considers the design of informative markets in three settings:

- In Section 5.2, we characterize securities that are *always informative*, revealing traders' information regardless of their signal structure. Complete markets, which offer one Arrow-Debreu security associated with each state of the world, are always informative for any set of events because they reveal traders' posterior distribution over the state space, but are typically too large to run in practice. We show that even if only one event is of interest, prohibitively large numbers of securities may be required to guarantee informativeness.
- Offering a large number of securities is undesirable from a practical point of view. In Section 5.3, we show that if the market designer knows the traders' signal structure, a *single* informative security can be constructed to reveal the traders' posterior distribution.
- Real markets have multiple securities, and a single security acting as a summary statistic for a complex market is unlikely to be considered natural. In Section 5.4 we consider design as an optimization problem where a designer attempts to

find the fewest securities that are informative for some given events of interest but is constrained to select its securities from a predefined set. This predefined set of securities could be interpreted as the set of securities that are natural. Solving this optimization problem perfectly is NP-hard, even when the set of securities is restricted to those paying \$0 or \$1 in each state of the world (like the securities in the above examples).

These results suggest, unsurprisingly, that deployed prediction markets are likely not revealing *all* their participants' information and that better design may improve upon their observed efficacy. The idea of partial informativeness, which may better describe prediction markets in practice, is discussed further in the conclusion. However, only by understanding the limits and opportunities of total informativeness, as discussed in this paper, can we understand the value and interest of partial informativeness.

2 RELATED WORK

There is a rich literature on the informational efficiency of markets, including theoretical work on the existence and characteristics of rational expectations equilibria [4, 21, 39] and empirical studies of experimental markets [35, 36]. Here we review only the most relevant theoretical work that either focuses on the dynamic process of information aggregation or takes a security design perspective.

The early theoretical foundations of information aggregation were laid by Aumann [5], who initiated a line of research on common knowledge, establishing a solid foundation to the understanding of the phenomenon of consensus. An event E is said to be *common knowledge* among a set of agents if every agent knows E, and every agent knows that every other agent knows E, ad infinitum. Aumann proved that if two rational agents have the same prior and their posterior probabilities for some event are common knowledge, then their posterior probabilities must be equal. This result was repeatedly refined and extended [18, 28, 29], and Nielsen et al. [30] showed that if n agents with the same prior but possibly different information announce their beliefs about the expectation of some random variable, their conditional expectations eventually are equal.

This line of work suggests that agents will reach consensus, but says nothing about whether such a consensus fully reveals agents' information. Feigenbaum et al. [14] studied a particular model of prediction markets (a Shapley-Shubik market game [41]) in which traders' information determines the value of a security. They characterized the conditions under which the market price of the security converges to its true value under the assumption that traders are non-strategic and honestly report their expectations.

The assumption that traders are non-strategic is arguably unrealistic. Ostrovsky [31] examined information aggregation in markets with strategic, risk-neutral traders. He considered two market models, market scoring rules [22, 23] and Kyle's model [25]. For both, he showed that a separability condition is necessary for the market price of a security to always converge to the expected value of the security conditioned on all information in every perfect Bayesian equilibrium. This condition is discussed extensively in Section 4. Iyer et al. [24] extended this model to risk-averse agents and identified a smoothness condition on the price in the market that ensures full information aggregation.

The work of Feigenbaum et al. [14], Ostrovsky [31], and Iyer et al. [24] focuses on understanding the aggregation of information relevant to the value of a given, fixed security. In contrast, this paper studies how to design securities to infer the likelihood of some events of interest. There have been other papers on security design. Pennock and Wellman [33], for example, examine the conditions under which an incomplete market with a compact set of securities allows traders to hedge any risk they have (and hence is "operationally complete"). Their work considers competitive equilibria, while our work focuses on information aggregation at game-theoretic equilibria of the market.

3 THE MODEL

In this section, we describe our model of traders' information and the market mechanism. Our model closely follows Ostrovsky [31], but is generalized to handle a *vector* of securities (often simply referred to as a set of securities) instead of a single security.

3.1 Modeling Traders' Information

We consider n traders, $1, \cdots, n$, and a finite set Ω of mutually exclusive and exhaustive states of the world. Traders share a common knowledge prior distribution P_0 over Ω. Before the market opens Nature draws a state ω^* from Ω according to P_0 and traders learn some information about ω^* that, following Aumann [5], is based on partitions of Ω. A *partition* of a set Ω is a set of nonempty subsets of Ω such that every element of Ω is contained in exactly one subset. For example, $\{\{A, B\}, \{C\}, \{D\}\}$ and $\{\{A, D\}, \{B, C\}\}$ are both partitions of $\{A, B, C, D\}$. We assume that every trader i receives $\Pi_i(\omega^*)$ as their private signal, where $\Pi_i(\omega)$ denotes the element of the partition Π_i that contains ω. In other words, trader i learns that the true

state of the world lies in the set $\Pi_i(\omega^*)$.

We refer to the vector $\Pi = (\Pi_1, \cdots, \Pi_n)$ as the traders' *signal structure*, which is assumed to be common knowledge for all traders. The *join* of the signal structure, denoted join(Π), is the coarsest common refinement of Π, that is, the partition with the smallest number of elements satisfying the property that for any ω_1 and ω_2 in the same element of the partition, $\Pi_i(\omega_1) = \Pi_i(\omega_2)$ for all i. For example, the join of the partitions $\{\{A, D\}, \{B, C\}\}$ and $\{\{A, C, D\}, \{B\}\}$ is $\{\{A, D\}, \{B\}, \{C\}\}$. The join is unique. We use $\Pi(\omega)$ to denote the element of the join containing ω. Note that if two states appear in the same element of the join, no trader can distinguish between these states.

3.2 Market Scoring Rules

The market mechanism that we consider is a market scoring rule [22, 23]. We will describe a market scoring rule as a mechanism that allows traders to sequentially report their probability distributions or expectations. While focusing on market scoring rules may seem restrictive, market scoring rules are surprisingly general. In particular, any market scoring rule that allows traders to report probability distributions over Ω has an equivalent implementation as a cost-function-based market where the mechanism acts as an automated market maker who sets prices for $|\Omega|$ Arrow-Debreu securities, one for each state and taking value 1 in that state and 0 otherwise, and is willing to buy and sell securities at the set prices [8, 22]. This result can easily be extended to general scoring rules by applying the results of Abernethy and Frongillo [1, 2]. In particular, their results imply that any market scoring rule that allows traders to report their expectations has an equivalent implementation as a cost-function-based market that allows traders to trade securities with the market maker. Thus, without loss of generality, our model and analysis are presented for market scoring rules.

Before describing the market scoring rule mechanism, we first review the idea of a strictly proper scoring rule. *Scoring rules* are most frequently used to evaluate and incentivize probabilistic forecasts [16, 19], but can also be used to elicit the mean or other statistics of a random variable [26]. The scoring rules that we consider will be used to elicit the mean of a *vector* of random variables [40]. Let $\mathbf{X} = (x_1, \cdots, x_m)$ be a vector of bounded real-valued random variables. A scoring rule s maps a forecast $\vec{y}$ in some convex region $\mathcal{K} \subseteq \mathbb{R}^m$ (e.g., the probability simplex in the case of probabilistic forecasts) and a realization of $\mathbf{X}$ to a score $s(\vec{y}, \mathbf{X}(\omega))$ in $\mathbb{R}$.[3] A scoring rule for eliciting an expectation is said to be *proper* if a risk neutral forecaster who believes that the true distribution over states Ω is P maximizes his expected score by reporting $\vec{y} = \mathrm{E}_P[\mathbf{X}]$, that is, if $\mathrm{E}_P[\mathbf{X}] \in \arg\max_{\vec{y} \in \mathcal{K}} \sum_{\omega \in \Omega} P(\omega) s(\vec{y}, \mathbf{X}(\omega))$. (For random vectors $\mathbf{X}$, we use $\mathrm{E}_P[\mathbf{X}]$ to denote the expected value $\Sigma_{\omega \in \Omega} P(\omega)\mathbf{X}(\omega)$.) A scoring rule is *strictly proper* if $\mathrm{E}_P[\mathbf{X}]$ is the unique maximizer.

One common example of a strictly proper scoring rule is the Brier scoring rule [7], which is based on Euclidean distance and can be written, for any $b > 0$, as $s(\vec{y}, \mathbf{X}(\omega)) = -b \sum_{j=1}^{m} (y_j - x_j(\omega))^2 = -b||\vec{y} - \mathbf{X}(\omega)||^2$.

Strictly proper scoring rules incentivize myopic traders to report truthfully, but do not provide a mechanism for aggregating predictions from multiple traders. Hanson [22, 23] introduced *market scoring rules* to address this problem. A market scoring rule is a sequentially shared strictly proper scoring rule.

Formally, let $\mathbf{X}$ be a vector of random variables.[4] The market operator specifies a strictly proper scoring rule s and chooses an initial prediction $\vec{y}_0$ for the expected value of $\mathbf{X}$; when there is a known common prior P_0, it is most natural to set $\vec{y}_0 = \mathrm{E}_{P_0}[\mathbf{X}]$. The market opens with initial prediction $\vec{y}_0$, and traders take turns submitting predictions. The order in which traders make predictions is common knowledge. Without loss of generality, we assume that traders $1, 2, \cdots, n$ take turns, in order, submitting predictions $\vec{y}_1, \vec{y}_2, \cdots, \vec{y}_n$, then the process repeats and the traders, in the same order, submit predictions $\vec{y}_{n+1}, \vec{y}_{n+2}, \cdots, \vec{y}_{2n}$. Traders repeat this process an infinite number of times before the market closes and Nature reveals ω^*. Each trader then receives a score $s(\vec{y}_t, \mathbf{X}(\omega^*))$ for each prediction made at some time t, but must pay $s(\vec{y}_{t-1}, \mathbf{X}(\omega^*))$, the score of the previous trader. The total payment to trader i (which may be negative) is then $\sum_{t=0}^{\infty} s(\vec{y}_{tn+i}, \mathbf{X}(\omega^*)) - s(\vec{y}_{tn+i-1}, \mathbf{X}(\omega^*))$.

3.3 Modeling Traders' Behavior

Together, the traders, state space, signal structure, security vector, and market scoring rule mechanism define an extensive form game with incomplete information. We consider Bayesian traders either acting in perfect Bayesian equilibrium or behaving myopically in this game. A perfect Bayesian equilibrium is a subgame perfect Bayesian Nash equilibrium. Loosely speaking, at a perfect Bayesian equilibrium, it must

[3] Technically, the region $\mathcal{K}$ should include the convex hull of the possible realizations of $\mathbf{X}$, a set equivalent to the possible expected values of $\mathbf{X}$. A full discussion of this and other properties of scoring rules is beyond the scope of this paper, but interested readers can see Savage [40].

[4] Typically market scoring rules are used for probabilistic forecasts in which case $\mathbf{X}$ would be a vector of indicator random variables, but this need not be the case.

be the case that each player's strategy is optimal (i.e., maximizes expected utility) given the player's beliefs and the strategies of other players at any stage of the game, and that players' beliefs are derived from strategies using Bayes' rule whenever possible. See González-Díaz and Meléndez-Jiménez [20] for a more formal description.

Perfect Bayesian equilibria can be difficult to compute and it is an open question whether they always exist in prediction markets, although in some special cases they do [10]. An alternative is to consider *myopic* Bayesian traders who simply maximize their expected payoff for the current round. Since strictly proper scoring rules myopically incentivize honest reports, these traders report their current posteriors each time they make a prediction.

4 AGGREGATION

Separability is used to characterize the conditions under which securities aggregate information about their own values. Building on ideas from DeMarzo and Skiadas [12, 13], Ostrovsky [31] characterized separability for a single security. He showed that in every perfect Bayesian equilibrium market prices will, in the limit, reflect the value of the security as if traders had revealed their private signals if and only if the security is separable. If a security is not separable, then there always exist priors and equilibrium strategies where no information aggregation occurs.

In this section, we generalize these prior definitions to multiple securities and arbitrary signal structures. Ostrovsky assumed a restricted class of signal structures without loss of generality, and these generalizations are uninteresting when only considering aggregation. They will be necessary to discuss informativeness, however, as the results of the next section demonstrate. We then restate Ostrovsky's equilibrium aggregation result in this setting. As previously discussed, perfect Bayesian equilibrium may or may not exist in prediction markets, and we also adapt and formalize prior work on information aggregation to show separability is also the necessary and sufficient condition for myopic traders to always aggregate their information.

Informative markets require separable securities. If a market uses separable securities then both traders in perfect Bayesian equilibrium and Bayesian traders acting myopically will, in the limit, value the security as if their private signals were revealed, and this allows a market designer to directly infer the likelihood of his events of interest from the securities' value. If a set of non-separable securities were used then the market designer could be required instead to perform additional inference and know the prior and traders' strategies.

As mentioned, we say a market aggregates information if, in the limit as time goes to infinity, the value of the securities approaches their value conditional on all the traders' private signals. Since each trader i receives the signal $\Pi_i(\omega^*)$, their pooled signal is $\bigcap_i \Pi_i(\omega^*) = \Pi(\omega^*)$.

Definition 1 (Aggregation)**.** *Information is* aggregated *with respect to a set of securities* $\mathbf{X}$*, signal structure* Π*, and common prior* P_0*, if the sequence of predictions* $\vec{y}_0, \vec{y}_1, \vec{y}_2, \cdots$ *converges in probability to the random vector* $E_{P_0}[\mathbf{X}|\Pi(\omega^*)]$.

A set of securities is separable if and only if the traders only agree on their value when it reflects their pooled information. That is, for any prior distribution there must be at least one trader whose private information causes them to dissent from a consensus, unless that consensus is the traders' collective best estimate.

Definition 2 (Separability)**.** *A set of securities* $\mathbf{X}$ *is* non-separable *under partition structure* Π *if there exists a distribution* P *over* Ω *and vector* $\vec{v}$ *such that* $P(\omega) > 0$ *on at least one state* $\omega \in \Omega$ *in which* $E_P[\mathbf{X}|\Pi(\omega)] \neq \vec{v}$*, and for every trader* i *and state* $\omega, P(\omega) > 0$*,*

$$E_P[\mathbf{X}|\Pi_i(\omega)] = \frac{\sum_{\omega' \in \Pi_i(\omega)} P(\omega')\mathbf{X}(\omega')}{\sum_{\omega' \in \Pi_i(\omega)} P(\omega')} = \vec{v}. \quad (1)$$

If a security is not non-separable then it is separable.

Here the vector $\vec{v}$ represents a possible consensus, only agreed upon if there is no alternative when the securities are separable. Separability is a property of the entire set of securities, as Example 2 demonstrates.

Example 2. *Let* $\Omega = \{\omega_1', \omega_2^*, \omega_3, \omega_4', \omega_5^*, \omega_6\}$*. Two traders have partitions as follows:*

$$\Pi_1 = \{\{\omega_1', \omega_2^*, \omega_3\}, \{\omega_4', \omega_5^*, \omega_6\}\}$$
$$\Pi_2 = \{\{\omega_1', \omega_5^*\}, \{\omega_3, \omega_4'\}, \{\omega_2^*, \omega_6\}\}$$

and there are two securities: x^* *with value one when* ω_2^* *or* ω_5^* *occurs and zero otherwise, and* x' *with value one when* ω_1' *or* ω_4' *occurs and zero otherwise.*

Both securities are individually non-separable with respect to Π*. If the prior* P *is uniform over* $\omega_1', \omega_2^*, \omega_5^*$*, and* ω_6*, then* $E_P[x^*|\Pi_i(\omega)] = 1/2$ *for* $i \in \{1, 2\}$ *and all* ω *such that* $P(\omega) > 0$*. Similarly, if* P *is uniform over* $\omega_1', \omega_3, \omega_4'$*, and* ω_5^**, then* $E_P[x'|\Pi_i(\omega)] = 1/2$ *for* $i \in \{1, 2\}$ *and all* ω *such that* $P(\omega) > 0$*. The join of traders' partitions, however, consists of singletons. Hence, both* $E_P[x^*|\Pi(\omega)]$ *and* $E_P[x'|\Pi(\omega)]$ *have value 0 or 1, not* $1/2$*, for all* ω*.*

But taken together the set of securities is separable with respect to Π*. Given any prior distribution* P

and a state ω, trader 2 either identifies ω with certain, which happens when P assigns 0 probability to the other state in its signal $\Pi_2(\omega)$, or assigns positive probability to both states in $\Pi_2(\omega)$. In the former case, $E_P[\mathbf{X}|\Pi_2(\omega)] = E_P[\mathbf{X}|\Pi(\omega)]$. In the latter case, trader 2's expected value for the securities is positive for both when $\omega \in (\omega_1', \omega_5^*)$, positive for only x' when $\omega \in (\omega_3, \omega_4')$, and positive for only x^* when $\omega \in (\omega_2', \omega_6)$. If the set of securities is non-separable there must exist a distribution $\tilde{P}$ and a vector $\vec{v}$ such that $\vec{v} \neq E_{\tilde{P}}[\mathbf{X}|\Pi(\tilde{\omega})]$ for some state $\tilde{\omega} \in \{\omega|P(\omega) > 0\}$ and $E_{\tilde{P}}[X|\Pi_2(\omega)] = \vec{v}$ for any state $\omega \in \{\omega|P(\omega) > 0\}$. This is possible only when $\tilde{P}$ assigns positive probability to the two states in $\Pi_2(\tilde{\omega})$ and 0 probability for all other states because each signal of player 2 has a distinct expectation of the securities. Given such a $\tilde{P}$, however, trader 1 always uniquely identifies the true state and has the correct expectation of the securities. Hence, the set of securities is separable with respect to Π.

4.1 Aggregation

Separability is a necessary and sufficient property for aggregation in two natural cases.

Theorem 1 (Equilibrium Aggregation, Ostrovsky [31])**.** *Consider a market with securities* $\mathbf{X}$ *and traders with signal structure* Π*. Information is aggregated in every perfect Bayesian equilibrium of this market if and only if the securities* $\mathbf{X}$ *are separable under* Π*.*

Theorem 2 (Myopic Aggregation)**.** *Consider a market with securities* $\mathbf{X}$ *and myopic traders with signal structure* Π*. Information is aggregated in finite rounds if and only if the securities* $\mathbf{X}$ *are separable under* Π*.*

Ostrovsky [31] proved a special case of Theorem 1 for markets with one security. Theorem 1 stated above accommodates any finite set of securities and is proved using a simple extension of Ostrovsky's proof. Specifically, the proof shows that traders' sequences of predictions at any perfect Bayesian equilibrium are bounded martingales and must converge. Separability implies that if information is not aggregated in the limit, there exists an agent who can make an arbitrarily large profit by deviating from his equilibrium strategy, a contradiction to traders being in equilibrium.

The proof of Theorem 2 makes use of prior work on convergence to common knowledge (particularly Geanakoplos [17]) and shows not only that myopic traders' sequences of predictions are bounded martingales but also that they must converge to the same random vector in a finite number of periods. Then, by separability, it is shown that this consensus prediction must equal $\mathrm{E}[X|\Pi(\omega^*)]$, implying aggregation. A full proof appears in the appendix of the long version of this paper, available on the authors' websites.

If the securities are not separable then there exists a distribution P satisfying (1) in the definition of separability. Letting this distribution be the prior, a perfect Bayesian equilibrium is simply for traders to report the common consensus value, not allowing any meaningful Bayesian updating and preventing aggregation from occurring. Myopic traders are constrained to report this same value.

5 SECURITY DESIGN

In this section we discuss the design of informative markets. While separability is a sufficient and necessary condition for aggregation in two natural settings, it only implies the value of the securities reflects all the traders' private information, not that the market designer can use this value to infer that private information or the likelihood of the events of interests. We define informative securities as securities that are both separable and allow for the likelihood of the events of interest to be inferred directly from their value.

As we will show, complete markets are always informative, but deployed prediction markets are rarely complete. These markets require too many securities to be practical, and their securities present challenges for traders. A prediction market for the U.S. presidential election, for example, may need one state per outcome in the electoral college. This is over 2^{50} states and requires traders to bid on securities like "The President wins Ohio, not Florida, Illinois, not Indiana ..." Even if alternative bidding methods were developed, traders would still be required to review the value of each security for aggregation to be formally implied. This is impractical, and so we consider good designs as those using a few natural securities. We first discuss the design requirements of markets that are always informative, and markets that are informative for a particular signal structure. The latter market allows a single security to be informative on any set of events, but arguably appears "unnatural." To describe the challenges of designing using only natural securities we then consider a constrained design process instead, where the market designer is restricted to an arbitrary subset of (possibly natural) securities.

5.1 Informative Securities

Informally, we would like to say that a market's securities are *informative* on a set of events with respect to a signal structure if the market organizer learns the likelihood of the events as if it knew all the traders' private signals. Assuming the values of the securities reflect traders' pooled information, if the likelihood of

the events is unambiguously implied from these values then functionally all the private signals are revealed. We call this latter property *distinguishability*.

Definition 3 (Distinguishability)**.** *Let* Π *be a signal structure over states* Ω *and* $P_{\text{join}(\Pi)}$ *be the set of all probability distributions over* Ω *that assign positive probability only to a subset of states in one element of* join(Π) *(i.e., a trader's possible posteriors after aggregation). A set of securities* $\mathbf{X}$ *on* Ω distinguishes *a set of events* $\mathcal{E}$ *with respect to* Π *if and only if for any* $P, P' \in P_{\text{join}(\Pi)}, E_P[\mathbf{X}] = E_{P'}[\mathbf{X}]$ *implies* $P(E) = P'(E), \forall E \in \mathcal{E}$.

Equivalently a set of securities distinguishes a set of events if there exists a function from the securities' values to the likelihood of the events. When a set of securities is both separable and distinguishable we describe it as *informative*.

Definition 4 (Informativeness)**.** *A set of securities* $\mathbf{X}$ *is* informative *on a set of events* $\mathcal{E}$ *with respect to a signal structure* Π *if and only if* $\mathbf{X}$ *both distinguishes* $\mathcal{E}$ *and is separable with respect to* Π.

Informativeness is a strong condition. Even if securities are not informative it might be possible for a market designer to infer some information from the market, or for the market to be described as partially informative. Generalizing our framework to account for partial aggregation would be an interesting line of future work.

5.2 Always Informative Securities

We first address the problem of designing a set of securities that is informative on a set of events with respect to *any* signal structure. We call such securities *always informative*. These securities may be of practical interest if the market designer is unsure of the traders' signal structure; using a set of always informative securities implies aggregation will occur no matter what the true signal structure is.

A market is said to be *complete* if by trading securities, agents can freely transfer wealth across states [27]. Rigorously, consider the set of securities that contains a constant payoff security plus all of the securities offered by a market. The market is complete if and only if this set includes $|\Omega|$ linearly independent securities. The most common is a market with $|\Omega|$ Arrow-Debreu securities, each associated with a different state of the world, taking value 1 on that state and 0 everywhere else. For an overview of complete markets, see Flood [15] or Mas-Colell et al. [27].

Complete markets are theoretically appealing because they allow traders to express any information about their beliefs. We formalize this well-known idea in our framework in the following proposition.

Proposition 1. *A market over state space* Ω *with securities* $\mathbf{X}$ *is complete if and only if for all distinct probability distributions* P *and* P' *over* Ω, $E_P[\mathbf{X}] \neq E_{P'}[\mathbf{X}]$.

Proof. Let M be a matrix containing the payoffs of $\mathbf{X}$, with one row for each outcome and one column for each security. The element at row i and column j of M takes value $\mathbf{x}_j(\omega_i)$. Consider a probability distribution P represented as a row vector so, $PM = \mathrm{E}_P[\mathbf{X}]$. The system of linear equations

$$P'M = \mathrm{E}_P[\mathbf{X}] \qquad \sum_{\omega \in \Omega} P'(\omega) = 1$$

has a unique solution $P' = P$ if and only if the matrix M', which is M augmented by a column of 1s to represent the summation constraint, has rank $|\Omega|$.

If the market is complete, M' has this rank so any distinct probability distribution has distinct expectation.

Now assume $\mathrm{E}_P[\mathbf{X}] \neq \mathrm{E}_{P'}[\mathbf{X}], \forall P \neq P'$, and, for a contradiction, that the market is not complete. Then the system of equations has at least two solutions, one of which is the probability distribution P and a distinct solution Q, such that $PM = QM = \mathrm{E}_P[X]$. Let U be the uniform distribution over Ω. Then there exists $c > 0$ such that $(1-c)U + cQ$ is a probability distribution (since Q satisfies $\sum_{\omega \in \Omega} Q(\omega) = 1$). Moreover, $(1-c)U + cP$ is also a probability distribution and

$$\big((1-c)U + cP\big)M = \big((1-c)U + cQ\big)M,$$

contradicting $\mathrm{E}_P[\mathbf{X}] \neq \mathrm{E}_{P'}[\mathbf{X}], \forall P \neq P'$. Thus, the market must be complete. □

This expressiveness is a necessary and sufficient condition for the likelihood of every event to be inferred, and suggests an alternative characterization of complete markets as those markets that are always informative on every event.

Theorem 3. *A market is always informative on every event* E *with respect to every signal structure* Π *if and only if it is complete.*

Proof. Distinguishing every event E is equivalent to distinguishing each state of the world $\omega \in \Omega$; the latter are also events and so must be distinguished, and if each is distinguished then the likelihood of any event can be inferred. Proposition 1 shows that completeness is a necessary and sufficient condition for distinguishing each state of the world.

It remains to show that complete markets are also separable with respect to any signal structure Π. Assume,

for a contradiction, there exists a signal structure Π and a complete market with securities $\mathbf{X}$ such that $\mathbf{X}$ is non-separable with respect to Π. Since $\mathbf{X}$ is non-separable there must exist distinct probability distributions P and P' over Ω such that $\mathrm{E}_P[\mathbf{X}] = \mathrm{E}_{P'}[\mathbf{X}]$; but by Proposition 1, in a complete market this equality only holds if $P = P'$, a contradiction. So complete markets are separable with respect to any signal structure and always distinguish every event, implying they are always informative on every event. □

Complete markets are often impractical, but rarely is every event of interest. Even if a single event is of interest, however, as many securities as almost half the states in the market may be required to create an always informative market. We let $\bar{E}$ denote the complement of E.

Theorem 4. *Any market that is always informative on an event E must have at least* $\min(|E|, |\bar{E}|) - 1$ *linearly independent securities.*

Proof. Let $\mathbf{X}$ be a set of securities, fewer than $\min(|E|, |\bar{E}|)) - 1$ of which are linearly independent, and assume, for a contradiction, that $\mathbf{X}$ is always informative on E. Restricting attention to states in E, the argument from Proposition 1 implies this market has too few securities to distinguish every probability distribution over E and there exist probability distributions P_E and P'_E such that $E_{P_E}[\mathbf{X}] = E_{P'_E}[\mathbf{X}]$. Let the difference between these distributions be the vector $\Delta_E = P_E - P'_E$, and define vectors Δ_E^+ and Δ_E^- such that $\Delta_E^+(\omega) = \max(0, \Delta_E(\omega))$ and $\Delta_E^-(\omega) = \min(0, \Delta_E(\omega))$. Since Δ_E is the difference of two probability distributions with the same expected value,

$$\sum_{\omega \in E} \frac{\Delta_E^+(\omega)}{||\Delta_E^+||_1} \mathbf{X}(\omega) = \sum_{\omega \in E} \frac{-\Delta_E^-(\omega)}{||\Delta_E^-||_1} \mathbf{X}(\omega). \qquad (2)$$

That is, $\frac{\Delta_E^+(\omega)}{||\Delta_E^+||_1}$ and $\frac{-\Delta_E^-(\omega)}{||\Delta_E^-||_1}$ are disjoint probability distributions over states in E with the same expected value, and the same argument can be made, *mutatis mutandi* for two such probability distributions over states in $\bar{E}$. Let these distributions over E be Q_E and Q'_E, and the ones over $\bar{E}$ be $Q_{\bar{E}}$ and $Q'_{\bar{E}}$. Although we have been referring to these as distributions over E and $\bar{E}$ we consider them to be distributions over Ω that assign zero probability to all states not previously included in the distributions, and we will use these names to stand for both these distributions and the states they assign positive probability to to reduce notation.

Now suppose there are two traders with signal structure

$$\Pi_1 = \{\{Q_E, Q_{\bar{E}}\}, \{Q'_E, Q'_{\bar{E}}\}\}$$
$$\Pi_2 = \{\{Q_E, Q'_{\bar{E}}\}, \{Q'_E, Q_{\bar{E}}\}\}$$

and prior

$$P_0 = \frac{Q_E + Q'_E + Q_{\bar{E}} + Q'_{\bar{E}}}{4}.$$

Each trader's expectation conditional on any signal is the same since $\mathrm{E}_{Q_E}[\mathbf{X}] = \mathrm{E}_{Q'_E}[\mathbf{X}]$ and $\mathrm{E}_{Q_{\bar{E}}}[\mathbf{X}] = \mathrm{E}_{Q'_{\bar{E}}}[\mathbf{X}]$ and each signal contains one distribution over states in E and another over states in $\bar{E}$. But the join of the signal structure is $\{\{Q_E\}, \{Q'_E\}, \{Q_{\bar{E}}\}, \{Q'_{\bar{E}}\}\}$, and if $\mathbf{X}$ is separable with respect to Π the expectation conditional on any such element must also, then, be the same. This implies $E_{Q_E}[\mathbf{X}] = E_{Q_{\bar{E}}}[\mathbf{X}]$, but by construction $Q_E(E) \neq Q_{\bar{E}}(E)$, so if $\mathbf{X}$ is separable with respect to Π it does not distinguish E, contradicting our assumption that $\mathbf{X}$ is always informative on E. □

This result demonstrates the need for a market designer to allow traders to express information it finds uninteresting. It also suggests that, in practice, few markets are acquiring all of their participants' information. This is unsurprising, but we think better designs will extract more information, and that this result shows knowledge of or assumptions about the traders' signal structure may be necessary to inform those designs.

5.3 Fixed Signal Structures

If the join of the traders' signal structure is known and has singleton sets for its elements, then there exists a single security that is informative on every event.

Theorem 5. *For any signal structure Π such that* $\mathrm{join}(\Pi)$ *consists only of singleton sets there exists a security $\mathbf{x}$ that is informative on every event E with respect to Π.*

The proof uses a result from Ostrovsky [31].

Theorem 6 (Ostrovsky [31])**.** *Let Π be a signal structure such that* $\mathrm{join}(\Pi)$ *consists of singleton sets of states, and let x be a security that can be expressed as $x(\omega) = \Sigma_i f(\Pi_i(\omega))$ for an arbitrary function f mapping signals to reals. Then x is separable under Π.*

Proof of Theorem 5. To construct the security, first assign a unique identifier $s_0, s_1, s_2, \ldots$ to every signal of every trader, and define $f(s_j) = 10^j$ for all j. Let S_ω denote the set of indices of the identifiers corresponding to the signals of each trader for state ω, i.e, corresponding to $\Pi_i(\omega)$ for each trader i. The security

$x(\omega) = \Sigma_{j \in S_\omega} f(s_j)$ is separable by Theorem 6. Additionally, the sum $\Sigma_{j \in J} f(s_j)$ for any $J \subset \{0, 1, 2, \ldots\}$ is unique, and each state ω has a unique associated set of signals since we assumed the join consists of singletons. This implies the value of the security for each element of the join is unique, so the security also distinguishes every event. □

The assumption that the join of traders' signal structure consists only of singleton sets is not without loss of generality. If the signal structure is known, however, the market designer can treat elements of the join as states of the world, identify the correct element of the join by running the market with a single security, then apply the prior to that element to learn the likelihood of each state as if he knew all the traders' private signals. If the prior is unknown this distribution can also be solicited from any single trader using a scoring rule.

5.4 Constrained Design

A single security acting as a summary statistic for an entire market is unlikely to be considered natural by any criterion. Real markets, like those on Intrade, use multiple securities. Instead of imposing our own definition of natural, in this section we consider adding a design constraint that the market's securities must be picked from a predefined set. The market designer is then challenged to find the fewest securities from this set that are informative on the events of interest with respect to the given signal structure. We call this the INFORMATIVE SET optimization problem. If the set of predefined securities is empty or has no informative subset then the problem is simply infeasible, so we assume there exists at least one such subset.

Demonstrating INFORMATIVE SET is hard would not be very interesting if exotic and unnatural securities were required for the proof. One commonly used class of securities are *event securities* which pay \$1 if an event occurs and \$0 otherwise. The corresponding optimization problem is INFORMATIVE EVENT SET, a restriction of INFORMATIVE SET, and even solving this restricted version of the problem is NP-hard.

Theorem 7. INFORMATIVE EVENT SET *is* NP*-hard.*

This immediately implies that the more general INFORMATIVE SET problem is also hard.

Corollary 1. INFORMATIVE SET *is* NP*-hard.*

The proof appears in the appendix and demonstrates a one-to-one correspondence between set cover instances and a minimal informative set of securities for a single fully informed trader.

The complexity of these problems suggests that while knowledge of the traders' signal structure allows for better designs, a perfect design will be intractable to compute or require additional assumptions about the relationship between traders' signal structure and the set of possible securities. Practically we can only ever hope to offer better (but not perfect) designs that extract more information from traders than current markets do. These results confirm we will always have to settle for some degree of error in our designs even if the traders' signal structure could be perfectly observed.

6 CONCLUSION

We developed a formal framework for the design of informative prediction markets. These markets reveal the posterior probabilities of a set of events of interest as accurately as if the traders had directly revealed their information, a commonly cited goal of prediction markets. These markets require that traders have an incentive to be accurate, that they can aggregate their information, and that the market designer can use this information to infer the likelihood of the events of interest.

Ideally informative markets would use a few natural securities. Complete markets, usually too large to be used in practice, are, however, the only markets to always be informative, regardless of the traders' signal structure. When the signal structure is known, a single security can be informative, but this security may appear strange and unintuitive to traders. Finding the smallest informative set of natural securities is computationally hard in general.

Real-world prediction markets do typically offer small numbers of simple and natural securities, and have been shown to aggregate information effectively in practice. This is not in contrast to our results, which only consider whether a market reveals *all* of the traders' private information. Our results demonstrate, however, the importance of security design and suggest that better designs that extract *more* of the traders' information are possible.

We hope this paper will allow future research on *partial* aggregation, like that which occurs in practice. Future work might also consider the effect of alternative communication channels outside the market's securities, like comments on Intrade, that allow traders to explain the reasoning behind their predictions. The development of this line of research is crucial to understanding why prediction markets work and how to make them work better.

Lifted Relational Variational Inference

Jaesik Choi and **Eyal Amir**

Abstract

Hybrid continuous-discrete models naturally represent many real-world applications in robotics, finance, and environmental engineering. Inference with large-scale models is challenging because relational structures deteriorate rapidly during inference with observations. The main contribution of this paper is an efficient relational variational inference algorithm that factors large-scale probability models into simpler variational models, composed of mixtures of iid (Bernoulli) random variables. The algorithm takes probability relational models of large-scale hybrid systems and converts them to a close-to-optimal variational models. Then, it efficiently calculates marginal probabilities on the variational models by using a latent (or lifted) variable elimination or a lifted stochastic sampling. This inference is unique because it maintains the relational structure upon individual observations and during inference steps.

1 Introduction

Many real-world systems can be described using continuous and discrete variables with relations among them. Such examples include measurements in environmental sensor networks, localizations in robotics, and economic forecasting in finance. In such large systems, efficient and precise inference is essential. As an example from environmental engineering, an inference algorithm can predict a posterior of unobserved groundwater levels and contamination levels at different locations, and making such an inference precisely is critical to decision makers.

Real-world systems have large numbers of variables including both discrete and continuous. Probabilistic first order languages, e.g. [3; 15; 24; 25; 14; 26; 28], describe probability distributions at a relational level with the purpose of capturing the structure of larger models. A key challenge of inference procedures with the languages is that they often result in intermediate density functions involving many random variables and complex relationship among them.

Lifted inference presently can address discrete models and continuous models, but not hybrid ones. For (d-valued) discrete variables, lifted inference can take an advantage of the insight which groups equivalent models into histogram representations with an order of $poly(d)$ entries [12; 22; 17] (instead of $exp(d)$ entries in traditional *ground* models). For Gaussian potentials, lifted inference can use an insight which enables maintaining compact covariance matrices during (and after) inference, e.g. [5; 7; 1].

Nonparametric variational models, e.g. NP-BLOG [4] and Latent Tree Models [32; 8], handle inference problems for discrete models and continuous Gaussian models. Here, our model and algorithms provide a solution for general (non-Gaussian) hybrid models.

In this paper, we first define **Relational Hybrid Models** (Section 2) and variational models (Section 3). We presents pragmatic algorithms (Section 4, 5 and 6) based on a new insight, **relational variational-inference lemmas** (Section 7), which accurately factors densities of relational models into mixtures of iid random variables. These lemmas enable us to build a variational approximation algorithm, which takes large-scale graphical models with hybrid variables and finds close to optimal relational variational models. Then, our inference algorithms, a variable elimination and a stochastic sampling, efficiently solve marginal inference problems on the variational models. We review the literature of statistical relational models and variational inference (Section 8). We show that the algorithm gives a better solution than solutions with existing methods (Section 9).

2 Relational Hybrid Models (RHMs)[1]

A **factor** $f = (A_f, \phi_f)$ is a pair, composed of a tuple of random variables (**rvs**) A_f and a potential function ϕ_f. Here, ϕ_f is an unnormalized probability density from the range of A_f to the nonnegative real numbers. The range of a rv can be discrete or continuous, i.e., hybrid domains. Given a **valuation v** of rvs, the **potential** of f on **v** is $\phi_f(v)$.

We define **parameterized (indexed) rvs** by using **predicates** those are functions mapping parameter values to rvs. A **relational atom** (or just **atom**) denotes a parametrized rv with free parameter variable(s). For example, an atom $\mathbf{X}(\mathbf{a})$ can be mapped to one of n rvs $\{X(a_1), \cdots, X(a_n)\}$ when the free parameter variable **a** is **substituted** by a value a_i.

A **parfactor** $g = [L, A_g, \phi_g]$ is a tuple composed of a set of parameters L, a tuple of relational atoms A_g and a potential function ϕ_g. A substitution θ is an assignment to L, and $A_g\theta$ the relational atom (possibly ground) resulting from replacing the logical variables by their values in θ. $gr(g)$ is a set of factors derived from the parfactor g by substitutions.

Following example is a parfactor:

$$[\ \underbrace{(\mathbf{a}, \mathbf{b})}_{\text{Parameter variables}},\ \underbrace{(\mathbf{X}(\mathbf{a}), \mathbf{Y}(\mathbf{b}))}_{\text{Relational atoms}}, \underbrace{f_{\mathcal{N}}(\mathbf{X}(\mathbf{a}) - \mathbf{Y}(\mathbf{b}); \mu, \sigma^2)}_{\text{A potential (linear Gaussian)}}]. \quad (1)$$

The domains of the parameter variables (**a** and **b**) are $\{a_1, \ldots, a_n\}$ and $\{b_1, \ldots, b_m\}$. Thus, any substitution (e.g. $\mathbf{a} = a_i, \mathbf{b} = b_j$) let two rvs (e.g. $\mathbf{X}(\mathbf{a_i})$, $\mathbf{Y}(\mathbf{b_j})$) hold the linear Gaussian relationship $f_{\mathcal{N}}$.

A **Relational Hybrid Model (RHM)** is a compact representation of graphical models with discrete and continuous rvs. An RHM is composed of a **domain**, the set of possible parameter values, and a set of parfactors **G**. The joint probability of an RHM G on a valuation v of rvs is as follows:

$$\frac{1}{z} \prod_{g \in \mathbf{G}} \prod_{f \in gr(g)} \phi_f(\mathbf{v})$$

where z is the normalizing constant.

This representation is rather straightforward. However, inference procedures often result in complex models. For example, eliminating $X(a_1)$ in Equation (1) makes all other rvs fully connected. To address this problem, we focus on an important property of RHMs such that ground rvs mapped from a relational atom are **exchangeable**, defined as follows:

[1]Parts of our model representations in this section are based on the previous works ([26; 12; 23; 6]).

Definition (Exchangeable Random Variables). A sequence of rvs $X(a_1), \cdots, X(a_n)$ is **exchangeable**, when for any finite permutation $\pi()$ of the indices the joint probability of the permuted sequence $X(a_{\pi(1)})$, $\cdots, X(a_{\pi(n)})$ is the same as the joint probability of the original sequence.

Note that RHMs may include atoms with non-exchangeable rvs.[2] In this case, our variational algorithm grounds, or shatters, any atom including non-exchangeable rvs. That is, the atom degenerates into a set of propositional rvs. The detail conditions to determine exchangeable rvs, see [26; 21; 4; 12].

For convenience, we use $\mathbf{X}^n$ to refer to the set of n rvs, which are mapped from a relational atom $X(\mathbf{a})$ by substitutions, i.e., $\mathbf{X}^n = \{X(a_1), \cdots, X(a_n)\}$. The joint probability of the rvs mapped from two atoms $\mathbf{X}(\mathbf{a})$ $\mathbf{Y}(\mathbf{b})$ can be represented as follows: $P(\mathbf{X}^n, \mathbf{Y}^m) = P(X(a_1), \cdots, X(a_n), Y(b_1), \cdots, Y(b_m))$.

Potentials with a large number of rvs in RHMs introduce several difficulties in representation, learning and inference. To address these difficulties, we propose a model-factorization based on a variational method and de Finetti's theorem [11].

3 Background: Variational Inference

Variational methods are used to convert a complex problem into a simpler problem, where the simpler problem is charaterized by a decoupling of the degrees of freedom in the original problem [19]. As an example of *ground* models, one variational representation of model $P(x_1, \cdots, x_n)$ can be as follows:

$$P(x_1, \cdots, x_n) \approx \sum_{\theta} \prod_{i} P(x_i, |\theta) P(\theta)$$

where θ is a latent random variable. Inference is a procedure which computes marginal probabilities, say $P(X')$ $(X' \in \{x_1, \cdots, x_n\})$. This can be done by eliminating (or summing out) all variables except ones in X'. The variational representation (right-hand side) allows efficient inference procedures because all random variables are factorized.

De Finetti-Hewitt-Savage's Theorem: For exchangeable rvs, de Finetti's theorem [11] showed that any probability distribution $P(\mathbf{X}^n)$ of an infinite number n of binary exchangeable rvs can be represented by a mixture of independent and identically distributed

[2]Lifted inference for RHMs with non-exchangeable rvs is out of scope of this paper. There are recent developments to handle some of such cases, e.g. [17; 2].

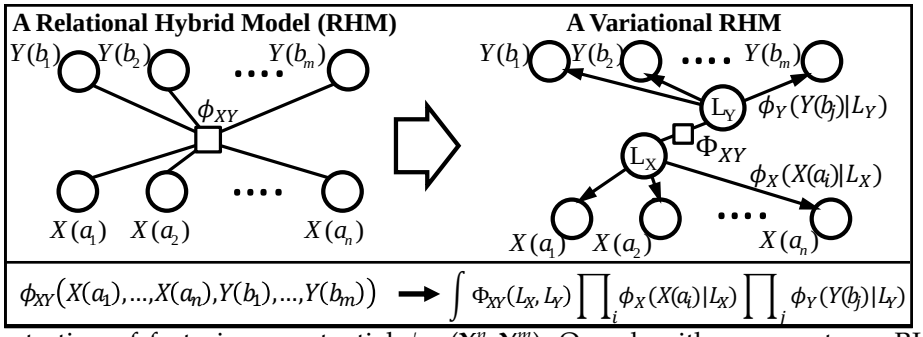

Figure 1: An illustration of factoring a potential $\phi_{XY}(\mathbf{X}^n, \mathbf{Y}^m)$. Our algorithm converts an RHM (left) into a variational (or factored) RHM (right) where the probability is represented by two latent variables L_X and L_Y.

(**iid**) Bernoulli rvs $P_{Miid}(\mathbf{X}^n)$ with a parameter θ:

$$\lim_{n\to\infty} P(\mathbf{X}^n) = \int_0^1 \theta^{t_n}(1-\theta)^{n-t_n}\Phi_X(\theta)\,\mathbf{d}\theta = P_{Miid}(\mathbf{X}^n),$$

where $t_n = \sum_i X(a_i)$, and $0 \leq \theta \leq 1$ is a **latent variable**. This observation is extended to multi-valued and continuous rvs by [16].

$$\lim_{n\to\infty} P(\mathbf{X}^n) = \int \prod_{i=1}^{n} \phi_X(X(a_i)|L_X)\Phi_X(\mathbf{d}L_X) = P_{Miid}(\mathbf{X}^n), \quad (2)$$

where L_X is a **latent variable** which chooses a distribution $\phi_X(\mathbf{X}(a)|L_X)$ of the iid rvs.[3] We represent the variational form as $P_{Miid}(\mathbf{X}^n)$ (or $\phi_{Miid}(\mathbf{X}^n)$ for unnormalized potentials).[4] Compared to the input distribution $P(\mathbf{X}^n)$, the number of parameters of the variational form, e.g. entries of conditional density tables in $P_{Miid}(\mathbf{X}^n)$, can be substantially reduced by this factorization. As shown in Figure 1, when the variational models are applied to two sets of exchangeable rvs, the variational model (the right hand side) requires parameters of $\phi_X(X(a_i)|L_X)$, $\phi_Y(Y(b_j)|L_Y)$ and $\Phi_{XY}(L_X, L_Y)$ not parameters of $\phi_{XY}(X(a_i), \cdots, Y(b_m))$.

We present variational representations for multiple sets of finite, exchangeable rvs, and new error anaysis (Section 7). Beforehand, we introduce our variational learning and inference algorithms.

4 Algorithms: Lifted Variational Inference

This section outlines our pragmatic variational inference algorithm, ***Lifted Relational Variational Inference*** **(LRVI)**. LRVI is composed of two main subroutines: learning a variational approximation, ***Find-Variational-RHM***; and eliminating latent variables (inference) ***Latent-Variable-Elimination*** which can be replaced by ***Lifted-MCMC*** (Section 6.3).

[3]Here, we consider Φ_X with a density. Thus $\Phi_X(\mathbf{d}L_X)$ in Equation (2) can be replaced by $\Phi(L_X)\,\mathbf{d}L_X$.

[4]Here, *Miid* stands for a mixture of iid rvs.

Input: G an *RHM* (a set of parfactors), Q a query (a set of relational atoms), O observations
Output: $P(Q)$ a (posterior) distribution of Q
begin
  // (One-time) Variational Learning
  if $G \notin$ {*Variational RHMs*} **then**
    $G \leftarrow$ **Find-Variational-RHM**(G);
  // Main Inference Routine
  $P(Q) \leftarrow$ **Latent-Variable-Elimination** (G, Q, O);
  return $P(Q)$;

Algorithm Lifted Relational Variational Inference: It receives an RHM, a query and observations, then returns a posterior of the query.

LRVI receives an RHM G, a query Q and observations O as inputs. It outputs the conditional probability, $P(Q|O)$. In the routine, it examines that each potential in G is the variational form, a mixture of product of iid rvs. If not, it calls *Find-Variational-RHM(G)* and receives a variational RHM G_{Miid}. The variational RHM is calculated once, and reused next time. With the G_{Miid}, *Latent-Variable-Elimination*(G_{Miid}, Q, O) solves the inference problem $P(Q|O)$. This is done by the variable elimination which iteratively eliminates non-query atoms.

Input: G, an RHM
Output: G_{Miid}, a variational RHM
begin
  for $g = (L, A, \phi) \in G$ **do**
    if *A has no continuous atom* **then**
      $\phi_{Miid} \leftarrow$ **Lifting-Discrete(**ϕ**)** (Section 5.1);
    else
      $\phi_{Miid} \leftarrow$ **Lifting-Continuous(**ϕ**)** (Section 5.2);
    $G_{Miid} \leftarrow G_{Miid} \bigcup \{(L, A, \phi_{Miid})\}$;
  return G_{Miid};

Algorithm Find-Variational-RHM: It finds a variational approximation for an input RHM (Section 5).

Find-Variational-RHM(G) converts the potential ϕ in each parfactor into a variational potential ϕ_{Miid}, a mixture of iid rvs as shown in Equation (2). For potentials with only discrete atoms, it calls *Lifting-Discrete(ϕ)* and receives a variational potential ϕ_{Miid}. For potentials including at least one continuous atom, it calls *Lifting-Continuous(ϕ)*. After iterating and converting all par-

factors in G, a variational RHM G_{Miid} is returned. Section 5 explains the procedures in detail.

Input: G_{Miid} a variational *RHM*, Q a query, O observations
Output: $P(Q)$ a (posterior) distribution of Q
begin
  $G_{Miid} \leftarrow$ Update-Obs(G_{Miid}, O) ; // For observations
  $\mathbf{A} \leftarrow$ a set of atoms in G_{Miid}; $\mathbf{\Phi} \leftarrow \{\phi_g | g \in G_{Miid}\}$;
  for $X \in \mathbf{A} \setminus Q$ **do**
    $\Phi_X \leftarrow \{\phi \in \mathbf{\Phi} | X$ is argument of $\phi\}$;
    if X *is discrete* **then**
      $\phi' \leftarrow$ **Inference-Discrete(**Φ_X**)** (Section 6.1);
    else
      $\phi' \leftarrow$ **Inference-Continuous(**Φ_X**)** (Section 6.2);
    $\mathbf{\Phi} \leftarrow (\mathbf{\Phi} \setminus \phi_X) \bigcup \{\phi'\}$;
  return $\mathbf{\Phi}$;

Algorithm Latent-Variable-Elimination: It sums out non-query latent variables, and returns a posterior of the query (Section 6).

Latent-Variable-Elimination(G_{Miid}, Q, O) call *Update-Obs*(G_{Miid}, O) to update the potentials of latent variables based on observations O. The intuition of *Update-Obs* is that each rv is conditionally independent given latent variables like the Naive Bayes models [18]. Variational RHMs allows a simple update algorithm to maintain the relational structure upon individual observations.[5] It iteratively eliminates all latent variables except the query without referring to ground variables. Section 6 includes detail procedures.

5 Variational Learning for RHMs

This section elaborates a learning algorithm which converts each potential in an RHM into a variational potential. Here, the key procedure is to extract the potential on latent variables (e.g. $\Phi_X(L_X)$).

The potential on latent variables can be derived analytically and exactly, when an input potential satisfies some conditions such as ∞-extendible (explained in Section 7). It is also known that discrete potentials[6] and some Gaussian potentials (e.g. pairwise Gaussian [5] and Gaussian processes [9; 31]) allow such derivations.

Unfortunately, it is hard to use such derivations in general hybrid models because many real-world potentials are neither ∞-extendible nor Gaussian. Here, we present our solutions for (more intuitive) discrete models first, and then for continuous models.

5.1 Lifting Discrete Potentials

For discrete potentials, we need to find the probability density $\Phi_X(L_X)$ over the iid (Bernoulli) rvs where L_X is the Bernoulli parameter. To represent an input potential $\phi(\mathbf{X}^n)$ compactly, we group equivalent value assignments according to the **value-histogram representation** [12; 23], $\phi(\mathbf{X}^n) = \phi_{\mathbf{h}}(h_X)$.[7] Learning variational parameters of Equation (2) with discrete rvs is formulated as follows:

$$\begin{aligned}
&\arg\max_{\Phi_X(p)} \left\| \phi(\mathbf{X}^n) - \int \Phi_X(p) \prod_{i=1}^{n} \phi_X(X(a_i)|p)\, dp \right\| \\
&= \arg\max_{\Phi_X(p)} \left\| \phi_{\mathbf{h}}(h_X) - \int \Phi_X(p) \cdot f_{\mathcal{B}/\mathcal{M}}(h_X; n, p)\, \mathbf{d}p \right\| \\
&\approx \arg\max_{\mathbf{w},\mathbf{p_X}} \left\| \phi_{\mathbf{h}}(h_X) - \sum_{l=1}^{k} w_l \cdot f_{\mathcal{B}/\mathcal{M}}(h_X; n, p_{X_l}) \right\|, \qquad (3)
\end{aligned}$$

where $||P - Q||$ (or $d_{TV}(P, Q)$) is the **total variation distance**[8]; $f_{\mathcal{B}/\mathcal{M}}(h_X; n, p)$ is a binomial (or multinomial) pdf; $\mathbf{w} = (w_1, \cdots, w_k)$ is a k-dimensional weight vector such that w_l=$\Phi_X(p_{X_l})$, $\sum_{l=1}^{k} w_l$=1; and $p_{\mathbf{X}} = (p_{X_1}, \cdots, p_{X_k})$ is a vector of k values chosen from $[0, 1]$, the domain of the latent variable p.

For **binary** exchangeable rvs, the iid potential $\phi_X(X(a_i)|p)$ is the Bernoulli distribution with a parameter p (i.e. $P(X(a_i)) = p$). When equivalent models in $\mathbf{X}^n$ are grouped into the histogram h_X, the variational terms can be represented as a binomial distribution (the second line in Equation (3)) because $\binom{n}{h_X} \prod_i \phi_X(X(a_i)|p) = f_{\mathcal{B}}(h_X; n, p)$. That is, the problem is reduced to learn a mixture of k binomial distributions where w_l is a weight for each binomial $f_{\mathcal{B}}(h_X; n, p_{X_l})$.

For **multi-valued** exchangeable rvs, the iid potential $\phi_X(X(a_i)|p)$ is the Categorical distribution, i.e. multi-valued Bernoulli. Thus, this problem is reduced to learn a mixture of multinomial distributions $f_{\mathcal{M}}$:

$$\arg\max_{\mathbf{w},\mathbf{p_X}} \left\| \phi_{\mathbf{h}}(h_X) - \sum_{l=1}^{k} w_l \cdot f_{\mathcal{M}}(h_X; n, p_{X_l}) \right\|. \qquad (4)$$

For potentials with two or more atoms, it can be formulated as follows:

$$\arg\max_{\mathbf{w},\mathbf{p_X},\mathbf{p_Y}} \left\| \phi_{\mathbf{h}}(h_X, h_Y) - \sum_{l=1}^{k} w_l f_{\mathcal{B}/\mathcal{M}}(h_X; n, p_{X_l}) f_{\mathcal{B}/\mathcal{M}}(h_Y; m, p_{Y_l}) \right\|,$$

where $p_{\mathbf{Y}}$ is a k-dimensional vector, $(p_{Y_1}, \cdots, p_{Y_k})$; and f is either the binomial or the multinomial depending on the domain of rvs.

We learn a mixture of binomials (or multinomials), e.g. $(\mathbf{w}, p_{\mathbf{X}})$ in Equation (3), from the original potential $\phi(\mathbf{X}^n)$ using an incremental EM algorithm.[9] Because the k is not known or given, the incremental EM algorithm increases k up to n until the variational error

[5] Existing lifted inference methods degenerate relational models upon observations. See Split [26] or Shatter [12].

[6] Section 8 includes an empirical comparison with existing lifted inference for discrete models

[7] h_X is a vector with $h_{Xv} = |\{i : X(a_i) = v\}|$.

[8] $||P-Q|| = \sup_{A \in \mathcal{B}}(P(A)-Q(A))$ when $\mathcal{B}$ is a class of Borel sets.

[9] EM algorithms are common to learn parameters for mixture models [30; 10; 27].

converges. Assuming that the EM algorithm interates up to a constant times given a fixed k, the computational complexity of the incremental EM algorithm for n binary, exchangeable rvs is bounded by $O(n^3)(=\sum_{k=1}^{n} c \cdot O(kn))$. Note that, the algorithm increases k from 1 to n. In each EM step, k components visit n histogram entries $O(kn)$.

5.2 Lifting Continuous and Hybrid Potentials

For a potential $\phi(\mathbf{X}^n)$ with continuous rvs, we use a mixture of non-parametric densities to represent variational potentials. Here, we generate samples from the input potential, then learn parameters for the mixture of non-parametric densities.

Equation (2) is used to formulate the learning problem as follows:

$$\arg\max_{\Phi_X(L_X)} \left\| \phi(\mathbf{X}^n) - \int \Phi_X(L_X) \cdot \prod_{i=1}^{n} \hat{f}_{L_X}(X(a_i))\, \mathbf{d}L_X \right\| \quad (5)$$

$$\approx \arg\max_{\mathbf{w}, \hat{f}_{\mathbf{X}}} \left\| \phi(\mathbf{X}^n) - \sum_{u=1}^{k} w_u \cdot \prod_{i=1}^{n} \hat{f}_{X_l}(X(a_i)) \right\|, \quad (6)$$

where $\hat{f}_{L_X}$ and $\hat{f}_{X_l}$ refer to (non-parametric) probability distributions. To solve the optimization problem, we generate N samples $\mathbf{v_1}, \cdots, \mathbf{v_N}$ from the input potential $\phi(\mathbf{X}^n)$ where $\mathbf{v_t} = (v_{t_1}, \cdots, v_{t_n})$ is a n-dimensional vector, value assignments for n rvs. Then, we solve the following maximum likelihood estimation (MLE) problem: $\arg\max_{\mathbf{w}, \hat{f}_{\mathbf{X}}} \sum_{t=1}^{N} \log\left(\sum_{l=1}^{k} w_l \cdot \prod_{i=1}^{n} \hat{f}_{X_l}(v_{t_i})\right)$, where we denote the kernel density estimator by $\hat{f}_{X_l}(x) = \frac{1}{S\sigma^2} \sum_{i=1}^{S} K\left(\frac{x-\mu_i}{\sigma^2}\right)$ where $(\mu_1, \cdots, \mu_S)$ are S data points that underlie the density, and σ^2 is a parameter. For simplicity, we use the Gaussian Kernel, $K(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}$.

It is interesting to note that the kernel density estimator is analogous to the value-histogram for discrete rvs [12; 23] in a sense that frequently observed regions (or bins) have the higher probability. This new insight enables us to represent continuous models compactly.

For potentials with two or more atoms, the approach can be formulated as follows:

$$\arg\max_{\mathbf{w}, \hat{f}_X, \hat{f}_Y} \sum_{t=1}^{N} \log\left(\sum_{l=1}^{k} w_l \cdot \prod_{i=1}^{n} \hat{f}_{X_l}(v_{t_i}^X) \cdot \prod_{j=1}^{m} \hat{f}_{Y_l}(v_{t_j}^Y) \right),$$

where v_t^X and v_t^Y are respectively the t^{th} samples of $\mathbf{X}^n$ and $\mathbf{Y}^m$.

This MLE problem is also solved by an EM algorithm. N samples are used to build k densities in the maximization (M) step, and the likelihood of each sample is calculated in the expectation (E) step. variation error converges.

6 Lifted Inference with RHMs

In this section we build on the result of previous sections and present lifted inference algorithms that utilize the learned variational models to speed up relational inference. The lifted inference algorithms find solutions without referring to ground rvs.

Latent-Variable-Elimination marginalizes relational atoms with the following steps: (i) choosing an atom; (ii) finding all potentials including the atom and making the product of them; (iii) summing out the atom; and (iv) repeating the steps until only query atoms are left. We demonstrate the key step (iii) with two variational potentials, $\phi_{Miid}(\mathbf{X}^n, \mathbf{Y}^m)$ and $\phi'_{Miid}(\mathbf{Y}^m)$.

6.1 Inference with Discrete Variables

The key intuition is that the variational form is maintained after eliminating an atom. We demonstrate the intuition by an example. The marginal probability of the latent variable L_X is calculated by eliminating (or summing) $\mathbf{Y}^m$ out: $\sum_{h_y} \phi_{\mathbf{h}}(h_x, h_y) \cdot \phi'_{\mathbf{h}}(h_y)$

$$\begin{aligned}
&\approx \sum_{h_y} \sum_{l=1}^{k} w_l f_{\mathcal{B}}(h_x; n, p_{X_l}) f_{\mathcal{B}}(h_y; m, p_{Y_l}) \sum_{l'=1}^{k'} w_{l'} f_{\mathcal{B}}(h_y; m, p_{Y_{l'}}) \\
&= \sum_{l=1}^{k} \sum_{l'=1}^{k'} w_l w_{l'} \left(\sum_{h_y} f_{\mathcal{B}}(h_y; m, p_{Y_l}) f_{\mathcal{B}}(h_y; m, p_{Y_{l'}}) \right) f_{\mathcal{B}}(h_x; n, p_{X_l}) \\
&\approx \sum_{l=1}^{k} \sum_{l'=1}^{k'} w_l w_{l'} \left(\int f_{\mathcal{N}}(h_y; \mu_l, \sigma_l^2) f_{\mathcal{N}}(h_y; \mu_{l'}, \sigma_{l'}^2)\, \mathbf{d}h_y \right) f_{\mathcal{B}}(h_x; n, p_{X_l}) \\
&= \sum_{l=1}^{k} w_{\overline{Y},l} \cdot f_{\mathcal{B}}(h_x; n, p_{X_l}) = \phi''(\mathbf{X}^n) \qquad (7)
\end{aligned}$$

when $\sum_{l=1}^{k} w_{\overline{Y},l} = 1$ and $f_{\mathcal{N}}(h_y; \mu_l, \sigma_l^2)$ is the Normal approximation to binomial such that $\mu_l (= m \cdot p_{Y_l})$ and $\sigma_l^2 (= m \cdot p_{Y_l} \cdot (1 - p_{Y_l}))$. It is important to note that binomial pdfs are not closed under the product operation. That is, a product of two binomial pdfs are not a binomial pdf unless the binomial parameters p_{X_l} p_{X_l} are identical. For large n and m, the Normal approximation to Binomial is an important step to maintain the variational structure during the inference procedure. In this way, after eliminating $\mathbf{Y}^m$, the marginal potential $\phi''_{Miid}(\mathbf{X}^n)$ is still represented as the variational form. The same principle is applied for potentials with more than two atoms.

Now, we will show that the product of variational forms in Step (iii) can also be represented as a variational form. Consider the following two variational potentials $\phi_{Miid}(\mathbf{X}^n)$ $\phi'_{Miid}(\mathbf{X}^n)$. The product operation is common during the elimination step as shown in Equation (7). The product of the two potentials is represented as follows:

$$\left(\sum_{l=1}^{k} w_l \cdot f_{\mathcal{B}}(h_x; n, p_{X_l}) \right) \cdot \left(\sum_{l'=1}^{k'} w'_{l'} \cdot f'_{\mathcal{B}}(h_x; n, p_{X_{l'}}) \right)$$

$$\approx \sum_{l=1}^{k}\sum_{l'=1}^{k'} w_l{\cdot}w'_{l'} \int f_{\mathcal{N}}(h_x;\mu_l,\sigma_l^2){\cdot}f'_{\mathcal{N}}(h_x;\mu_{l'},\sigma_{l'}^2)\,\mathbf{d}h_x$$

$$= \sum_{l=1}^{k}\sum_{l'=1}^{k'} w_l{\cdot}w'_{l'}{\cdot}z_{l,l'}\, f_{\mathcal{N}}(h_x;\mu_{new},\sigma^2_{new}) = \phi'''_{Miid}(\mathbf{X}^n), \quad (8)$$

$z_{l,l'}$ is the inverse of the normalizing constant. This derivation shows that a product of variational potentials results in a variational potential as $\phi'''_{Miid}(\mathbf{X}^n)$.[10]

6.2 Inference with Continuous Variables

For continuous variables, we also demonstrate the intuition by an example with two potentials $\phi_{Miid}(\mathbf{X}^n,\mathbf{Y}^m)$ $\phi'_{Miid}(\mathbf{Y}^m)$ where $\mathbf{X}^n$ and $\mathbf{Y}^m$ are two sets of continuous rvs. Each potential is represented as shown in Section 5.2. When we eliminate $\mathbf{Y}^m$, it can be formulated as follows:

$$\int\left(\sum_{l=1}^{k} w_l\prod_{i=1}^{n}\hat{f}_{X_l}(X(a_i))\prod_{j=1}^{m}\hat{f}_{Y_l}(Y(b_j))\right)\phi'_{Miid}(\mathbf{Y}^m)\,\mathbf{d}\mathbf{Y}$$
$$=\sum_{l=1}^{k}\sum_{l'=1}^{k'} w_l w_{l'}\prod_{i=1}^{n}\hat{f}_{X_l}(X(a_i))\prod_{j=1}^{m}\left(\int\hat{f}_{Y_l}(Y(b_j))\hat{f}_{Y_{l'}}(Y(b_j))\,\mathbf{d}Y(b_j)\right)$$
$$=\sum_{l=1}^{k}\sum_{l'=1}^{k'} w_l w_{l'}\frac{1}{{z_{l,l'}}^m}\prod_{i=1}^{n}\hat{f}_{X_l}(X(a_i)) = \phi''_{Miid}(\mathbf{X}^n), \quad (9)$$

$z_{l,l'}$ is the normalizing constant calculated from the product of two mixtures of Normals: $\hat{f}_{Y_l}(Y(b_j))$; and $\hat{f}_{Y_{l'}}(Y(b_j))$.

Finally, we show that the product of two variational potentials becomes a variational form: $\left(\sum_{l=1}^{k} w_l{\cdot}\prod_{i=1}^{n}\hat{f}_{X_l}(X(a_i))\right){\cdot}\left(\sum_{l'=1}^{k'} w'_{l'}{\cdot}\prod_{i=1}^{n}\hat{f}_{X_{l'}}(X(a_i))\right)$

$$=\sum_{l=1}^{k}\sum_{l'=1}^{k'} w_l w'_{l'}\prod_{i=1}^{n}\hat{f}_{X_l}(X(a_i))\hat{f}_{X_{l'}}(X(a_i))$$
$$=\sum_{l=1}^{k}\sum_{l'=1}^{k'} w_l w'_{l'}\frac{1}{{z_{l,l'}}^n}\cdot\prod_{i=1}^{n}\hat{f}^{new}_{X_{l,l'}}(X(a_i)) = \phi'''_{Miid}(\mathbf{X}^n). \quad (10)$$

6.3 Lifted Markov chain Monte Carlo (MCMC)

When variational RHMs include a large number of mixture compoments. The latent variable elimination may take long time. In this case, we use a lifted MCMC algorithm: (i) choosing a latent variable (e.g L_X) randomly; (ii) calculating the conditional probability of the latent variable (e.g. $\Phi_X(L_X)$) using assignment of neighboring latent variables; (iii) choosing an assignment from the probability (e.g. $L_X{=}p_{X_l}$ $(1{\le}l{\le}k)$); and (iv) repeating until convergence.

[10] $\phi'''_{Miid}(\mathbf{X}^n)$ is a mixture of $|k\cdot k'|$ Normals. When $|k\cdot k'|$ is large, it is possible to collapse the mixture into a mixture of fewer components.

Here, the steps (ii) and (iii) are main steps. Step (ii) is a subset of the procedure in Equations (7) and (9), because the values of neighboring latent variables (e.g. $L_Y{=}p_{Y_{l'}}$ $(1{\le}l'{\le}k')$) can be simply assigned. Step (iii) is a straightforward sampling procedure which chooses one compoment based on its weight. For example, $w_l{\cdot}w'_{l'}{\cdot}z_{l,l'}$ in Equation (8) is a weight for one of $|k|\cdot|k'|$ Normal distributions in $\phi'''_{Miid}(\mathbf{X}^n)$.

7 Relational-Variational Lemmas

This section provides error analysis of our variational approximations for a single atom, multiple atoms and the general case (RHMs). Beforehand, we define a term, $\overline{\mathbf{n}}$**-extendible**:

Definition ($\overline{\mathbf{n}}$**-extendible).** $P(\mathbf{X}^n)$, a probability with n exchangeable rvs, is $\overline{\mathbf{n}}$**-extendible** when the followings hold: (1) there is $P(\mathbf{X}^{\overline{n}})$, a probability with $\overline{n}$ exchangeable rvs ($\overline{n} > n$); and (2) $P(\mathbf{X}^n)$ is the marginal distribution of $P(\mathbf{X}^{\overline{n}})$, i.e., eliminating $(\overline{n}-n)$ rvs.

Figure 2 explains the intuition of $\overline{\mathbf{n}}$-extendible potentials for discrete models. If a potential is not extendible, it has rugged bars, e.g. a single peak. If a potential is extendible to a large number $\overline{n}$, the potential has a smoothed histogram. If a potential is ∞-extendible, it is represented by a mixture of binomials exactly.

Lemma 1. [13] *If $P(\mathbf{X}^n)$, a probability with n exchangeable rvs, is $\overline{n}$-extendible, then the* **total variation distance** *$d_{TV}(P(\mathbf{X}^n),P_{Miid}(\mathbf{X}^n))$ of the input probability $P(\mathbf{X}^n)$ and the variational form $P_{Miid}(\mathbf{X}^n)$ in Equation* (2) *is bounded as follows: (i) when $X(a_i)$ are d-valued discrete rvs, $d_{TV}(P(\mathbf{X}^n),P_{Miid}(\mathbf{X}^n)) \le \frac{2dn}{\overline{n}}$; and (ii) when $X(a_i)$ are continuous rvs, $d_{TV}(P(\mathbf{X}^n),P_{Miid}(\mathbf{X}^n)) \le \frac{n(n-1)}{\overline{n}}$.*

7.1 Our Results: Variational RHMs

Factoring Potentials with Multiple Atoms: De Finetti-Heweitt-Savage's theorem (Section 3) is applicable only to potentials with a single atom. Here, we present our new theoretical results on variational RHMs.

Lemma 2. [Existence of a Variational Form] *For $P(\mathbf{X}^n,\mathbf{Y}^m)$, a probability with two atoms in an RHM, there are two new latent variables, L_X and L_Y, and a new potential $\Phi_{XY}(L_X,L_Y)$ such that the following holds,* $\lim_{n,m\to\infty} P(\mathbf{X}^n,\mathbf{Y}^m)$

$$=\int\Phi(L_X,L_Y)\prod_{i=1}^{n}\phi_X(X(a_i)|L_X)\prod_{j=1}^{m}\phi_Y(Y(b_j)|L_Y)\,\mathbf{d}L_X L_Y$$
$$= P_{Miid}(\mathbf{X}^n,\mathbf{Y}^m).$$

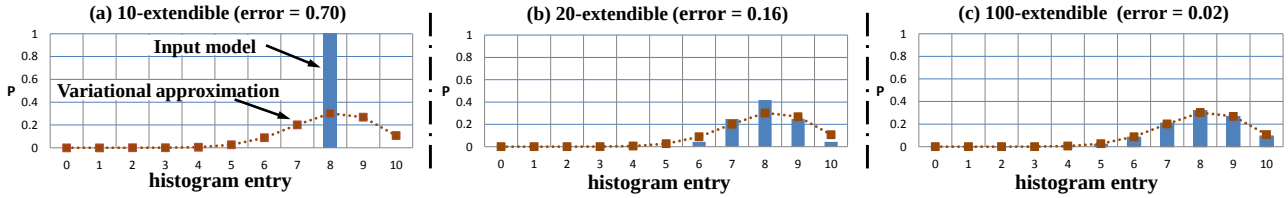

Figure 2: Illustrations of three different value-histograms of 10 exchangeable binary rvs. Dotted lines with markers represent the best possible variational approximation, i.e., a mixture of binomials. (a), (b) and (c) respectively present potentials extendible up to 10, 20 and 100 rvs. For the potential in (1), the variational approximation has a high error, total variation, and thus is a poor approximation. When a potential is extendible to the larger number, the variational approximation is smaller as shown in (2) and (3).

Sketch of proof. Assigning values to one atom is fixed (e.g. $\mathbf{Y}^m$=$\mathbf{v}$) results in a new potential with one atom, $\phi(\mathbf{X}^n)$, which can be factored into $\int \Phi(L_X|\mathbf{v}) \prod_i \phi_X(X(a_i)|L_X)\mathbf{d}L_X$. Because $\Phi(L_X|\mathbf{v})$ is conditioned on $\mathbf{v}$, $\Phi(L_X|\mathbf{Y}^m)$ can be factored into $\int \Phi(L_X, L_Y) \prod_j \phi_Y(Y(b_j)|L_Y)\mathbf{d}L_Y$. □

To analyze variational error of potentials with multiple atoms, we introduce another term $(\overline{\mathbf{n}}, \overline{\mathbf{m}})$-**extendible**.

Definition ($(\overline{\mathbf{n}}, \overline{\mathbf{m}})$**-extendible).** $P(\mathbf{X}^n, \mathbf{Y}^m)$ is $(\overline{\mathbf{n}}, \overline{\mathbf{m}})$-**extendible** when (1) there is $P(\mathbf{X}^{\overline{n}}, \mathbf{Y}^{\overline{m}})$, a probability with two sets of exchangeable rvs ($\overline{n}$>n, $\overline{m}$>m); and (2) $P(\mathbf{X}^n, \mathbf{Y}^m)$ is the marginal distribution of $P(\mathbf{X}^{\overline{\mathbf{n}}}, \mathbf{Y}^{\overline{\mathbf{m}}})$.

Lemma 3 (Error of the Variational Parfactor). *If $P(\mathbf{X}^n, \mathbf{Y}^m)$, a probability with two exchangeable rvs in an RHM, is $(\overline{n}, \overline{m})$-extendible, then the total variation $d_{TV}(P(\mathbf{X}^n, \mathbf{Y}^m), P_{Miid}(\mathbf{X}^n, \mathbf{Y}^m))$ is bounded as follows: (i) when $\mathbf{X}^n$ and $\mathbf{Y}^m$ are respectively d_x-valued and d_y-valued discrete rvs, $d_{TV}(P, P_{Miid}) \leq \frac{2d_x n}{\overline{n}} + \frac{2d_y m}{\overline{m}}$; (ii) when $\mathbf{X}^n$ are d_x-valued discrete and $\mathbf{Y}^m$ are continuous, $d_{TV}(P, P_{Miid}) \leq \frac{2d_x n}{\overline{n}} + \frac{m(m-1)}{\overline{m}}$; (iii) when $\mathbf{X}^n$ and $\mathbf{Y}^m$ are continuous, $d_{TV}(P, P_{Miid}) \leq \frac{n(n-1)}{\overline{n}} + \frac{m(m-1)}{\overline{m}}$.*

proof. The intuition is that the error of a variational model is additive with an additional atom. We used the principle in [13] such that a $\bar{n}$-extendible pdf, $P(X^n)$, can be represented by a mixture of extreme pdfs (e.g. $P(X^n) = \sum_e w_e p_e$). Here, an extreme pdf p_e is a probability of n draws made at random without replacement from an urn, U, which contains $\bar{n}$ balls marked by one of c colors. Let e a unique marking in U. The variation distance of each extreme point p_e and its variational form $P_{Miid}(X^n|e)$ is bounded $\leq \frac{2cn}{\bar{n}}$ for discrete rvs.

For a distribution with the multiple atoms, each extreme point corresponds to the joint distribution of n draws from U_X of $\bar{n}$ balls, and m draws from U_Y of $\bar{m}$ balls. Because the draws can be done independently for each urn, an extreme pdf (e.g. p_{e_x,e_y}) can be represented as the product of independent extreme pdfs (e.g. $p_{e_x} \cdot p_{e_y}$). From the Lemma 1, the variation distances of variational forms of p_{e_x} and p_{e_y} are respectively bounded. WLOG, we can represent the errors with ϵ_x and ϵ_y,

$$d_{TV}(p_{e_x}, \phi_{iidx}) \leq \epsilon_x, d_{TV}(p_{e_y}, \phi_{iidy}) \leq \epsilon_y.$$

Note that,

$$\begin{aligned} & d_{TV}(p_{e_x}p_{e_y}, \phi_{iidx}\phi_{iidy}) \\ \leq\ & d_{TV}(p_{e_x}p_{e_y}, p_{e_x}\phi_{iidy}) + d_{TV}(\phi_{iidy}p_{e_x}, \phi_{iidy}\phi_{iidx}) * \\ \leq\ & d_{TV}(p_{e_y}, \phi_{iidy}) + d_{TV}(p_{e_x}, \phi_{iidx}) * * = \epsilon_x + \epsilon_y. \end{aligned}$$

The second step (marked as $*$) is derived from the following equations (Here, A is $p_{e_x}\phi_{iidy}$):

$$\begin{aligned} p_{e_x}p_{e_y} - \phi_{iidx}\phi_{iidy} &= p_{e_x}p_{e_y} - \phi_{iidx}\phi_{iidy} - A + A \\ &= (p_{e_x}p_{e_y} - A) + (A - \phi_{iidx}\phi_{iidy}). \end{aligned}$$

The third step (marked as $**$) is derived from the fact that p_{e_x} and ϕ_{iidy} are pdfs, e.g. $\sum_{X^n} p_{e_x}(X^n) = 1$. That is, $d_{TV}(p_{e_x}p_{e_y}, p_{e_x}\phi_{iidy}) \leq d_{TV}(p_{e_y}, \phi_{iidy})$. The derivation can be applied to ϕ_{iidy} and continuous cases.

Thus, the total variation distance between two probabilities, $P(X^n, Y^m)$ and $P_{Miid}(X^n, Y^m)$ is bounded by the sum of two error bounds. □

Now, we present error analsys for RHMs with more than two atoms, e.g. $P(\mathbf{X}^n, \mathbf{Y}^m, \mathbf{Z}^u)$.

Theorem 4 (*Error of Variational RHMs*). *Let $\mathbf{X}_g$ and $\mathbf{X}_G$ is respectively the set of all rvs in a parfactor g and an RHM G. Let $P(\mathbf{X}_g)(= \frac{1}{z_g} \prod_{f \in gr(g)} w_f(\mathbf{X}_f))$; and $P(\mathbf{X}_G)(= \frac{1}{z} \prod_{g \in G} P(\mathbf{X}_g))$. The total variation $d_{TV}\left(P(\mathbf{X}_G) - P_{Miid}(\mathbf{X}_G)\right)$ is bounded by $\frac{1}{z}\sum_{g \in G} \epsilon_g$ where $\epsilon_g = d_{TV}(P(\mathbf{X}_g) - P_{Miid}(\mathbf{X}_g))$ and z is the normalizing constant.*

Sketch of proof. We can build a fully joint probability of all relational atoms with the RHM. Then, Lemma 3 can be used to prove the total variation of the variational RHM. □

8 Related Work

Nonparametric Bayesian Logic (NP-BLOG) [4] presents a new variational representation for relational discrete models using the Dirichlet Process. In principle, the NP-BLOG and the variational RHMs have in common: compact representations for exchangeable rvs. The difference is that NP-BLOG handles ∞-extendible exchangeable, discrete rvs. Here, we investigated further for several new directions: model learning, continuous domains, and approximation errors. Our error bounds provide an in-depth understanding for models with finite exchangeable discrete rvs.

For discrete models, the value-histogram [12; 23] represents potentials with polynomial numbers of histogram entries. When aggregate operators are given, [6] shows that the histgram representations can be approximately replaced by a Normal with linear constraints. We generalize and expand the concept to compress general-purpose histogram representations.

For continuous potentials, unfortunately, the histogram representation is not applicable because it is not clear how to discretize continuous domains to build up such histograms. Thus, most existing lifted inference for continuous models are limited to Gaussian potentials [5; 7; 1]. Thus, our representation is a unique lifted inference for non-Gaussian continuous potentials.

Lifted Belief Propagation (LBP) [29] solves inference problems in many practial models by grouping rvs. Here, rvs in an atom send the same messages to neighboring rvs, and are not constrained among rvs in an atom. Instead, our lifted MCMC sends a distribution, has more expressive power, and requires fewer samples until the convergence. The advance promises that our variational models and the lifted MCMC method can be a good complement to existing sampling methods such as LBP.

9 Experimental Results

We provide experimental results regarding the variational approximations and the efficiency and the accuracy of our LRVI in a real-world groundwater model.

First, we analyze variational approximations on the competing workshops models C-FOVE [23] which includes two parfactors, $\phi_1(\mathit{attends}(X), \mathit{hot}(W))$ and $\phi_2(\mathit{attends}(X), \mathit{series})$. We can exactly represent ϕ_2 with a Binomial:

$$\begin{aligned}&\phi_2(\#X[\mathit{attends}(X)], \mathit{series})\\ &\quad = \quad w(\mathit{series}) f_{\mathcal{B}}(\#X[\mathit{attends}(X)]; n, p(\mathit{series})),\end{aligned}$$

Here, n is the number of people; w and l are functions: $\{\top, \bot\} \rightarrow \mathbf{R}$; and $\#X[\mathit{attends}(X)]$ is a histogram representation in [23] such that $|\{i|\mathit{attends}(X_i) = \top\}|$. ϕ_1 is also represented by a mixture of $|W|$. ϕ_1 is the bivariate multiplicative binomial [20] and conditionally binomial. E.g., when $\#W[\mathit{hot}(W)]$ is fixed to 5, $\phi_1(\#X[\mathit{attends}(X)], \#W[\mathit{hot}(W)] = 5) = w_5 f_{\mathcal{B}}(\#X[\mathit{attends}(X)]; n, l_5)$.

When using the same parameters in [23], $\phi_1(\mathit{attends}(X), \mathit{hot}(W))$ is represented by a single binomial distribution accurately because weights of other $|W - 1|$ binomials are small with -9 orders of magnitude. We make similar observations with different parameters. When we randomly choose parameters (50 times), a single binomial was enough to represent ϕ_1 with a small total variation (< 0.001) for more than 90% (46 times). For other parameters, at most three binomials can represent ϕ_1 with a very small error (<0.0001).

Second, we apply our variational learning algorithm to a real-world groundwater dataset shown in Figure 3 (a) Republican River Compact Administration (RRCA). The dataset is composed of measurements (water levels) at over 10,000 wells and baseflow observations at 65 gages from 1918 until 2007.[11] After calibration, the training dataset is a set of partial observations in a 480 (months) by 3420 (wells) matrix. First, we cluster the 3420 wells by k-means into 10 groups based on means and variances (approximately exchangeable).[12] From the dataset, the EM algorithm directly learns a variational model until the log-likelihood converges. As a result, from 6 to 14 mixtures of Gaussians (MoGs) are learned for each cluster. Figure 3 (b) shows some learned empirical distributions, cdfs of MoGs, with high weights from two clustered area, A and B. To represent the joint distribution over the clusters, we convert the 480X3240 input matrix into a 480 (months) by 92 (MoGs) matrix.

For each test month, we compute the empirical distribution of the query variables given the partial observations. Our lifted VE returns queries in average 0.3 secs and a ground VE inference returns in average 37.9 secs. In fact, ground and variational inference algorithms use different sizes of matrices 480X3420 and 480X92, respectively. That explains the reason why the variational inference is efficient. The average total variations are 0.35 (ground) and 0.29 (variational), where smaller is more accurate.

Third, we compare the accuracy and the efficiency of

[11] Head predictions are available via the RRCA official website, http://www.republicanrivercompact.org.

[12] Although the means and variances do not guarantee the exchangeability in the clusters, here we focus on measuring the computational efficiency of our variational method.

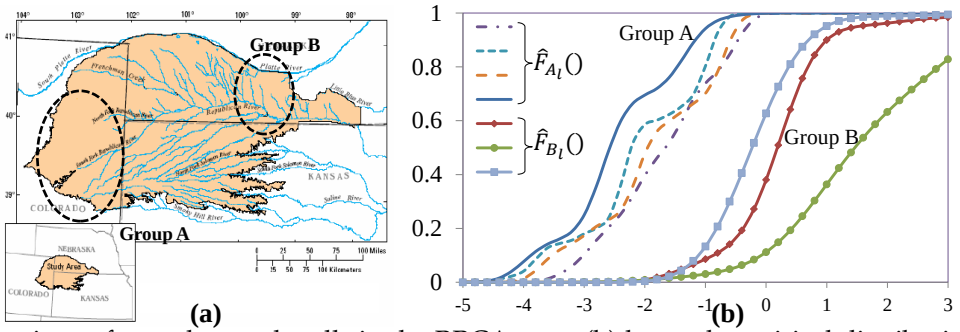

Figure 3: (a) locations of two clustered wells in the RRCA map; (b) learned empirical distributions, cdfs ($\hat{F}_{A_l}()$ and $\hat{F}_{B_l}(x)$) for two regions A and B.

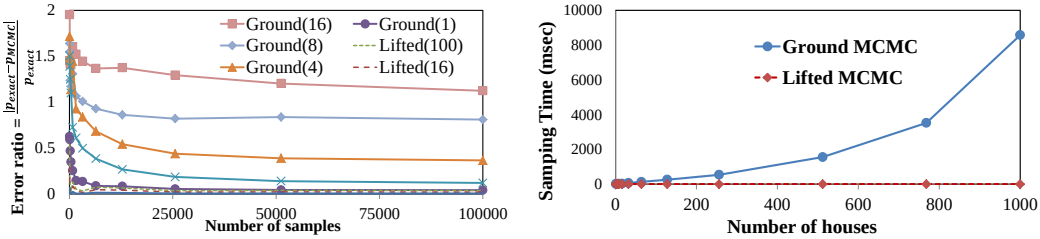

Figure 4: (a) The accuracy of the lifted MCMC and the ground MCMC with various numbers of houses. Here, () indicates the number of houses, e.g., Ground(16) is the ground MCMC with 16 houses. (b) The average time to generate samples in each MCMC step.

our lifted MCMC algorithm with a vanilla (ground) MCMC algorithm on an already factored variational model. The model is composed of two relational atoms: a binary atom $\mathbf{Job}^n$, saying whether each individual has a job, and a continuous atom $\mathbf{HP}^m$, saying the price change of each house. p_{Job} is a latent variable, which represents the Bernoulli parameters of $\phi_{Miid}(\mathbf{Job}^n)$. p_D is a latent variable (probability of market down), which represents the mixture of two Gaussians, $\phi_{Miid}(\mathbf{HP}^m)$ =

$$p_D \prod_{j=1}^{m} f_{\mathcal{N}}(HP(h_j); -0.3, \sigma_D^2) + (1-p_D) \prod_{j=1}^{m} f_{\mathcal{N}}(HP(h_j); 0.1, \sigma_{UP}^2).$$

Here, we assume that the two latent variables follows a linear Gaussian: $\Phi(p_{Job}, p_D) = f_{\mathcal{N}}(p_{Job} - p_D; 0, \sigma^2_{JobHouse})$. Figure 4 (a) shows the accuracy of the two algorithms after generating the same number of samples. That is, it measure the ratio of error to estimate a probability of a randomly chosen variable $HP(h_j)$, $|p_{exact}(HP(h_j)) - p_{MCMC}(HP(h_j))|/p_{exact}(HP(h_j))$. It shows that our lifted MCMC converges to the true density much faster than the ground MCMC.[13] Figure 4 (b) shows the average sampling time (per step) with different number of rvs, i.e. the number of houses.

[13]The lifted Belief Propagation (LBP) [29] is not directly applicable because the target distribution is a mixture of two iid Gaussians. The LBP assumes that each house sends the same message, i.e. price estimation. However, here, the messages among houses should be constrained. That is, the prices of some houses go down, and then prices of the other houses should go up.

10 Conclusions

We propose new lifted relational variational inference algorithms for relational hybrid models. Our main contributions are two folds: (1) in theory, we show that a relational model, which can represent large-scale systems, is accurately represented by a variational relational model; (2) our lifted algorithms are the first to solve inference problems without referring ground rvs for non-Gaussian continuous models. Experiments show that our method outperforms the existing possible methods in various cases including a real-world environmental problem.

A Bayesian Approach to Constraint Based Causal Inference

Tom Claassen and Tom Heskes
Institute for Computer and Information Science
Radboud University Nijmegen
The Netherlands

Abstract

We target the problem of accuracy and robustness in causal inference from finite data sets. Some state-of-the-art algorithms produce clear output complete with solid theoretical guarantees but are susceptible to propagating erroneous decisions, while others are very adept at handling and representing uncertainty, but need to rely on undesirable assumptions. Our aim is to combine the inherent robustness of the Bayesian approach with the theoretical strength and clarity of constraint-based methods. We use a Bayesian score to obtain probability estimates on the input statements used in a constraint-based procedure. These are subsequently processed in decreasing order of reliability, letting more reliable decisions take precedence in case of conflicts, until a single output model is obtained. Tests show that a basic implementation of the resulting Bayesian Constraint-based Causal Discovery (BCCD) algorithm already outperforms established procedures such as FCI and Conservative PC. It can also indicate which causal decisions in the output have high reliability and which do not.

1 Introduction: Robust Causal Discovery

In many real-world systems the relations and interactions between variables can be modeled in the form of a causal directed acyclic graph (DAG) $\mathcal{G}_C$ over a set of variables $\mathbf{V}$. A directed path from A to B in such a graph indicates a *causal relation* $A \Rightarrow B$ in the system, where cause A *influences* the value of its effect B, but not the other way around. An edge $A \rightarrow B$ in $\mathcal{G}_C$ indicates a *direct* causal link. In data from a system with a causal relation $A \Rightarrow B$ (direct or indirect), the values of A and B have a tendency to vary together, i.e. they become probabilistically dependent.
Two assumptions are usually employed to link the underlying, asymmetric causal relations to observable, symmetric probabilistic dependencies:

The **Causal Markov Condition** states that each variable in a causal DAG $\mathcal{G}_C$ is (probabilistically) independent of its non-descendants, given its parents.
The **Causal Faithfulness Condition** states that there are no independencies between variables that are not entailed by the Causal Markov Condition.

The first makes it possible to go from causal graph to observed probabilistic independencies; the second completes the way back. Together, they imply that the causal DAG $\mathcal{G}_C$ is also *minimal*, in the sense that no proper subgraph can satisfy both assumptions *and* produce the same probability distribution (Zhang and Spirtes, 2008).

Before we continue with causal discovery methods, first a quick recap of some standard concepts and terminology. The joint probability distribution induced by a causal DAG $\mathcal{G}_C$ factors according to a *Bayesian network* (BN): a pair $\mathcal{B} = (\mathcal{G}, \boldsymbol{\Theta})$, where $\mathcal{G} = (\mathbf{V}, \mathbf{A})$ is DAG over random variables $\mathbf{V}$, and the parameters $\boldsymbol{\theta}_V \subset \boldsymbol{\Theta}$ represent the conditional probability of variable $V \in \mathbf{V}$ given its parents $\mathbf{Pa}(V)$ in the graph $\mathcal{G}$.
Probabilistic independencies can be read from the graph $\mathcal{G}$ via the well-known *d-separation* criterion: X is conditionally independent of Y given $\mathbf{Z}$, denoted $X \perp\!\!\!\perp Y \,|\, \mathbf{Z}$, iff there is no unblocked path between X and Y in $\mathcal{G}$ conditional on the nodes in $\mathbf{Z}$; see e.g. (Pearl, 1988; Neapolitan, 2004).

If some of the variables in the causal DAG are hidden then the independence relations between the observed variables may be represented in the form of a *(maximal) ancestral graph* (MAG) (Richardson and Spirtes, 2002). MAGs form an extension of the class of DAGs that is closed under marginalization and selection. In

addition to directed arcs, MAGs can also contain *bi-directed arcs* $X \leftrightarrow Y$ (indicative of marginalization) and undirected edges $X - - Y$ (indicative of selection). The *causal sufficiency* assumption states that there are no hidden common causes of the observed variables in $\mathcal{G}$, which implies that the distribution over the observed variables still conforms to a Bayesian network. In this article we ignore selection bias (= no undirected edges), but do *not* rely on causal sufficiency.

The *equivalence class* $[\mathcal{G}]$ of a graph $\mathcal{G}$ is the set of all graphs that are indistinguishable in terms of (Markov) implied independencies.[1] For a DAG or MAG $\mathcal{G}$, the corresponding equivalence class $[\mathcal{G}]$ can be represented as a *partial ancestral graph* (PAG) $\mathcal{P}$, which keeps the skeleton (adjacencies) and all invariant edge marks, i.e. tails ($-$) and arrowheads ($>$) that appear in all members of the equivalence class, and turns the remaining non-invariant edge marks into circles ($\circ$) (Zhang, 2008). The invariant arrowhead at an edge $A *\!\!\rightarrow B$ in $\mathcal{P}$ signifies that B is *not* a cause of A. An edge $A \rightarrow B$ implies a causal link $A \Rightarrow B$ that is also direct.

With this in mind, the task of a causal discovery algorithm is to find as many invariant features of the equivalence class corresponding to a given data set as possible. From this, all identifiable, present or absent causal relations can be read.

Causal discovery procedures

A large class of **constraint-based** causal discovery algorithms is based directly on the faithfulness assumption: if a conditional independence $X \perp\!\!\!\perp Y \,|\, \mathbf{Z}$ can be found for *any* set of variables $\mathbf{Z}$, then there is no direct causal relation between X and Y in the underlying causal graph $\mathcal{G}_C$, and hence no edge between X and Y in the equivalence class $\mathcal{P}$. In this way, an exhaustive search over all pairs of variables can uncover the entire skeleton of $\mathcal{P}$. In the subsequent stage a number of orientation rules are executed that find the invariant tails and arrowheads.

Members of this group include the IC-algorithm (Pearl and Verma, 1991), PC/FCI (Spirtes et al., 2000), Grow-Shrink (Margaritis and Thrun, 1999), TC (Pellet and Elisseef, 2008), and many others. All involve repeated independence tests in the adjacency search phase, and employ orientation rules as described in Meek (1995). The differences lie mainly in the search strategy employed, size of the conditioning sets, and additional assumptions imposed. Of these, the FCI algorithm in conjunction with the additional orientation rules in (Zhang, 2008) is the only one that is sound and complete in the large-sample limit when hidden common causes and/or selection bias may be present.

Constraint-based procedures tend to output a single, reasonably clear graph, representing the class of all possible causal DAGs. The downside is that for finite data they give little indication of which parts of the network are stable (reliable), and which are not: if unchecked, even one erroneous, borderline independence decision may be propagated through the network, leading to multiple incorrect orientations (Spirtes, 2010).

To tackle the perceived lack of robustness of PC, Ramsey et al. (2006) proposed a **conservative approach** for the orientation phase. The standard rules draw on the implicit assumption that, after the initial adjacency search, a single $X \perp\!\!\!\perp Y \,|\, \mathbf{Z}$ should suffice to orient an unshielded triple $\langle X, Z, Y \rangle$, as Z should be either part of *all* or part of *no* sets that separate X and Y. The Conservative PC (CPC) algorithm tests explicitly whether this assumption holds, and only orients the triple into a noncollider resp. v-structure $X \rightarrow Z \leftarrow Y$ if found true. If not, then it is marked as *unfaithful*. Tests show that CPC significantly outperforms standard PC in terms of overall accuracy, albeit often with less informative output, for only a marginal increase in run-time.

This idea can be extended to FCI: the set of potential separating nodes is now conform FCI's adjacency search, and any of Zhang's orientation rules that relies on a particular unshielded (non-)collider does not fire on an unfaithful triple. See (Glymour et al., 2004; Kalisch et al., 2011) for an implementation of Conservative FCI (CFCI) and many related algorithms.

The **score-based** approach is an alternative paradigm that builds on the implied *minimality* of the causal graph: define a scoring criterion $S(\mathcal{G}, \mathbf{D})$ that measures how well a Bayesian network with structure $\mathcal{G}$ fits the observed data $\mathbf{D}$, while preferring simpler networks, with fewer free parameters, over more complex ones. If the causal relations between the variables in $\mathbf{D}$ form a causal DAG $\mathcal{G}_C$, then in the large sample limit the highest scoring structure $\mathcal{G}$ must be part of the equivalence class of $[\mathcal{G}_C]$.

An example is the (Bayesian) likelihood score: given a Bayesian network $\mathcal{B} = (\mathcal{G}, \mathbf{\Theta})$, the likelihood of observing a particular data set $\mathbf{D}$ can be computed recursively from the network. Integrating out the parameters $\mathbf{\Theta}$ in the conditional probability tables (CPTs) then results in:

$$p(\mathbf{D}|\mathcal{G}) = \int_{\mathbf{\Theta}} p(\mathbf{D}|\mathcal{G}, \mathbf{\Theta}) f(\mathbf{\Theta}|\mathcal{G}) \, \mathrm{d}\mathbf{\Theta}, \qquad (1)$$

where f is a conditional probability density function over the parameters $\mathbf{\Theta}$ given structure $\mathcal{G}$.

[1] We follow the standard assumption that Markov equivalence implies statistical equivalence (Spirtes, 2010).

A closed form solution to eq.(1) is used in algorithms such as K2 (Cooper and Herskovits, 1992) and the Greedy Equivalence Search (GES) (Chickering, 2002) to find an optimal structure by repeatedly comparing scores for slightly modified alternatives until no more improvement can be found. See also Bouckaert (1995) for an evaluation of different strategies using these and other measures such as the BIC-score and minimum description length.

Score-based procedures can output a set of high-scoring alternatives. This ambiguity makes the result arguably less straightforward to read, but does allow for a measured interpretation of the reliability of inferred causal relations, and is not susceptible to incorrect categorical decisions (Heckerman et al., 1999). The main drawback is the need to rely on the causal sufficiency assumption.

2 The Best of Both Worlds

The strength of a constraint-based algorithm like FCI is its ability to handle data from arbitrary faithful underlying causal DAGs and turn it into sound and clear, unambiguous causal output. The strength of the Bayesian score-based approach lies in the robustness and implicit confidence measure that a likelihood weighted combination of multiple models can bring.

▶ Our idea is to improve on conservative FCI by using a Bayesian approach to estimate the reliability of different constraints, and use this to decide if, when, and how that information should be used.

Instead of classifying pieces of information as reliable or not, we want to rank and process constraints according to a confidence measure. This should allow to avoid propagating unreliable decisions while retaining more confident ones. It also provides a principled means for conflict resolution. The end-result is hopefully a more informative output model than CFCI, while obtaining a higher accuracy than standard FCI can deliver.

To obtain a confidence measure that can be compared across different estimates we want to compute the *probability* that a given independence statement holds from a given data set $\mathbf{D}$. In an ideal Bayesian approach we could compute a likelihood $p(\mathbf{D}|\mathcal{M})$ for each $\mathcal{M} \in \mathbf{M}$ (see section 3 on how to approximate this). If we know that the set $\mathbf{M}$ contains the 'true' structure, then the probability of an independence hypothesis I follows from normalized summation as:

$$p(I|\mathbf{D}) \propto \sum_{\mathcal{M} \in \mathbf{M}(I)} p(\mathbf{D}|\mathcal{M}) p(\mathcal{M}), \qquad (2)$$

(Heckerman et al., 1999), where $\mathbf{M}(I)$ denotes the subset of structures that entail independence statement I, and $p(\mathcal{M})$ represents a prior distribution over the structures (see §3.4).

Two remarks. Firstly, it is well known that the number of possible graphs grows very quickly with the number of nodes $\mathbf{V}$. But eq.(2) equally applies when we limit data and structures to *subsets* of variables $\mathbf{X} \subset \mathbf{V}$. For sparse graphs we can choose to consider only subsets of size $K \ll |\mathbf{V}|$. We opt to go one step further and follow a search strategy similar to PC/FCI, using structures of increasing size. Secondly, it would be very inefficient to compute eq.(2) for each independence statement we want to evaluate. From a single likelihood distribution over structures over $\mathbf{X}$ we can immediately compute the probability of *all* possible independence statements between variables in $\mathbf{X}$, including complex combinations such as those implied by v-structures, just by summing the appropriate contributions for each statement.

Having obtained probability estimates for a list of in/dependence statements $\mathcal{I}$, we can rank these in decreasing order of reliability, and keep the ones based on a decision threshold $p(I|\mathbf{D}) > \theta$, with $\theta = 0.5$ as intuitive default. In case of remaining conflicting statements, the ones with higher confidence take precedence. The resulting algorithm is outlined below:

Algorithm 1 Outline

Start : database $\mathbf{D}$ over variables $\mathbf{V}$
Stage 1 - Adjacency search
1: fully connected graph $\mathcal{P}$, empty list $\mathcal{I}$, $K = 0$
2: **repeat**
3: **for all** $X - Y$ still connected in $\mathcal{P}$ **do**
4: **for all** adjacent sets $\mathbf{Z}$ of K nodes in $\mathcal{P}$ **do**
5: estimate $p(\mathcal{M}|\mathbf{D})$ over $\{X, Y, \mathbf{Z}\}$
6: sum to $p(I|\mathbf{D})$ for independencies I
7: update $\mathcal{I}$ and $\mathcal{P}$ for each $p(I|\mathbf{D}) > \theta$
8: **end for**
9: **end for**
10: $K = K + 1$
11: **until** all relevant found
Stage 2 - Orientation rules
12: rank and filter $\mathcal{I}$ in decreasing order of reliability
13: orient unshielded triples in $\mathcal{P}$
14: run remaining orientation rules
15: return causal model $\mathcal{P}$

In this form, the Bayesian estimates are only used to guide the adjacency search (update skeleton $\mathcal{G}$, l.7), and to filter the list of independencies $\mathcal{I}$ (l.12). Ideally, we would like the probabilities to guide the orientation phase as well. This implies processing the independence statements sequentially, in decreasing order of reliability. For that we can use a recently developed

variant of the FCI algorithm (Claassen and Heskes, 2011), that breaks up the inference into a series of *modular* steps that can be executed in arbitrary order. It works by translating observed independence constraints into **logical statements** about the presence or absence of certain causal relations.

Using square brackets to indicate *minimal* sets of nodes: if a variable Z either *makes* or *breaks* an independence relation between $\{X, Y\}$, then

1. $X \perp\!\!\!\perp Y \,|\, [\mathbf{W} \cup Z] \;\; \vdash \;\; (Z \Rightarrow X) \;\vee\; (Z \Rightarrow Y)$,
2. $X \not\perp\!\!\!\perp Y \,|\, \mathbf{W} \cup [Z] \;\; \vdash \;\; Z \not\Rightarrow (\{X, Y\} \cup \mathbf{W})$.

In words: from a minimal independence we infer the *presence* of at least one from two causal relations, whereas a dependence identifies the *absence* of causal relations. Subsequent causal statements follow from deduction on the properties *transitivity* $(X \Rightarrow Y) + (Y \Rightarrow Z) \vdash (X \Rightarrow Z)$, and *irreflexivity* $(X \not\Rightarrow X)$.

3 Sequential Causal Inference

This section discusses the steps needed to turn the previous idea into a working algorithm in the next section. Main issues are: probability estimates for logical causal statements from substructures, Bayesian likelihood computation, and inference from unfaithful DAGs. Proofs are detailed in (Claassen and Heskes, 2012).

A word on notation: we use $\mathbf{D}$ to denote a data set over variables $\mathbf{V}$ from a distribution that is faithful to some (larger) causal DAG $\mathcal{G}_C$. Ł denotes the set of logical causal statements L over two or three variables in $\mathbf{V}$, of the form given in the r.h.s. of rules 1 and 2, above. We use $\mathbf{M_X}$ to represent the set of MAGs over $\mathbf{X}$, and $\mathbf{M_X}(L)$ to denote the subset that entails logical statement L. We also use $\mathcal{G}$ to explicitly indicate a DAG, $\mathcal{M}$ for a MAG, and $\mathcal{P}$ for a PAG.

3.1 A Modular Approach

In order to process available information in (decreasing) order of reliability we need to obtain probability estimates for logical statements on causal relations from data. Similar to eq.(2), this follows from summing the normalized posterior likelihoods of all MAGs that entail that statement through m-separation:

Lemma 1. The probability of a logical causal statement L given a data set $\mathbf{D}$ is given by

$$p(L|\mathbf{D}) = \frac{\sum_{\mathcal{M} \in \mathbf{M}(L)} p(\mathbf{D}|\mathcal{M}) p(\mathcal{M})}{\sum_{\mathcal{M} \in \mathbf{M}} p(\mathbf{D}|\mathcal{M}) p(\mathcal{M})}, \qquad (3)$$

using the notational conventions introduced above.

As stated, in many cases considering only a small subset of the variables in $\mathbf{V}$ is already sufficient to infer L. But that also implies that there are multiple subsets that imply L, each with different probability estimates. As these relate to different sets of variables, they should not be combined as in standard multiple hypothesis tests, but instead we want to look for the *maximum* value that can be found.

Lemma 2. Let $\mathbf{D}$ be a data set over variables $\mathbf{V}$. Then $\forall \mathbf{X} \subseteq \mathbf{V} : p(L|\mathbf{D}) \geq \sum_{\mathcal{M} \in \mathbf{M_X}(L)} p(\mathcal{M}|\mathbf{D})$.

Proof. Let $p(\mathcal{M}|\mathbf{D})$ be the posterior probability of MAG $\mathcal{M}$ given data $\mathbf{D}$. Let $\mathcal{M}(\mathbf{X})$ denote the MAG $\mathcal{M}$ marginalized to variables $\mathbf{X}$, then:

$$\begin{aligned} p(L|\mathbf{D}) &= \sum_{\mathcal{M} \in \mathbf{M_V}(L)} p(\mathcal{M}|\mathbf{D}) \\ &\geq \sum_{\mathcal{M} \in \mathbf{M_V}(L) : \mathcal{M}(\mathbf{X}) \in \mathbf{M_X}(L)} p(\mathcal{M}|\mathbf{D}) \\ &= \sum_{\mathcal{M} \in \mathbf{M_X}(L)} p(\mathcal{M}|\mathbf{D}) \end{aligned}$$

The inequality follows from the fact that, by definition, no marginal MAG $\mathcal{M}(\mathbf{X})$ entails a statement not entailed by $\mathcal{M}$, whereas the converse can (and does) occur. □

As a result: $p(L|\mathbf{D}) \geq \max_{\mathbf{X} \subset \mathbf{V}} \sum_{\mathcal{M} \in \mathbf{M_X}(L)} p(\mathcal{M}|\mathbf{D})$.

It means that while searching for logical causal statements Ł, it makes sense to keep track of the maximum probabilities obtained so far.

However, computing $p(\mathcal{M}|\mathbf{D})$ for $\mathcal{M} \in \mathbf{M_X}$ still involves computing likelihoods over all structures over $\mathbf{V}$, which is precisely what we want to avoid. A reasonable approximation is provided by $p(\mathcal{M}|\mathbf{D_X})$, i.e. the estimates obtained by only including data in $\mathbf{D}$ from the variables $\mathbf{X}$. It means that the lower bound is no longer guaranteed to hold universally, but should still be adequate in practice.

3.2 Obtaining likelihood estimates

If we know that the 'true' structure over a subset $\mathbf{X} \subseteq \mathbf{V}$ takes the form of a DAG, then computing the required likelihood estimates $p(\mathbf{D_X}|\mathcal{G})$ is relatively straightforward. Cooper and Herskovits (1992) showed that, under some reasonable assumptions, for discrete random variables the integral (1) has a closed-form solution. In the form presented in (Heckerman et al., 1995) this score is known as the *Bayesian Dirichlet* (BD) metric:

$$p(\mathbf{D}|\mathcal{G}) = \prod_{i=1}^{n} \prod_{j=1}^{q_i} \frac{\Gamma(N'_{ij})}{\Gamma(N_{ij} + N'_{ij})} \prod_{k=1}^{r_i} \frac{\Gamma(N_{ijk} + N'_{ijk})}{\Gamma(N'_{ijk})}, \qquad (4)$$

with n the number of variables, r_i the multiplicity of variable X_i, q_i the number of possible instantiations of the parents of X_i in $\mathcal{G}$, N_{ijk} the number of cases in data set $\mathbf{D}$ in which variable X_i has the value $r_{i(k)}$ while its parents are instantiated as $q_{i(j)}$, and with $N_{ij} = \sum_{k=1}^{r_i} N_{ijk}$. The $N'_{ij} = \sum_{k=1}^{r_i} N'_{ijk}$ represent the pseudocounts for a Dirichlet prior over the parameters in the corresponding CPTs.

Different strategies for choosing the prior exist: for example, choosing $N'_{ijk} = 1$ (uniform prior) leads to the original *K2-metric*, see (Cooper and Herskovits, 1992). Setting $N'_{ijk} = N'/(r_i q_i)$ gives the popular *BDeu*-metric, which is *score equivalent* in the sense that structures from the same equivalence class $[\mathcal{G}]$ receive the same likelihood score, cf. (Buntine, 1991). In this article, we opt for the $K2$-metric, as it seems more appropriate in causal settings (Heckerman et al., 1995). But having to consider only one instance of every equivalence class may prove a decisive advantage of the BDe(u)-metric in future extensions.

However, eq.(4) only applies to DAGs. We know that, even when assuming causal sufficiency applies for the variables $\mathbf{V}$, considering arbitrary subsets size $|\mathbf{X}| \geq 4$ in general will require MAG representations to account for common causes that are not in $\mathbf{X}$. Extending the derivation of eq.(4) requires additional assumptions on multiplicity and number of the hidden variables, and turns the nice closed-form solution into an intractable problem that requires approximation, e.g. through sampling (Heckerman et al., 1999). This would make each step in our approach much more expensive. Recently, Evans and Richardson (2010) showed a maximum likelihood approach to fit acyclic directed mixed graphs (a superset of MAGs) directly on binary data. Unfortunately, this method cannot provide the likelihood estimates per model we need for our purposes. Silva and Ghahramani (2009) do present a Bayesian approach, but need to put additional constraints on the distribution in the form of (cumulative) Gaussian models.

In short, even though we would like to use MAGs to compute $p(\mathbf{D_X}|\mathcal{M})$ directly in eq.(3), at the moment we have to rely on DAGs to obtain approximations to the 'true' value. This will result in less accurate reliability estimates for $p(L|\mathbf{D})$, but also means that we may miss certain pieces of information, or, even worse, that the inference may become invalid.

3.3 Unfaithful inference: DAGs vs. MAGs

Fortunately we can show that, even when the true independence structure over a subset $\mathbf{X} \subset \mathbf{V}$ is a MAG, we can still do valid inference via $p(L|\mathbf{D_X})$ from likelihood scores over an exhaustive set of DAGs over $\mathbf{X}$, provided we account for unfaithful DAG representations. This part discusses unfaithful inference, and how the mapping from structures to logical causal statements can be modified. Much of what we show builds on (Bouckaert, 1995).

In the large-sample limit, the Bayesian likelihood score picks the smallest DAG structure(s) that can capture the observed probability distribution exactly.

Definition 1 (Optimal uDAG). A DAG $\mathcal{G}$ is an (unfaithful) **uDAG** approximation to a MAG $\mathcal{M}$ over a set of nodes $\mathbf{X}$, iff for any probability distribution $p(\mathbf{X})$, generated by an underlying causal graph faithful to $\mathcal{M}$, there is a set of parameters $\mathbf{\Theta}$ such that the Bayesian network $\mathcal{B} = (\mathcal{G}, \mathbf{\Theta})$ encodes the same distribution $p(\mathbf{X})$. The uDAG is **optimal** if there exists no uDAG to $\mathcal{M}$ with fewer free parameters.

A uDAG is just a DAG for which we do not know if it is faithful or not. Reading in/dependence relations from a uDAG goes as follows:

Lemma 3. Let $\mathcal{B} = (\mathcal{G}, \mathbf{\Theta})$ be a Bayesian network over a set of nodes $\mathbf{X}$, with $\mathcal{G}$ a uDAG for some MAG that is faithful to a distribution $p(\mathbf{X})$. Let $\mathcal{G}_{X \| Y}$ be the graph obtained by eliminating the edge $X - Y$ from $\mathcal{G}$ (if present). Then, if $X \perp\!\!\!\perp_{\mathcal{G}_{X\|Y}} Y \,|\, \mathbf{Z}$ then:

$$(X \perp\!\!\!\perp_{\mathcal{G}} Y \,|\, \mathbf{Z}) \Leftrightarrow (X \perp\!\!\!\perp_{p} Y \,|\, \mathbf{Z}).$$

Proof sketch. The independence rule $(X \perp\!\!\!\perp_{\mathcal{G}} Y \,|\, \mathbf{Z}) \Rightarrow (X \perp\!\!\!\perp_{p} Y \,|\, \mathbf{Z})$ follows (Pearl, 1988). The dependence rule $(X \perp\!\!\!\perp_{\mathcal{G}_{X\|Y}} Y \,|\, \mathbf{Z}) \wedge (X \not\perp\!\!\!\perp_{\mathcal{G}} Y \,|\, \mathbf{Z}) \Rightarrow (X \not\perp\!\!\!\perp_{p} Y \,|\, \mathbf{Z})$ is similar to the 'coupling' theorem (3.11) in (Bouckaert, 1995), but stronger. As we assume a faithful MAG, a dependence $X \not\perp\!\!\!\perp_{p} Y \,|\, \mathbf{Z}$ cannot be destroyed by in/excluding a node U that has no unblocked path in the underlying MAG to X and/or Y given $\mathbf{Z}$. This eliminates one of the preconditions in the coupling theorem. See (Claassen and Heskes, 2012) for details. □

So, in a uDAG all independencies from d-separation are still valid, but the identifiable dependencies are restricted.

Example 1. Treating the uDAG in Figure 1(b) as a faithful DAG would suggest $X \perp\!\!\!\perp_{p} T \,|\, [Z]$, and hence $(Z \Rightarrow X) \vee (Z \Rightarrow T)$. This is wrong: Figure 1(a) shows that Z is ancestor of neither X nor T. Lemma 3 would not make this mistake, as it allows to deduce $X \perp\!\!\!\perp_{p} T \,|\, Z$, but not the erroneous $X \not\perp\!\!\!\perp_{p} T$.

We can generalize Lemma 3 to *indirect* dependencies.

Lemma 4. Let $\mathcal{G}$ be a uDAG for a faithful MAG $\mathcal{M}$. Let X, Y, and $\mathbf{Z}$ be disjoint (sets of) nodes. If $\pi = \langle X, .., Y \rangle$ is the *only* unblocked path from X to Y given $\mathbf{Z}$ in $\mathcal{G}$, then $X \not\perp\!\!\!\perp_{p} Y \,|\, \mathbf{Z}$.

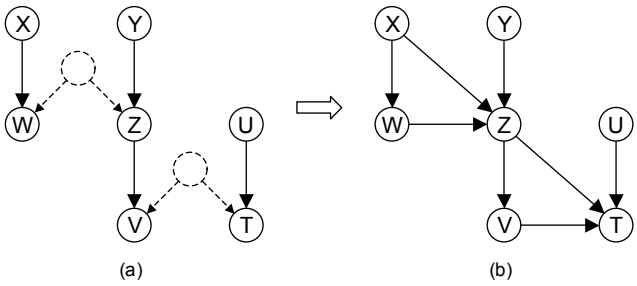

Figure 1: (a) causal DAG with hidden variables, (b) uDAG with unfaithful $X \perp\!\!\!\perp_{\mathcal{G}} T \,|\, [Z]$

Example 2. With Lemma 4 we infer from Figure 1(b) that $X \not\perp\!\!\!\perp_p T \,|\, \{V, W\}$. We also find that $Y \not\perp\!\!\!\perp_p V$, from which, in combination with $Y \perp\!\!\!\perp_p V \,|\, [Z]$, we (rightly) conclude that $(Z \Rightarrow Y) \vee (Z \Rightarrow V)$, see (a).

In general, Lemmas 3 and 4 assert different dependencies for different uDAG members of the same equivalence class. If the uDAG $\mathcal{G}$ is *optimal*, then all in/dependence statements from any uDAG member of the corresponding equivalence class $[\mathcal{G}]$ are valid. In that case we can do the inference based on the PAG representation $\mathcal{P}$ of $[\mathcal{G}]$. This provides additional information, but also simplifies some inference steps. Again, see (Claassen and Heskes, 2012) for details.

For example, identifying an absent causal relation (arrowhead) $X \not\Leftarrow Y$ from an optimal uDAG becomes identical to the inference from a faithful MAG. Let a *potentially directed path* (p.d.p.) be a path in a PAG that could be oriented into a directed path by changing circle marks into appropriate tails/arrowheads, then

Lemma 5. Let $\mathcal{G}$ be an optimal uDAG to a faithful MAG $\mathcal{M}$, then the absence of a causal relation $X \not\Leftarrow Y$ can be identified, iff there is no potentially directed path from X to Y in the PAG $\mathcal{P}$ of $[\mathcal{G}]$.

Proof sketch. The optimal uDAG $\mathcal{G}$ is obtained by (only) adding edges between variables in the MAG $\mathcal{M}$ to eliminate invariant bi-directed edges, until no more are left. At that point the uDAG is a representative of the corresponding equivalence class $\mathcal{P}$ (Theorem 2 in Zhang (2008)). For any faithful MAG all and only the nodes not connected by a p.d.p. in the corresponding PAG have a definite non-ancestor relation in the underlying causal graph. At least one uDAG instance in the equivalence class of an optimal uDAG over a given skeleton leaves the ancestral relations of the original MAG intact.Therefore, any remaining invariant arrowhead in the PAG $\mathcal{P}$ matches a non-ancestor relation in the original MAG. □

For the presence of causal relations (tails) a similar, but more complicated criterion can be found; see Supplement. Ultimately, the impact of having to use uDAGs boils down to a modified mapping of structures to logical causal statements, based on the inference rules above.

Finally, it is worth mentioning that in the large-sample limit, matching uDAGs over increasing sets of nodes we are guaranteed to find all independencies needed to obtain the skeleton, as well as all invariant arrowheads and many invariant tails. However, as the primary goal remains to improve accuracy/robustness when the large-sample limit does *not* apply, we do not pursue this matter further here.

3.4 Consistent prior over structures

The computation of $p(L|\mathbf{D}_{\mathbf{X}})$ requires a prior distribution $p(\mathcal{M})$ over the set of MAGs over $\mathbf{X}$. A straightforward solution is to use a uniform prior, assigning equal probability to each $\mathcal{M} \in \mathbf{M}$. Alternatively, we can use a predefined function that penalizes complexity or deviation w.r.t. some reference structure (Chickering, 2002; Heckerman et al., 1995). If we want to exploit score-equivalence with the BDe(u) metric in eq.(4), we can weight DAG representatives according to the size of their equivalence class.

If we have background information on expected (or desired) properties of the structure, such as max. node degree, average connectivity, or small-world/scale-free networks, we can use this to construct a prior $p(\mathcal{M})$ through *sampling*: generate random graphs over all variables in accordance with the specified characteristics, sample one or more random subsets of variables size K, and compute the marginal structure over that subset. Averaging over structures that are PAG-isomorphs (equivalence classes identical under relabeling) improves both consistency and convergence.

Irrespective of the method, it is essential to ensure the prior is also *consistent* over structures of different size. Perhaps surprisingly, this is *not* obtained by applying the same strategy at different levels: a uniform distribution over DAGs over $\{X, Y, Z\}$ implies $p(\text{“}X \perp\!\!\!\perp Y\text{”}) = 6/25$, whereas a uniform distribution over two-node DAGs implies $p(\text{“}X \perp\!\!\!\perp Y\text{”}) = 1/3$. We obtain a consistent multi-level prior by starting from a preselected level K, and then extend to different sized structures through marginalization.

4 The BCCD algorithm

We can now turn the results from the previous section into a working algorithm. The implementation largely follows the outline in Algorithm 1, except that now

uDAGs (instead of MAGs) are used to obtain a list of logical causal statements (instead of independencies), and that logical inference takes the place of the orientation rules, resulting in the Bayesian Constraint-based Causal Discovery (BCCD) algorithm.

A crucial step in the algorithm is the mapping $\mathcal{G} \times$ Ł from optimal uDAG structures to causal statements in line 9. This mapping is the same for each run, so it can be precomputed from the rules in section 3.3 and the Supplement, and stored for use afterwards (l.1) The uDAGs $\mathcal{G}$ are represented as adjacency matrices. For speed and efficiency purposes, we choose to limit the structures to size $K \leq 5$, which gives a list of 29,281 uDAGs at the highest level. For details about representation and rules, see (Claassen and Heskes, 2012).

Algorithm 2 Bayesian Constr. Causal Discovery

In : database $\mathbf{D}$ over variables $\mathbf{V}$, backgr.info $\mathcal{I}$
Out: causal relations matrix $\mathbf{M}_C$, causal PAG $\mathcal{P}$
Stage 0 - Mapping
1: $\mathcal{G} \times$ Ł $\leftarrow Get\_uDAG\_Mapping(\mathbf{V}, K_{max} = 5)$
2: $p(\mathcal{G}) \leftarrow Get\_Prior(\mathcal{I})$
Stage 1 - Search
3: fully connected $\mathcal{P}$, empty list Ł, $K = 0$, $\theta = 0.5$
4: **while** $K \leq K_{max}$ **do**
5: **for all** $X \in \mathbf{V}, Y \in Adj(X)$ in $\mathcal{P}$ **do**
6: **for all** $\mathbf{Z} \subseteq Adj(X)_{\setminus Y}$, $|\mathbf{Z}| = K$ **do**
7: $\mathbf{W} \leftarrow Check\_Unprocessed(X, Y, \mathbf{Z})$
8: $\forall \mathcal{G} \in \mathcal{G}_{\mathbf{W}}$: compute $p(\mathcal{G}|\mathbf{D}_{\mathbf{W}})$
9: $\forall L : p(L_{\mathbf{W}}|\mathbf{D}_{\mathbf{W}}) \leftarrow \sum_{\mathcal{G} \rightarrow L_{\mathbf{W}}} p(\mathcal{G}|\mathbf{D}_{\mathbf{W}})$
10: $\forall L : p(L) \leftarrow \max(p(L), p(L_{\mathbf{W}}|\mathbf{D}_{\mathbf{W}}))$
11: $\mathcal{P} \leftarrow p(\text{“}W_i \not\times W_j\text{”}|\mathbf{D}_{\mathbf{W}}) > \theta$
12: **end for**
13: **end for**
14: $K = K + 1$
15: **end while**
Stage 2 - Inference
16: $\mathbf{L}_C$ = empty 3D-matrix size $|\mathbf{V}|^3$, $i = 1$
17: Ł $\leftarrow Sort\_Descending$ (Ł, $p(L)$)
18: **while** $p(L_i) > \theta$ **do**
19: $\mathbf{L}_C \leftarrow Run\_Causal\_Logic(\mathbf{L}_C, L_i)$
20: $i \leftarrow i + 1$
21: **end while**
22: $\mathbf{M}_C \leftarrow Get\_Causal\_Matrix(\mathbf{L}_C)$
23: $\mathcal{P} \leftarrow Map\_To\_PAG(\mathcal{P}, \mathbf{M}_C)$

We verified the resulting mapping from uDAG rules to logical statements against a *brute-force approach* that checks the intersection of all logical causal statements implied by all MAGs that can have a particular uDAG as an optimal approximation. We found that at least for uDAG structures up to five nodes our rules are still sound and complete. Interestingly enough, for uDAGs up to four nodes all implied statements are *identical* to those that would be obtained if we just treated uDAGs as faithful DAGs. Only at five+ nodes do we have to take into account that uDAGs are unfaithful.

The adjacency search (l.3-15), loops over subsets from neigbouring nodes for identifiable causal information, while keeping track of adjacencies that can be eliminated (l.11). For structures over five or more nodes we need to consider nodes from FCI's *Possible-D-Sep* set (Spirtes et al., 1999). In practice, it rarely finds any additional (reliable) independencies, and we opt to skip this step for speed and simplicity (l.6), similar to the RFCI approach in (Colombo et al., 2011). As the set $\mathbf{W} = \{X, Y\} \cup \mathbf{Z}$ can be encountered in different ways, line (7) checks if the test on that set has been performed already. A list of probability estimates $p(L|\mathbf{D})$ for each logical causal statement is built up (l.10), until no more information is found.

The inference stage (l.16-21) then processes the list Ł in decreasing order of reliability, until the threshold is reached. Statements in Ł are added one-by-one to the matrix of logical causal statements $\mathbf{L}_C$ (encoding identical to Ł), with additional information inferred from the causal logic rules. Basic conflict resolution is achieved through not overriding existing information (from more reliable statements). The final step (l.22,23) retrieves all explicit causal relations in the form of a causal matrix $\mathbf{M}_C$, and maps this onto the skeleton $\mathcal{P}$ obtained from Stage 1 to return a graphical PAG representation.

5 Experimental Evaluation

We have tested various aspects of the BCCD algorithm in many different circumstances, and against various other methods. The principal aim at this stage is to verify the viability of the Bayesian approach. We compare our results and that of other methods from data against known ground-truth causal models. For that, we generate random causal graphs with certain predefined properties (adapted from Melancon et al. (2000); Chung and Lu (2002)), generate random data from this model, and marginalize out one or more hidden confounders. We looked at the impact of the number of data points, size of the models, sparseness, choices for parameter settings etc. on the performance to get a good feel for expected strengths and weaknesses in real-world situations.

It is well-known that the relative performance of different causal discovery methods can depend strongly on the performance metric and/or specific test problems used in the evaluation. Therefore, we will not claim that our method is inherently better than others based on the experimental results below, but simply note that the fact that in nearly all test cases the BCCD algorithm performed as good or better than

other methods, is a clear indication of the viability and potential of this approach.

Having limited space available, we only include results of tests against the two other state-of-the-art methods that can handle hidden confounders: FCI as the de facto benchmark, and its equivalent adapted from conservative PC. For the evaluation we use two complementary metrics: the *PAG accuracy* looks at the graphical causal model output and counts the number of edge marks that matches the PAG of true equivalence class (excluding self-references). The *causal accuracy* looks at the proportion of all causal decisions, either explicit as BCCD does or implicit from the PAG for FCI, that are correct compared to the generating causal graph.

In a nutshell: we found that in most circumstances conservative FCI outperforms vanilla FCI by about $3-4\%$ in terms of PAG accuracy and slightly more in terms of causal accuracy. In its standard form, with a uniform prior over structures of 5 nodes, the BCCD algorithm consistenly outperforms conservative FCI by a small margin of about $1-2\%$ at default decision thresholds ($\theta = 0.5$ for BCCD, $\alpha = 0.05$ for FCI). Including additional tests / nodes per test and using an extended mapping often increases this difference to about $2-4\%$ at optimal settings for both approaches (cf. Figure 3). This gain does come at a cost: BCCD has an increase in run-time of about a factor two compared to conservative FCI, which in turn is marginally more expensive than standard FCI. Evaluating many large structures can increases this cost even further, unless we switch to evaluating equivalence classes via the BDe metric in §3.2. However, the main benefit of the BCCD approach lies not in a slight improvement in accuracy, but in the added insight it provides into the generated causal model: even in this simple form, the algorithm gives a useful indication of which causal decisions are reliable and which are not, which seems very useful to have in practice.

The figures below illustrate some of these findings.

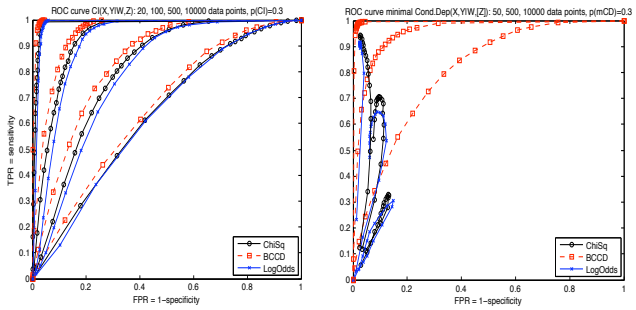

Figure 2: BCCD approach to (complex) independence test in eq.(2); (a) conditional independence $X \perp\!\!\!\perp Y \mid W, Z$, (b) *minimal* conditional dependence $X \not\perp\!\!\!\perp Y \mid W \cup [Z]$

First we implemented the BCCD approach as a (minimal) independence test. Figure 2 shows a typical example in the form of ROC-curves for different sized data sets, compared against a chi-squared test and a Bayesian log-odds test from (Margaritis and Bromberg, 2009), with the prior on independence as the tuning parameter for BCCD. For 'regular' conditional independence there was no significant difference (BCCD slightly ahead), but other methods reject minimal independencies for both high and low decision thresholds, resulting in the looped curves in (b); BCCD has no such problem.

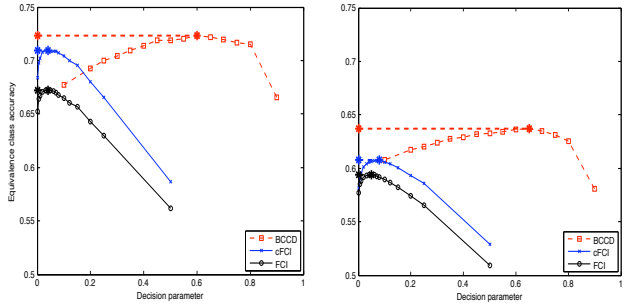

Figure 3: Equivalence class accuracy (% of edge marks in PAG) vs. decision parameter; for BCCD and (conservative) FCI, from 1000 random models; (a) 6 observed nodes, 1-2 hidden, 1000 points, (b) idem, 12 observed nodes

Figure 3 shows typical results for the BCCD algorithm itself: for a data set of 1000 records the *PAG accuracy* for both FCI and conservative FCI peaks around a threshold $\alpha \approx 0.05$ - lower for more records, higher for less - with conservative FCI consistently outperforming standard FCI. The BCCD algorithm peaks at a cut-off value $\theta \in [0.4, 0.8]$ with an accuracy that is slightly higher than the maximum for conservative FCI. The PAG accuracy tends not to vary much over this interval, making the default choice $\theta = 0.5$ fairly safe, even though the number of invariant edge marks does increase significantly (more decisions).

Table 5 shows the *confusion matrices* for edge marks in the PAG model at standard threshold settings for each of the three methods. We can recognize how FCI makes more explicit decisions than the other two (less circle marks), but also includes more mistakes. Conservative FCI starts from the same skeleton: it is more reluctant to orient uncertain v-structures, but manages to increase the overall accuracy as a result (sum of diagonal entries). The BCCD algorithm provides the expected compromise: more decisions than CFCI, but less mistakes than FCI, resulting in a modest improvement on the output PAG.

Figure 4 depicts the *causal accuracy* as a function of the tuning parameter for the three methods. The BCCD dependency is set against $(1-\theta)$ so that going

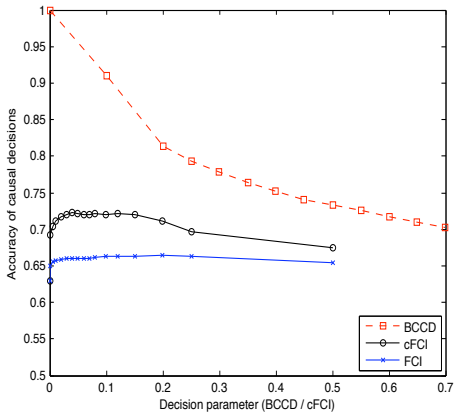

Figure 4: Accuracy of causal decisions as a function of the decision parameter

from $0 \rightarrow 1$ matches processing the list of statements in decreasing order of reliability. As hoped/expected: changing the decision parameter θ allows to access a range of accuracies, from a few very reliable causal relations to more but less certain indications. In contrast, the accuracy of the two FCI algorithms cannot be tuned effectively through the decision parameter α. The reason behind this is apparent from Figure 2(b): changing the decision threshold in an independence test shifts the balance between dependence and independence decisions, but it cannot identify or alter the balance in favor of more reliable decisions. We consider the fact that the BCCD *can* do exactly that as the most promising aspect of the Bayesian approach.

6 Extensions and Future Work

The experimental results confirm that the Bayesian approach is both viable and promising: even in a basic implementation the BCCD algorithm already outperforms other state-of-the-art causal discovery algorithms. It yields slightly better accuracy, both for optimal and standard settings of the decision parameters. Furthermore, BCCD comes with a decision threshold that is easy to interpret and can be used to vary from making just a few but very reliable causal statements to many possibly less certain decisions. Perhaps counterintuitively, changing the confidence level in (conservative) FCI does not lead to similar behavior as it only affects the balance between dependence and independence decisions, which in itself does not increase the reliability of either.

An interesting question is how far off from the theoretical optimum we are: at the moment it is not clear whether we are fighting for the last few percent or if sizeable gains can still be made. There are many opportunities left for improvement, both in speed and accuracy. An easy option is to try to squeeze out as much as possible from the current framework: scoring equivalence classes with the BDe metric should bring a significant performance gain for large structures, without any obvious drawback, as the likelihood contributions of all members are aggregated anyway.

A hopeful but ambitious path is to tackle some of the fundamental problems: as stated, we would like to score MAGs directly instead of having to go via uDAGs. This would improve both the mapping and the probability estimates of the inferred logical causal statements. We can try to include higher order independencies (larger substructures) through sampling: reasonable probability estimate can be obained from a limited number of high scoring alternatives, see, e.g. (Bouckaert, 1995). Finally, we would like to obtain principled probability estimates for new statements derived during the inference process: this would improve conflict resolution, and would ultimately allow to give a meaningful estimate for the probability of all causal relations inferred from a given data set.

Abstract

Decentralized partially observable Markov decision processes (Dec-POMDPs) are rich models for cooperative decision-making under uncertainty, but are often intractable to solve optimally (NEXP-complete). The transition and observation independent Dec-MDP is a general subclass that has been shown to have complexity in NP, but optimal algorithms for this subclass are still inefficient in practice. In this paper, we first provide an updated proof that an optimal policy does not depend on the histories of the agents, but only the local observations. We then present a new algorithm based on heuristic search that is able to expand search nodes by using constraint optimization. We show experimental results comparing our approach with the state-of-the-art Dec-MDP and Dec-POMDP solvers. These results show a reduction in computation time and an increase in scalability by multiple orders of magnitude in a number of benchmarks.

1 Introduction

There has been substantial progress on algorithms for multiagent sequential decision making represented as decentralized partially observable Markov decision processes (Dec-POMDPs) [18, 20, 7, 2]. Algorithms that are able to exploit domain structure when it is present have been particularly successful [24, 1, 25]. Unfortunately, because the general Dec-POMDP problem is NEXP-complete [8], even these methods cannot solve moderately sized problems optimally.

The decentralized Markov decision process (Dec-MDP) with independent transitions and observations represents a general subclass of Dec-POMDPs that has complexity in NP rather than NEXP [5]. A few algorithms for solving this Dec-MDP subclass have been recently proposed [5, 21, 22]. While these approaches can often solve much larger problems than Dec-POMDP methods, they cannot solve truly large problems or those with more than 2 agents.

In this paper, we present a novel algorithm for optimally solving Dec-MDPs with independent transitions and observations that combines heuristic search and constraint optimization. We show that one can cast any Dec-MDP with independent transitions and observations as a continuous deterministic MDP where states are probability distributions over states in the original Dec-MDP, which we call state occupancy distributions. This allows us to adapt continuous MDP techniques [6, 4] to solve decentralized MDPs. Following this insight, we designed an algorithm where the state occupancy exploration is performed similarly to learning real-time A* [13] and the policy selection is in accordance with decentralized POMDP techniques [10, 15]. The result is an approach that is able to leverage problem structure through heuristics, limiting the space of policies that are explored by bounding their value and efficiently generating policies with the use of constraint optimization. This algorithm (termed Markov policy search or MPS), is shown to be a much more efficient algorithm than any other approach that can be used in Dec-MDPs with independent transitions and observations.

The remainder of this paper is organized as follows. First, we provide some motivating examples utilizing properties of Dec-MDPs with independent transitions and observations. Next, we describe the Dec-MDP framework and discuss the related work. We then present theoretical results, showing that the optimal policy for Dec-MDPs with independent transitions and observations does not depend on the agent histories. While this has been proven before, we offer a more general proof that permits additional insights. Next, we describe the decentralized Markov policy search algorithm, which combines constraint optimization and heuristic search to more efficiently produce optimal solutions for Dec-MDPs with independent transitions and observations. Finally, we present an empirical evaluation of this algorithm with respect to the state-of-the-art solvers that apply in decentralized MDPs, showing the ability to

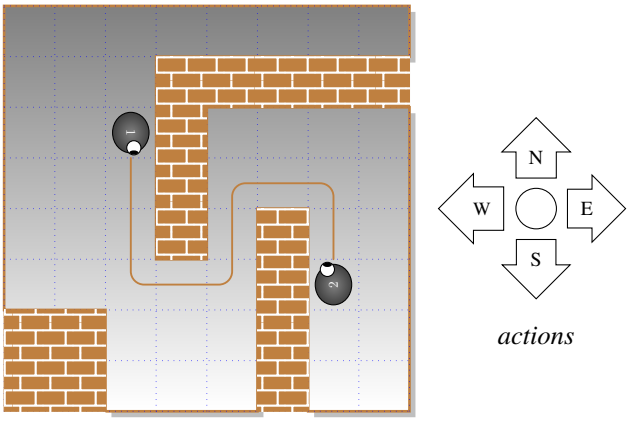

Figure 1: A meeting-grid under uncertainty scenario on a 8×8 grid, inspired from Seuken and Zilberstein [24].

solve problems that are multiple orders of magnitude larger and those that include up to 10 agents.

2 Motivating examples

To illustrate the characteristics of decentralized partially observable Markov decision processes (Dec-POMDPs) that we are interested in, consider a simple two-agent "meeting-in-a-grid under uncertainty" domain in Figure 1. In this scenario, two agents want to meet as soon as possible on a two-dimensional grid. In this world, each agent's possible actions include moving north, south, west, east and staying in the same place. The actions of a given agent do not affect the other agents. After taking an action, each agent can sense some information, which in this case corresponds to its own location. Here, each agent's own partial information is insufficient to determine the global state of the world. This is mainly because agents are not permitted to explicitly communicate their local locations with each other. However, if this (instantaneous and noise-free) communication were allowed the agents' partial information together would reveal the true state of the world, (i.e., the agents' joint location). It is the presence of this *joint full observability* property that differentiates Dec-MDPs from Dec-POMDPs.

More generally, in partially observable models including Dec-POMDPs, the agents' partial information together can map to multiple different states of the world. As a consequence, decisions in such models depend on the entire past histories of actions and observations that the agents ever experienced. In the meeting-in-a-grid under uncertainty problem, since both transitions and observations are not affected by the other agents, each agent's decision depends only on its last piece of partial information, (i.e., the agent's own location) [5]. These characteristics appear in many real-world applications including:

Mars exploration rovers. The meeting-in-a-grid domain was motivated by a real problem of controlling the operation of multiple space exploration rovers, such as the ones used by NASA to explore the surface of Mars [27].

Distributed sensor net surveillance. The sensor net domain [17], where a team of stationary or moveable UAVs, satellites, or other sensors must coordinate to track targets while sensors have independent transitions and observations, is particularly suited to our model.

Distributed smart-grid domains. This application aims at finding the optimal schedules and amounts of generated power for a collection of generating units, given demands, and operational constraints over a time horizon.

3 Background and Related Work

In this section, we review the decentralized MDP model, the assumptions of transition and observation independence, the associated notation, and related work.

Definition 1 (The decentralized MDP) *A n-agent decentralized MDP (S, A, p, r) consists of:*

- *A finite set $S = Z^1 \times Z^2 \times \cdots Z^n$ of states $s = \langle z^1, z^2, \cdots, z^n \rangle$, where Z^i denotes the set of local observations z^i of agent $i = 1, 2, \ldots, n$.*
- *A finite set $A = A^1 \times A^2 \times \cdots A^n$ of joint actions $a = \langle a^1, a^2, \cdots, a^n \rangle$, where A^i is the set of local actions a^i of agent $i = 1, 2, \ldots, n$.*
- *A transition function $p(s, a, s')$, which denotes the probability of transiting from state $s = \langle z^1, z^2, \ldots, z^n \rangle$ to state $s' = \langle z'^1, z'^2, \ldots, z'^n \rangle$ when taking joint action $a = \langle a^1, a^2, \ldots, a^n \rangle$*
- *A reward function $r\colon S \times A \mapsto \mathbb{R}$, where $r(s, a)$ denotes the reward received when executing joint action a in state s*

As noted above, decentralized MDPs are distinguished by the state being *jointly fully observable*. This property ensures that the global state would be known if all agents shared their observations at a given step (i.e., there is no external uncertainty in the problem) and follows trivially from the definition of states as observations for each agent. The Dec-MDP is parameterized by the initial state distribution η_0. When the agents operate over a bounded number of steps (typically referred to as the problem horizon) T, the model is referred to as a finite-horizon decentralized MDP. Solving a decentralized MDP for a given planning horizon T and start state distribution η_0 can be seen as finding n individual *policies* that maximize the expected cumulative reward over the steps of the problem.

3.1 Additional Assumptions

We are interested in decentralized MDPs that exhibit two properties. The first is the transition independence assumption where the local observation of each agent depends only on its previous local observation and the local action taken by that agent.

Definition 2 (The transition independent assumption) *An n-agent decentralized MDP is said to be transition independent if there exists local transition functions $p^1 \colon Z^1 \times A^1 \times Z^1 \mapsto [0,1]$, $p^2 \colon Z^2 \times A^2 \times Z^2 \mapsto [0,1]$, $\ldots$, $p^n \colon Z^n \times A^n \times Z^n \mapsto [0,1]$ such that*

$$p(s,a,s') \quad = \quad \prod_{i=1,\ldots,n} p^i(z^i, a^i, z'^i),$$

where $s = \langle z^1, z^2, \ldots, z^n \rangle$ and $s' = \langle z'^1, z'^2, \ldots, z'^n \rangle$ and $a = \langle a^1, a^2, \ldots, a^n \rangle$.

We also implicitly assume observation independence, which states that the observation function of each agent does not depend on the dynamics of the other agents. That is, $P(z'^1, z'^2, \ldots, z'^n | s, a^1, a^2, \ldots, a^n) = \times_i \; P(z'^i | s, a^i)$. Because we are assuming a Dec-MDP with the state factored into local observations then this becomes the same as transition independence: $\prod_i \; P(z'^i | z^i, a^i)$.

3.2 Preliminary Definitions and Notations

The goal of solving a Dec-MDP is to find a decentralized deterministic joint policy $\pi = \langle \pi^1, \ldots, \pi^n \rangle$. An individual policy π^i is a sequence of decision rules $\pi^i = \langle \sigma^i_0, \ldots, \sigma^i_{T-1} \rangle$. In addition, we call decentralized decision rule σ_τ at time τ an n-tuple of decision rules $(\sigma^1_\tau, \ldots, \sigma^n_\tau)$, for $\tau = 0, 1, \ldots, T-1$. In this paper, we distinguish between history-dependent and Markov decision rules.

Each *history-dependent decision rule* σ^i_τ at time τ maps from τ-step local action-observation histories $h^i_\tau = \langle a^i_0, z^i_1, \ldots, a^i_{\tau-1}, z^i_\tau \rangle$ to local actions: $\sigma^i_\tau(h^i_\tau) = a^i_\tau$, for $\tau = 0, 1, \ldots, T-1$. A sequence of history-dependent decision rules defines a history-dependent policy.

In contrast, each *Markov decision rule* σ^i_τ at time τ maps from local observations z^i_τ to local actions: $\sigma^i_\tau(z^i_\tau) = a^i_\tau$, for $\tau = 0, 1, \ldots, T-1$. A sequence of Markov decision rules defines a Markov policy. Moreover, it is worth noticing that decentralized Markov policies are exponentially smaller than decentralized history-dependent ones.

The *state occupancy* is another important notion in this paper. The τ-th state occupancy of a system under the control of a decentralized Markov policy $\langle \sigma_0, \sigma_1, \cdots, \sigma_{\tau-1} \rangle$, denoted $\sigma_{0:\tau-1}$, and starting at η_0 is given by: $\eta_\tau(s) = P(s | \sigma_{0:\tau-1}, \eta_0)$, for all $\tau \geq 1$. Moreover, the current state occupancy η_τ depends on the past decentralized Markov policy $\sigma_{0:\tau-1}$ only through previous state occupancy $\eta_{\tau-1}$ and decentralized Markov decision rule $\sigma_{\tau-1}$. That is, $\eta_\tau(s') = \sum_s p(s, \sigma_{\tau-1}(s), s') \cdot \eta_{\tau-1}(s)$, for all $\tau \geq 1$. Following [11], this update-rule is denoted $\eta_\tau = \chi_\tau(\eta_{\tau-1}, \sigma_{\tau-1})$ for the sake of simplicity. We also denote $\triangle_\tau$ the state occupancy space at the τ-th horizon, that is the standard $|S|$-dimensional simplex.

Distinction with belief states. The state occupancy may be thought of as a belief state, but there are differences. Formally, a belief state b_τ is given by $b_\tau(s) = P(s | h_\tau, \sigma_{0:\tau-1}, \eta_0)$, for all $\tau \geq 1$ [3]. That is, in belief states, the information agents have about states is typically conditioned on a single joint action-observation history h_τ. From the total probability property, we then have that $\eta_\tau(s) = \sum_{h_\tau} P(s | h_\tau, \sigma_{0:\tau-1}, \eta_0) \cdot P(h_\tau | \sigma_{0:\tau-1}, \eta_0)$. Overall, the τ-th state occupancy summarizes all the information about the world states contained in all belief states at horizon τ. In other words, the doubly exponentially joint action-observation histories are summarized in a single state occupancy that does not make use of local information.

3.3 Related Work

In this section, we focus on approaches for solving Dec-MDPs with independent transitions and observations as well as other relevant solution methods. For a thorough introduction to solution methods in Dec-POMDPs, the reader can refer to [24, 20, 7, 2].

Becker et al. [5] were the first to describe the transition and observation independent Dec-MDP subclass and solve it optimally. Their approach, called the coverage set algorithm, consists of three main steps. First, sets of augmented MDPs are created which incorporate the joint reward into local reward functions for each agent. Then, all best responses for any of the other agent policies are found using these augmented MDPs. Finally, the joint policy that has the highest value from all agents' best responses is returned. While this algorithm is optimal, it keeps track of the complete set of policy candidates for each agent, requiring a large amount of time and memory.

Petrik and Zilberstein [22] reformulated the coverage set algorithm as a bilinear program, thereby allowing optimization approaches to be utilized. The bilinear program can be used as an anytime algorithm, providing online bounds on the solution quality at each iteration. The representation is also better able to take advantage of sparse joint reward distributions by representing independent rewards as linear terms and compressing the joint reward matrix. This results in greatly increased efficiency in many cases, but when the agents' rewards often depend on the other agents the bilinear program can still be inefficient due to lack of reward sparsity.

In general Dec-POMDPs, approximate approaches have at-

tempted to scale to larger problems and horizons by not generating the full set of policies that may be optimal. These approaches, known as memory-bounded algorithms, were introduced by Seuken and Zilberstein [24] and then successively refined [10, 15]. Memory-bounded algorithms sample forward a bounded number of belief states, and back up (i.e., generate next step policies for) one decentralized history-dependent policy for each belief state. To avoid the explicit enumeration of all possible policies, Kumar and Zilberstein [15] perform the backup by solving a corresponding constraint optimization problem (COP) [9], that represents the decentralized backup. Although, memory-bounded techniques are suboptimal, the decentralized backup can be applied in exact settings as we demonstrate in our algorithm.

More specifically, the decentralized backup can build a horizon-τ decentralized policy that is maximal with respect to a belief state and horizon-$(\tau + 1)$ policies available for each agent. The associated COP is given by: a set of variables, one for each local observation of each agent; a set of domains, where the domain for the variables corresponding to an agent is the set of horizon-$(\tau + 1)$ policies available for that agent; a set of soft constraints, one for each joint observation. The soft constraint maps assignments to real values. Intuitively, these values represent the expected reward accrued when agents together perceive a given joint observation and follow a given horizon-$(\tau + 1)$ decentralized policy. Since horizon-τ decentralized policies consist of horizon-$(\tau+1)$ policies, it is easy to see that maximizing the sum of the soft constraints yields a maximal horizon-τ decentralized policy.

Closer to our model is the ND-POMDP framework [19]. It aims at modeling multiagent teamwork where agents have strong locality of interaction, often through binary interactions. That is, the reward model in such domains is decomposed among sets of agents. There has been a substantial body of work that extend general Dec-POMDP techniques (discussed above) to exploit the locality of interaction [19, 14, 16]. Nair *et* al. [19] introduced the only optimal algorithm for this model, namely the General Optimal Algorithm (GOA). When the domain does not contain binary interactions, there is no reason to expect GOA to outperform general Dec-POMDP algorithms, as all methods use similar strategies in selecting policy candidates. However, when the domain contains primarily binary interactions (or more generally when each agent's rewards are not dependent on many other agents), GOA is likely to outperform general Dec-POMDP algorithms.

It is worth noting that ND-POMDPs and transition and observation independent Dec-MDPs make the same assumptions about transition and observation independence, but make different assumptions about the reward model and partial observability. More specifically, ND-POMDPs assume the reward can be decomposed into the sum of local reward models for sets of agents, while the reward model for transition and observation independent Dec-MDPs is more general, allowing global rewards for all agents (i.e., considering all agents to be in one set). Dec-MDPs assume that the state is jointly fully observable (i.e., that the state is fully determined by the combination of local observations of all agents), while ND-POMDPs do not make this limiting assumption. Both models therefore make different assumptions to address complexity and the choice of model depends on which assumptions best match the domain being solved.

4 Theoretical Properties

In this section, we demonstrate the main theoretical results of this paper.

4.1 Optimal Policies

A decentralized MDP solver aims to calculate an optimal decentralized policy π^* that maximizes the expected cumulative reward:

$$\pi^* \quad = \quad \arg\max_\pi E[\sum_{\tau=0}^{T-1} r(s_\tau, a_\tau)|\pi, \eta_0]. \qquad (1)$$

The following theorem proves that decentralized Markov policies yield the optimal performance in decentralized MDPs with independent transitions and observations. Goldman *et* al. [12] established the optimality of Markov policy for an agent under the assumption that the other agents choose Markov policies. Here, we state the optimality of Markov policies for an agent no matter what its teammates' policies are. We also construct the proof in a manner that more directly relates policies to values (rather than information sets). This may be more clear to some readers.

Theorem 1 (Optimality of decentralized Markov policies) *In Dec-MDPs with independent transitions and observations, optimal policies for each agent depend only on the local state and not on agent histories.*

Proof Without loss of generality, we construct a proof by induction for two agents, 1 and 2, from agent 1's perspective. We first show that in the last step of the problem, agent 1's policy does not depend on its local history.

Agent 1's local policy on the last step is: $\sigma^{1^*}_{T-1}(h^1_{T-1}) = \arg\max_{a^1} \sum_{h^2_{T-1}} P(h^2_{T-1}|h^1_{T-1}) \cdot R(s, a^1, \sigma^2_{T-1}(h^2_{T-1}))$, which chooses a local action to maximize value based on the possible local histories of agent 2 and resulting states of the system $s = \langle z^1_{T-1}, z^2_{T-1}\rangle$.

Based on transition and observation independence and the use of decentralized policies, it can be shown that $P(h^2_{T-1}|h^1_{T-1}) = P(h^2_{T-1})$. Due to space limitations, we

do not include full proof of this claim. Intuitively it holds because each agent does not receive any information about the other agents' local histories due to transition independence. Therefore, we can represent agent 1's policy on the last step as $\sigma^{1^*}_{T-1}(h^1_{T-1}) = \arg\max_{a^1} \sum_{h^2_{T-1}} P(h^2_{T-1}) \cdot R(s, a^1, \sigma^2_{T-1}(h^2_{T-1}))$ which no longer depends on the history h^1_{T-1}. Therefore, the policy on the last step for either agent does not depend on history.

This allows us to define the value function on the last step as $\upsilon_{T-1}(s, \sigma^1_{T-1}(z^1_{T-1}), \sigma^2_{T-1}(z^2_{T-1}))$.

Then for the induction step, we can show that if the policy at step $\tau + 1$ does not depend on history, then the policy at step τ also does not depend on its local history. Again, we show this from agent 1's perspective.

Agent 1's policy on step τ can be represented by: $\sigma^{1^*}_{\tau}(h^1_{\tau}) = \arg\max_{a^1} \sum_{h^2_{\tau}} P(h^2_{\tau}|h^1_{\tau}) \cdot \upsilon_{\tau+1}(s, a^1, \sigma^2_{\tau}(h^2_{\tau}))$, where the value function $\upsilon_{\tau+1}$ is assumed to not depend on history. We can again show that $P(h^2_{\tau}|h^1_{\tau}) = P(h^2_{\tau})$ because of transition independence and represent agent 1's policy on step τ as:

$$\sigma^{1^*}_{\tau}(h^1_{\tau}) = \arg\max_{a^1} \sum_{h^2_{\tau}} P(h^2_{\tau}) \cdot \upsilon_{\tau+1}(s, a^1, \sigma^2_{\tau}(h^2_{\tau}))$$

which no longer depends on the local history h^1_{τ}.

Therefore, the policy of either agent does not depend on local history for any step of the problem. ∎

We now establish the sufficient statistic for the selection of decentralized Markov decision rules.

Theorem 2 (Sufficient Statistic) *The state occupancy is a sufficient statistic for decentralized Markov decision rules.*

Proof We build upon the proof of the optimality of decentralized Markov policies in Theorem 1. We note that an optimal decentralized Markov policy starting in η_0 is given by:

$$\pi^* = \arg\max_{\pi} \sum_{\tau} \sum_{h_{\tau}} P(h_{\tau}|\sigma_{0:\tau-1}, \eta_0) \cdot r(s_{\tau}, \sigma_{\tau}[s_{\tau}])$$

The substitution of h_{τ} by $(h_{\tau-1}, a_{\tau-1}, s_{\tau})$ plus the sum over all pairs $(h_{\tau-1}, a_{\tau-1})$ yields

$$\pi^* = \arg\max_{\pi} \sum_{\tau} \sum_{s_{\tau}} P(s_{\tau}|\sigma_{0:\tau-1}, \eta_0) \cdot r(s_{\tau}, \sigma_{\tau}[s_{\tau}]),$$

We denote $\eta^{\pi}_{\tau} = P(s_{\tau}|\sigma_{0:\tau-1}, \eta_0)$ the state occupancy distribution that decentralized Markov policy π produced at horizon τ. And hence,

$$\pi^* = \arg\max_{\pi} \sum_{\tau} \sum_{s_{\tau} \in S} \eta^{\pi}_{\tau}(s_{\tau}) \cdot r(s_{\tau}, \sigma_{\tau}[s_{\tau}])$$

So, state occupancy η^{π}_{τ} summarizes all possible joint action-observation histories h_{τ} decentralized Markov policy π produced at horizon τ for the estimate of joint decision rule σ_{τ}. Thus, the state occupancy is a sufficient statistic for decentralized Markov decision rules since their estimates depend only upon a state occupancy, and no longer on all possible joint observation-histories. ∎

States, belief states, and multi-agent belief states are all sufficient to select directly actions for MDPs, POMDPs, and decentralized POMDPs, respectively. This is mainly because all these statistics summarize the information about the world states from a single agent perspective. The state occupancy, instead, summarizes the information about the world states from the perspective of a team of agents that are constrained to execute their policies independently from each other. In such a setting, joint actions cannot be selected independently, instead, they are selected jointly through decentralized Markov decision rules.

4.2 Optimality Criterion

This section presents the optimality criterion based on the policy value functions.

We first define *the τ-th expected immediate reward function* $r_{\tau}(\cdot, \sigma_{\tau}) \colon \triangle_{\tau} \mapsto \mathbb{R}$ that is given by $r_{\tau}(\eta_{\tau}, \sigma_{\tau}) = E_{s \sim \eta_{\tau}}[r(s, \sigma_{\tau}[s])]$. This quantity denotes the immediate reward of taking decision rule σ_{τ} when the system is in state occupancy η_{τ} at the τ-th time step.

Let $\upsilon_{\pi}(\eta_0)$ represent *the expected total reward* over the decision making horizon if policy π is used and the system is in state occupancy η_0 at the first time step $\tau = 0$. For π in the space of decentralized Markov policies, the expected total reward is given by:

$$\upsilon_{\pi}(\eta_0) \equiv E_{(\eta_1, \cdots, \eta_{T-1})} \left[\sum_{\tau=0}^{T-1} r_{\tau}(\eta_{\tau}, \sigma_{\tau}) \mid \eta_0, \pi \right]$$

We say that a decentralized Markov policy π^* is *optimal* under the total reward criterion whenever $\upsilon_{\pi^*}(\eta_0) \geq \upsilon_{\pi}(\eta_0)$ for all decentralized Markov policies π.

Following the Bellman principle of optimality [23], one can separate the problem of finding the optimal policy π^* into simpler subproblems. Each of these subproblems consists of finding policies $\sigma_{\tau:T-1}$ that are optimal for all $\tau = 0, \cdots, T-1$. To do so, we then define the *τ-th value function* $\upsilon_{\sigma_{\tau:T-1}} \colon \triangle_{\tau} \mapsto \mathbb{R}$ under the control of decentralized Markov policy $\sigma_{\tau:T-1}$ as follows:

$$\upsilon_{\sigma_{\tau:T-1}}(\eta_{\tau}) = r_{\tau}(\eta_{\tau}, \sigma_{\tau}) + \upsilon_{\sigma_{\tau+1:T-1}}(\chi_{\tau+1}(\eta_{\tau}, \sigma_{\tau}))$$

where quantity $\upsilon_{\sigma_{\tau:T-1}}(\eta_{\tau})$ denotes the expected sum of rewards attained by starting in state occupancy η_{τ}, taking one joint action according to σ_{τ}, taking the next joint action according to $\sigma_{\tau+1}$, and so on. We slightly abuse notation and write the τ-th value function under the control of an "unknown" decentralized Markov policy $\sigma_{\tau:T-1}$ using $\upsilon_{\tau} \colon \triangle_{\tau} \mapsto \mathbb{R}$.

We further denote $\mathscr{V}_{\tau}$ to be the space of bounded value functions at the τ-th horizon. For each $\upsilon_{\tau+1} \in \mathscr{V}_{\tau+1}$, and decentralized Markov decision rule σ_{τ}, we define the *linear transformation* $\mathscr{L}_{\sigma_{\tau}} \colon \mathscr{V}_{\tau+1} \mapsto \mathscr{V}_{\tau}$ by

$$[\mathscr{L}_{\sigma_{\tau}} \upsilon_{\tau+1}](\eta_{\tau}) = r_{\tau}(\eta_{\tau}, \sigma_{\tau}) + \upsilon_{\tau+1}(\chi_{\tau+1}(\eta_{\tau}, \sigma_{\tau})).$$

As such, the τ-th value function υ_τ can be built from a $(\tau+1)$-th value function $\upsilon_{\tau+1}$ as follows:

$$\begin{array}{rcl} \upsilon_\tau(\eta_\tau) & = & \max_{\sigma_\tau}\ [\mathscr{L}_{\sigma_\tau}\upsilon_{\tau+1}](\eta_\tau), \\ \upsilon_T(\eta_T) & = & 0. \end{array} \tag{2}$$

In our setting, Equations (2) denote the optimality equations. It is worth noting that the decentralized Markov policy solution $\pi = \langle \sigma_0, \cdots, \sigma_{T-1}\rangle$ of the optimality equations is greedy with respect to value functions $\upsilon_0, \ldots, \upsilon_{T-1}$.

5 Markov Policy Search

In this section, we compute optimal decentralized Markov policy $\langle \sigma_0^*, \cdots, \sigma_{T-1}^*\rangle$ given initial state occupancy η_0 and planning horizon T. Note that while state occupancies are used to calculate heuristics in this algorithm, the final choices at each step do not depend on the state occupancies. That is, the result is a nonstationary policy for each agent mapping local observations to actions at each step.

We cast decentralized MDPs (S, A, p, r) as continuous and deterministic MDPs where: states are state occupancy distributions η_τ; actions are decentralized Markov policies σ_τ; the update-rules $\chi_\tau(\cdot, \sigma_{\tau-1})$ define transitions; and mappings $r_\tau(\cdot, \sigma_\tau)$ denote the reward function. So, techniques that apply in continuous and deterministic MDPs also apply in decentralized MDPs with independent transitions and observations. For the sake of efficiency, we focus only on optimal techniques that exploit the initial information η_0.

The *learning real-time A** (LRTA*) algorithm can be used to solve deterministic MDPs [13]. This approach updates only states that agents actually visit during the planning stage. Therefore, it is suitable for continuous state spaces. Algorithm 1, namely *Markov Policy Search* (MPS), illustrates an adaptation of the LRTA* algorithm for solving decentralized MDPs with independent transitions and observations. The MPS algorithm relies on lower and upper bounds $\underline{\upsilon}_\tau$ and $\bar{\upsilon}_\tau$ on the exact value functions for all planning horizons $\tau = 0, \ldots, T-1$.

We use the following definitions. Q-value functions $\bar{q}_\tau(\eta_\tau, \sigma_\tau)$ denote rewards accrued after taking decision rule σ_τ at state occupancy η_τ and then following the policy defined by upper-bound value functions for the remaining planning horizons. We denote $\Psi_\tau(\eta_\tau) = \{\sigma_\tau\}$ to be the set of all stored decentralized Markov decision rules for state occupancy η_τ. Thus, $\bar{\upsilon}_\tau(\eta_\tau) = \max_{\sigma_\tau \in \Psi_\tau(\eta_\tau)} \bar{q}_\tau(\eta_\tau, \sigma_\tau)$ represents the upper-bound value at state occupancy η_τ. Formally, we have that $\bar{q}_\tau(\eta_\tau, \sigma_\tau) = [\mathscr{L}_{\sigma_\tau}\bar{\upsilon}_{\tau+1}](\eta_\tau)$.

Next, we describe two variants of the MPS algorithm. The exhaustive variant replaces states by state occupancy distributions, and actions by decentralized Markov decision rules in the LRTA* algorithm. The second variant uses a constraint optimization program instead of the memory demanding exhaustive backup operation that both the LRTA* algorithm and the exhaustive variant use.

5.1 The exhaustive variant

The exhaustive variant consists of three major steps: the initialization step (line 1); the backup operation step (line 5); and the update step (lines 6 and 8). It repeats the execution of these steps until convergence ($\bar{\upsilon}_0(\eta_0) - \underline{\upsilon}_0(\eta_0) \leq \varepsilon$). At this point, an ϵ-optimal decentralized Markov policy has been found.

Algorithm 1: The MPS algorithm.

```
begin
1     Initialize bounds υ̲ and ῡ.
2     while ῡ_0(η_0) − υ̲_0(η_0) > ε do
3         MPS-TRIAL(η_0)

MPS-TRIAL(η_τ) begin
4     while ῡ_τ(η_τ) − υ̲_τ(η_τ) > ε do
5         σ_greedy,τ ← arg max_{σ_τ} q̄_τ(η_τ, σ_τ)
6         Update the upper bound value function.
7         MPS-TRIAL(χ_{τ+1}[η_τ, σ_greedy,τ])
8         Update the lower bound value function.
```

Initialization. We initialize lower bound $\underline{\upsilon}_\tau$ with the τ-th value function of any decentralized Markov policy, such as a randomly generated policy $\pi_{\text{rand}} = \langle \sigma_{\text{rand},0}, \ldots, \sigma_{\text{rand},T-1}\rangle$, where $\underline{\upsilon}_\tau = \upsilon_{\sigma_{\text{rand},\tau}, \ldots, \sigma_{\text{rand},T-1}}$. We initialize the upper bound $\bar{\upsilon}_\tau$ with the τ-th value function of the underlying MDP. That is, $\pi_{\text{mdp}} = \langle \sigma_{\text{mdp},0}, \ldots, \sigma_{\text{mdp},T-1}\rangle$, where $\bar{\upsilon}_\tau = \upsilon_{\sigma_{\text{mdp},\tau}, \ldots, \sigma_{\text{mdp},T-1}}$.

The exhaustive backup operation. We choose decentralized Markov decision rule $\sigma_{\text{greedy},\tau}$, which yields the highest value $\bar{\upsilon}_\tau(\eta_\tau)$ through the explicit enumeration of all possible decentralized Markov decision rules σ_τ. We first store all decentralized Markov decision rules σ_τ for each visited state occupancy η_τ together with corresponding values $\bar{q}_\tau(\eta_\tau, \sigma_\tau)$. Hence, the greedy decentralized Markov decision rule $\sigma_{\text{greedy},\tau}$ is $\arg\max_{\sigma_\tau} \bar{q}_\tau(\eta_\tau, \sigma_\tau)$ at state occupancy η_τ.

Update of lower and upper bounds. We update the lower bound value function based on decentralized Markov policies $\pi_{\text{greedy}} = \langle \sigma_{\text{greedy},0}, \ldots, \sigma_{\text{greedy},T-1}\rangle$ selected at each trial. If π_{greedy} yields a value higher than that of the current lower bound, $\underline{\upsilon}_0(\eta_0) < \upsilon_{\pi_{\text{greedy}}}(\eta_0)$, we set $\underline{\upsilon}_\tau = \upsilon_{\sigma_{\text{greedy},\tau}, \ldots, \sigma_{\text{greedy},T-1}}$ for $\tau = 0, \ldots, T-1$, otherwise we leave the lower bound unchanged. We update the upper bound value function based on decentralized Markov decision rules $\sigma_{\text{greedy},\tau}$ and the $(\tau+1)$-th upper-bound value function $\bar{\upsilon}_{\tau+1}$, as follows $\bar{\upsilon}_\tau(\eta_\tau) = [\mathscr{L}_{\sigma_{\text{greedy},\tau}}\bar{\upsilon}_{\tau+1}](\eta_\tau)$.

Theoretical guarantees. The exhaustive variant of MPS yields both advantages and drawbacks. On the one hand, it inherits the theoretical guarantees from the LRTA* al-

gorithm. In particular, it terminates with a decentralized Markov policy within $\varepsilon = \bar{v}_0(\eta_0) - \underline{v}_0(\eta_0)$ of the optimal decentralized Markov policy. Indeed, the upper bound value functions $\bar{v}_\tau$ never underestimate the exact value at any state occupancy η_τ. This is because we update the upper bound value at each state occupancy based upon a greedy decision rule for this state occupancy. On the other hand, the exhaustive variant algorithm requires the exhaustive enumeration of all possible decentralized Markov decision rules at each backup step (Algorithm 1, line 5). In MDP techniques, the exhaustive enumeration is not prohibitive since the action space is often manageable. In decentralized MDP planning, however, the space of all decentralized Markov decision rules increases exponentially with increasing observations and agents. As such, the exhaustive variant can scale only to problems with a moderate number of observations (local states) and two agents.

5.2 The constraint optimization formulation

To overcome the memory limitation of the exhaustive variant, we use constraint optimization instead of the exhaustive backup operation. More precisely, our constraint optimization program returns a greedy decentralized Markov decision rule $\sigma_{\text{greedy},\tau}$ for each state occupancy η_τ visited, but without performing the exhaustive enumeration.

In our constraint optimization formulation, variables are associated with decision rules $\sigma_\tau^i(z^i)$ for all agents $i = 1, \ldots, n$ and all local observations $z^i \in Z^i$. The domain for each variable $\sigma_\tau^i(z^i)$ is action space A^i. For each state $s \in S$, we associated a single soft constraint $c_\tau(s, \cdot)\colon A \mapsto \mathbb{R}$. Each of these assigns a value $c_\tau(s,a) = r(s,a) + \sum_{s'} p(s,a,s') \cdot v_{\sigma_{\text{mdp},\tau+1},\ldots,\sigma_{\text{mdp},T-1}}(s')$ to each joint action $a \in A$. Value $c_\tau(s,a)$ denotes the reward accrued at horizon τ when taking joint action a in state s and then following the underlying MDP joint policy for the remaining planning horizons. For each decentralized Markov decision rule $\sigma_\tau \in \Psi_\tau(\eta_\tau)$, we also associate a single soft constraint $g_\tau(\cdot)$. Each of these assigns value $g_\tau(\sigma_\tau) = \bar{q}_\tau(\eta_\tau, \sigma_\tau) - \bar{q}_{\text{mdp}}(\eta_\tau, \sigma_\tau)$, where $\bar{q}_{\text{mdp}}(\eta_\tau, \sigma_\tau) = [\mathscr{L}_{\sigma_\tau} v_{\sigma_{\text{mdp},\tau+1},\ldots,\sigma_{\text{mdp},T-1}}](\eta_\tau)$. The objective of our constraint optimization model is to find an assignment $\sigma_{\text{greedy},\tau}$ of actions a^i to variables $\sigma_\tau^i(z^i)$ such that the aggregate value is maximized. Stated formally, we wish to find $\sigma_{\text{greedy},\tau} = \arg\max_{\sigma_\tau} g_\tau(\sigma_\tau) + \sum_s \eta_\tau(s) c_\tau(s, \sigma_\tau(s))$. To better understand our constraint optimization program, note that by the definition of mapping $\bar{q}_{\text{mdp}}$ we have that $\sum_s \eta_\tau(s) \cdot c_\tau(s, \sigma_\tau(s)) = \bar{q}_{\text{mdp}}(\eta_\tau, \sigma_\tau)$. Hence, if we use $\bar{q}_{\text{mdp}}(\eta_\tau, \sigma_\tau)$ instead of $\sum_s \eta_\tau(s) \cdot c_\tau(s, \sigma_\tau(s))$, we get $\sigma_{\text{greedy},\tau} = \arg\max_{\sigma_\tau} \bar{q}_\tau(\eta_\tau, \sigma_\tau)$. Thus, our constraint optimization program returns a decentralized Markov decision rule with the highest upper-bound value. Techniques that solve our constraint optimization formulation abound in the literature of constraint programming [9], allowing many different approaches to be utilized.

Theoretical guarantees. The constraint optimization variant yields the same guarantees as the exhaustive variant without the major drawback of exhaustive enumeration of all decentralized Markov decision rules. Instead, it uses a constraint optimization formulation that returns a greedy decentralized Markov decision rule, which will often be much more efficient than exhaustive enumeration. And hence, we retain the property that stopping the algorithm at any time, the solution is within $\varepsilon = \bar{v}_0(\eta_0) - \underline{v}_0(\eta_0)$ of an optimal decentralized Markov policy.

Comparison to COP based algorithms. There is a rich body of work that replaces the exhaustive backup operation by a constraint optimization formulation in decentralized control settings [15, 14, 19]. These constraint optimization programs compute a decentralized history-dependent policy for a given belief state. While MPS also takes advantage of a constraint optimization formulation, it remains fundamentally different. The difference lies in both the COP formulation and the heuristic search. In existing COP based algorithms for decentralized control, authors try to find the best assignment of sub-policies to histories. Instead, in our case the COP formulation aims at mapping local observations to local actions. This provides considerable memory and time savings. Moreover, existing algorithms proceed by backing up policies in a backward direction (i.e., from last step to first) using a set pre-selected belief states. In contrast, the MPS algorithm proceeds forward, expanding the state occupancy distributions and selecting greedily decision rules. Finally, the MPS algorithm returns an optimal solution, whereas other COP based algorithms for Dec-POMDPs return only locally optimal solutions [15, 14]. Approximate solutions are returned by the other algorithms because they plan over (centralized) belief states, which do not constitute a sufficient statistic for Dec-POMDPs (or Dec-MDPs).

6 Empirical Evaluations

We evaluated our algorithm using several benchmarks from the decentralized MDP literature. For each benchmark, we compared our algorithms with state-of-the-art algorithms for solving Dec-MDPs and Dec-POMDPs. Note that we do not compare with ND-POMDP methods. Since our benchmarks allow all agents to interact with all teammates at all times, there is no reason to expect the optimal ND-POMDP method (GOA [19]) to outperform the algorithms presented here. We report on each benchmark the optimal value $v_0(\eta_0)$ together with the running time in seconds for different planning horizons.

The MPS variants were run on a Mac OSX machine with 2.4GHz Dual-Core Intel and 2GB of RAM available. We solved the constraint optimization problems using the aolib library[1]. The bilinear programming approach (listed as

Table 1: Experimental results for the *COP* and *exh.* variants of MPS as well as GMAA*-ICE (labeled ICE), IPG, and BLP.

BLP) was run on a 2.8GHz Quad-Core Intel Mac with 2GB of RAM with a time limit of 3 hours. We used the best available version of the bilinear program approach which was the iterative best response version with standard parameters. This is a generic solution method which does not perform as well as the more specialized approaches in [22], but we do not expect results to differ by more than a single order of magnitude. We do not compare to the coverage set algorithm because the bilinear programming methods have been shown to be more efficient for all available test problems.

We provide values for the exhaustive variant, *exh*, on small problems and constraint optimization formulation, *COP*, for all problems. We tested our algorithms on six benchmarks: recycling robot, meeting-in-a-grid 3x3 and 8x8; and navigation problems[2]. These are the largest and hardest benchmarks we could find in the literature. We compare our algorithms with: GMAA*-ICE [25], IPG [1], and BLP. The GMAA*-ICE heuristic search consistently outperforms other generic exact solvers such as (G)MAA* [25]. The IPG algorithm is a competitive alternative to the GMAA* approach and performs well on problems with reduced reachability [1]. Results for GMAA*-ICE were provided by Matthijs Spaan and as such were conducted on a different machine. Similarly, results for IPG were collected on different machine. As a result, the timing results for GMAA*-ICE and IPG are not directly comparable to the other methods, but are likely to only differ by a small constant factor from those that would be obtained on our test machine.

The results can be seen in Table 1. In all benchmarks, the *COP* variant of MPS outperforms the other algorithms. The results show that the *COP* variant produces the optimal policies in much less time for all tested benchmarks. For example, in the meeting in a 3x3 grid problem for $T = 5$: the *COP* variant computed the optimal policies approximately 33, 4358 and 4580 times faster than the GMAA*-ICE, BLP and IPG algorithms, respectively. We also note that the *COP* variant is very useful for the medium and large domains. For example, in all large domains, the *exh.* variant ran out of memory while the *COP* variant computed the optimal solutions for horizons up to 100. Yet, the *exh.* variant can compute the optimal solution of small problems faster than the *COP* variant. For instance, in the recycling robot for horizon $T = 1000$, the *exh.* variant computed the optimal solution in about 5 times faster than the *COP* variant of the MPS algorithm due to overhead in the constraint optimization formulation and a lack of structure that can be utilized.

There are many different reasons for these results. The MPS algorithm outperforms GMAA*-ICE and IPG mainly because they perform a policy search in the space of decentralized history-dependent policies. Instead, the MPS algorithm performs its policy search in the space of decentralized Markov policies, which is exponentially smaller than that of the decentralized history-dependent policies. The MPS outperforms the BLP algorithm mainly because of the dimension of its solution representation. More specifically, the number of bilinear terms in the BLP approach grows polynomially in the horizon of the problem, causing it to not perform well for large problems and large horizons with tightly coupled reward values.

We continue the evaluation of the MPS algorithm on randomly generated instances with multiple agents. The random instances were built upon the recycling robot problem described in Sutton and Barto [26]. Given n such models, each of which is associated with a single agent, we choose a number of interaction events. An interaction event is a pair of joint states and actions (s, a) where the reward $r(s, a)$

http://graphmod.ics.uci.edu/group/aolibWCSP/

[2]All problem definitions are available at the following website: http://users.isr.ist.utl.pt/∼ mtjspaan/decpomdp/

is randomly chosen. This structure ties all agents together since the reward model cannot be decomposed among subgroups of agents. In an effort to provide insight on the degree of interaction among all agents, we distinguish between four classes $\{c_0, c_1, c_2, c_3\}$, each of which depends on the number of interaction events e. For each class c_k, we randomly choose e such that $e \in [\frac{k}{4}e_{\max}; \frac{k}{4}(1 + e_{\max})]$, where $e_{\max}$ denotes the number of joint state and action pairs.

As depicted in Figure 2, the constraint formulation allows us to deal with larger numbers of agents. We calculated optimal value functions for 100 instances of each class, and reported the average computational time. The *COP* variant was able to scale up to 6 agents at horizon 10 in about $5,000$ seconds. We could also produce results for up to 10 agents in about $40,000$ seconds using a more powerful machine. It can also be seen that increasing the number of interaction events on each problem does not substantially increase the amount of time required to solve these problems. This shows that even for dense reward matrices, our approach will continue to perform well. Despite this high running time, MPS is the first generic algorithm that scales to teams of more than two agents without taking advantage of the locality of interaction. For example the BLP algorithm as it currently stands can only solve two-agent problems. Moreover, ND-POMDP techniques exploit the small number of local interactions among agents to scale to multiple agents, but in this problem all agents interact.

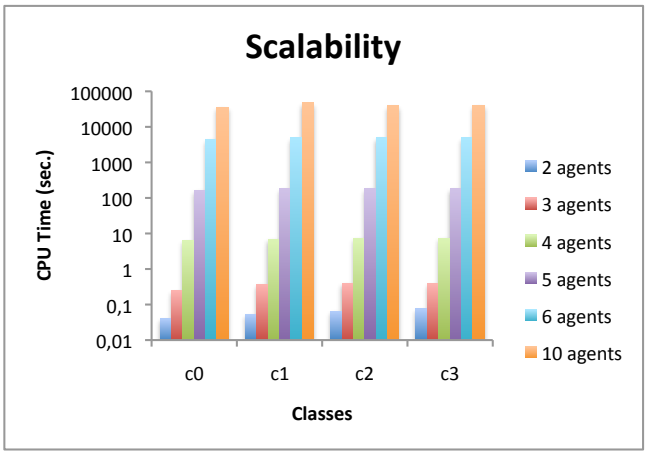

Figure 2: The MPS performance for increasing number of agents at planning horizon $N = 10$ for randomized instances of the recycling robot scenario.

7 Conclusion and Future Work

This paper explores new theory and algorithms for solving independent transition and observation Dec-MDPs. We provide a new proof that optimal policies do not depend on agent histories in this subclass, generalizing previous theoretical results. We also describe a novel algorithm that combines heuristic search and constraint optimization to more efficiently produce optimal solutions for this class of problems. This new algorithm, termed learning Markov policy or MPS, was shown to scale up to large problems and planning horizons, reducing computation time by multiple orders of magnitude over previous approaches. We were also able to demonstrate scalability with respect to the number of agents in domains with up to 10 agents. These results show that our approach could be applied to many large and realistic domains.

In the future, we plan to explore extending the MPS algorithm to other classes of problems and larger teams of agents. For instance, we may be able to produce an optimal solution to more general classes of Dec-MDPs or provide approximate results for Dec-POMDPs by extending the idea of an occupancy distribution to those problems. Furthermore, the scalability of our approach to larger numbers of agents is encouraging and we will pursue methods to increase this even further. In particular, we think our approach could help increase the number of agents that interact in conjunction with other structure in the model such as locality of interaction (as in ND-POMDPs) or sparse joint reward matrices (as in bilinear programming approaches).

Abstract

We develop Graph-Coupled Hidden Markov Models (GCHMMs) for modeling the spread of infectious disease locally within a social network. Unlike most previous research in epidemiology, which typically models the spread of infection at the level of entire populations, we successfully leverage mobile phone data collected from 84 people over an extended period of time to model the spread of infection on an individual level. Our model, the GCHMM, is an extension of widely-used Coupled Hidden Markov Models (CHMMs), which allow dependencies between state transitions across multiple Hidden Markov Models (HMMs), to situations in which those dependencies are captured through the structure of a graph, or to social networks that may change over time. The benefit of making infection predictions on an individual level is enormous, as it allows people to receive more personalized and relevant health advice.

1 INTRODUCTION

Growing amounts of information available from social network data afford us an unprecedented opportunity to answer questions about the individual agents who are represented in these social networks, typically as nodes, via the use of statistical models. The goal of this paper is to provide a framework for modeling the dynamical interactions between individual agents in a social network, and to specifically apply it to modeling the spread of infection.

We present the Graph-Coupled Hidden Markov Model (GCHMM), a discrete-time model for analyzing the interactions between agents in a dynamic social network.

New data and computational power have driven recent developments in models of epidemic dynamics, in which individuals in a population can express different epidemic states, and change state according to certain events. These dynamics models range from assuming homogeneous individuals and relations [Kermack and McKendrick, 1927] to incorporating increasingly more information on individuals and their relationships [Eubank et al., 2004, Salathé et al., 2010, Stehlé et al., 2011, Hufnagel et al., 2004]. For example, Eubank [Eubank et al., 2004] predicted outbreaks ahead of time by placing sensors in key locations, and contained epidemics through a strategy of targeted vaccination using land-use and population-mobility from census data. Salath [Salathé et al., 2010] looked at matching absentee records at a high school with the epidemic size predicted by the susceptible-exposed-infectious-recovered (SEIR) model.

In this paper, we focus on modeling the spread of infection at an individual level, instead of for an entire population. We aim to predict the state of each individual's health, and the paths of illness transmission through individuals in a social network. This information helps us to understand how disease is transmitted locally within a network, and to give individual-level behavioral advice about how to best maintain good health.

The social network data that we employ for this research is mobile phone data collected from 84 people over an extended period of time. The data track each person's proximity to others within the network, and daily symptom reports signal whether individual members of the network might be ill.

Our graph coupled hidden Markov model (GCHMM) incorporates dynamic social network structure into a coupled hidden Markov model [Brand et al., 1997]. A GCHMM allows us to predict at an individual level how the spread of illness occurs and can be avoided. Our results point to a new paradigm of infection control based on sensor networks and individual-level modeling.

Access to dynamic social networks is an essential part of modeling the spread of disease, and is useful for many other real-world social applications as well. The study of dynamic social networks has attracted considerable research in the machine-learning community [Goldenberg et al., 2010]. Since diffusion within dynamic social networks is important in many applications, we believe the GCHMM will also be useful for studying the dynamics of fads, rumors, emotions, opinions, culture, jargon, and so on [Castellano et al., 2009]. Even though we focus on epidemiology in this paper, the same model could be applied to determining, for example, to what extent an individual will change his opinion to match the value of a random neighbor in the formation of community consensus [Holley and Liggett, 1975], to what extent an individual will change one of his traits to match the value of a random neighbor using the Axelrod model of culture formation [Axelrod, 41], how a real-world vocabulary is formed at the society level through imitation and alignment at the individual level [Steels, 1995], and for any of these what further implications might be at both the individual level and the network level.

This paper therefore makes several novel contributions to the field of human behavior modeling and machine learning: 1) We introduce a new class of models, GCHMMs, which combine coupled HMMs with dynamic social networks. We inject dynamic social network structure into the CHMM allowing us to use this class of models for a potentially very wide range of multi-agent network or behavior modeling tasks (e.g. rumor, innovation, or organizational flow in social networks). 2) We specify a particular model in that class, which is a novel model for epidemics. This model allows us to make individual-level epidemics predictions not enabled by previous epidemics methods. 3) We provide methods for performing inference, generally in the case of 1) and specifically in the case of 2), and discuss how they relate to each other and previous work. These methods provide tools for researchers interested in a broad range of multi-agent and social network applications. 4) We validate our epidemics model on an interesting new dataset which tracks the spread of illness on a local, individual level.

The rest of the paper is organized as follows. In section 2 we review the coupled hidden Markov model. In section 3 we introduce the GCHMM for multi-agent modeling in dynamic social networks. In section 4 we show how the GCHMM can be applied to modeling the spread of infection in networks, and in 5 we derive the Gibbs sampler for parameter learning and latent state estimation of the GCHMM for epidemics. In section 6 we apply the GCHMM to our epidemic data from an undergraduate university residence hall, which includes daily symptom reports and hourly proximity tracking.

2 COUPLED HIDDEN MARKOV MODELS

A coupled hidden Markov model (CHMM) describes the dynamics of a discrete-time Markov process that links together a number of distinct standard hidden Markov models (HMMs). In a standard HMM, the value of the latent state at time t (X_t) is dependent on only the value of the latent state at time $t-1$ (X_{t-1}). In contrast, the latent state of HMM i at time t in the CHMM ($X_{i,t}$) is dependent on the latent states of all HMMs in the CHMM at time $t-1$ ($X_{\cdot,t-1}$).

The CHMM generative model is defined as follows:

$$X_{i,t} \sim \text{Categorical}(\phi_{i,X_{\cdot,t-1}}) \quad (1)$$

$$Y_{i,t} \sim F(\theta_{X_{i,t}}) \quad (2)$$

where $X_{i,t}$ is the hidden state of HMM i at time t, $Y_{i,t}$ is the emission of HMM i at time t, $X_{\cdot,t-1}$ is a vector of the state values of all HMMs at time $t-1$, and $\phi_{i,X_{\cdot,t-1}}$ is a vector the dimensionality of which is equal to the number of states in the HMM and the entries of which sum to 1. The entries in $\phi_{i,X_{\cdot,t-1}}$ represent the probability that the state variable in HMM i will transition from its state at time $t-1$ to each possible state at time t, given the states of all other HMMs at time $t-1$. $\theta_{X_{i,t}}$ is the emission parameter for observations that derive from state $X_{i,t}$. The graphical model for the CHMM can be seen in figure 1.

Historically, inference in CHMMs has been achieved via maximum likelihood estimation, usually using an Expectation-Maximization (EM) algorithm. Specialized CHMMs are often used in practice, however, because a CHMM with M_i states for HMM i has $\prod_i M_i$ states in total, and the state transition kernel ϕ_i is a $\prod_i M_i \times \prod_i M_i$ matrix, both of which are a considerable size. Many specializations either omit the inter-chain probability dependence, such as in the factorial hidden Markov model [Ghahramani and Jordan, 1997, Brand et al., 1997], or introduce fixed sparse inter-chain probability dependence, such as in hidden Markov decision trees [Jordan et al., 1996]. The dynamic influence model [Pan et al., 2012] allows one chain to probabilistically depend on all other chains through only a few sufficient statistics without increasing modeling complexity.

However, in the following sections we introduce the GCHMM, which differs from the models described above in considering HMMs that are coupled based

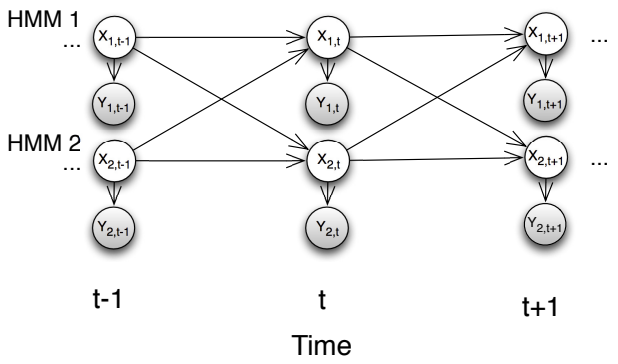

Figure 1: CHMM graphical model

on social network structure, and for which efficient inference can be performed based on the inter-chain "relations" of sufficient statistics.

The CHMM generative model can easily be formulated in a Bayesian manner, which helps to avoid overfitting problems in real-world applications [Beal, 2003]:

$$\theta_{X_i} \sim \text{Conj}(\gamma) \quad (3)$$
$$\phi_{i,X_\cdot} \sim \text{Dirichlet}(\alpha) \quad (4)$$

where Conj refers to the distribution conjugate to F, above, and γ and α are shared hyperparameters. Here, θ_{X_i} and $\phi_{i,X_\cdot}$ are drawn once for all times t. X_i is the set of all state values that HMM i can take on, while $X_\cdot$ is the set of all state values that all HMMs can take on in the CHMM.

This is the Bayesian formulation of the CHMM that we extrapolate in the next section in order to deal with situations wherein the relationship between HMMs is mediated by a dynamic social network.

3 GRAPH-COUPLED HIDDEN MARKOV MODELS

Here, we introduce the graph-coupled hidden Markov model (GCHMM) to model how infection and influence spread via the interactions of agents in a dynamic social network.

Let $G_t = (N, E_t)$ be a dynamic network, where each $n \in N$ is a node in G_t representing an individual agent, and $E_t = \{(n_i, n_j)\}$ is a set of edges in G_t representing interactions between agents n_i and n_j at time t. Graph G_t changes over time, where there is a discrete number of observations of the structure of the graph at times $t \in \{1 \dots T\}$. Changes in G_t over time represent changes in interactions between agents in the network over time.

We can use the CHMM in conjunction with dynamic network G_t if we let $X_{n,t}$ be the state of agent (node) n at time t, and $Y_{n,t}$ be noisy observations about agent n at time t. G_t restricts the connections between latent state variables in the CHMM, allowing us to model multi-agent phenomena of interest while potentially allowing for efficient inference.

The generative model of the GCHMM in its most general form is as follows:

$$X_{n,t} \sim \text{Categorical}(\phi_{n,X_{e:\{n,\cdot\}\in G_t,t-1}}) \quad (5)$$
$$Y_{n,t} \sim F(\theta_{X_{n,t}}) \quad (6)$$
$$\theta_{X_n} \sim \text{Conj}(\gamma) \quad (7)$$
$$\phi_{n,X_{e:\{n,\cdot\}\in G_t}} \sim H(X_{e:\{n,\cdot\}\in G_t}, \mu) \quad (8)$$

Unlike the CHMM, whose transition matrix ϕ_n for HMM n is dependent on all other HMMs, ϕ_n in the GCHMM is dependent on only the HMMs that have edges in the graph connected to node n. Thus, $\phi_{i,X_\cdot}$ becomes $\phi_{n,X_{e:\{n,\cdot\}\in G_t}}$. We assume that n itself is also included in this set of HMMs on which n is dependent. There is also a difference in the prior distribution of ϕ_n. In the CHMM, the prior is the same for all rows of the transition matrix, whereas in the GCHMM the prior on ϕ_n, H, depends on the values of the states of the HMMs on which n is dependent at the previous time step.

The graphical model for the GCHMM is given in figure 2. Here, we show a GCHMM with 3 HMMs. Network structure G_t is depicted in the bubbles above each time step, also showing the dependency structure corresponding to G_t in the GCHMM graphical model. The structure for G_{t-1} is not displayed, since it would be off the left side of the figure.

This is a discrete-time multi-agent model, and thus it approximates its continuous-time multi-agent counterpart: a Markov jump process, also called a compound Poisson process. This approximation works well only when the time step size in the discrete-time model is smaller than the average rate of interaction events. In our setting, as in many settings in which these multi agent models may be used, this is not an issue.

In the following, we describe an application of the GCHMM to fit susceptible-infectious-susceptible epidemic dynamics. Here, we assume specific forms for distributions F and H. Much like in the CHMM, efficient inference may not always be possible in the GCHMM, but we show that efficient inference can easily be done in our specific application. We expect that efficient inference in the GCHMM will be possible for many applications, since the incorporation of social networks in the GCHMM leads to sparsity in the con-

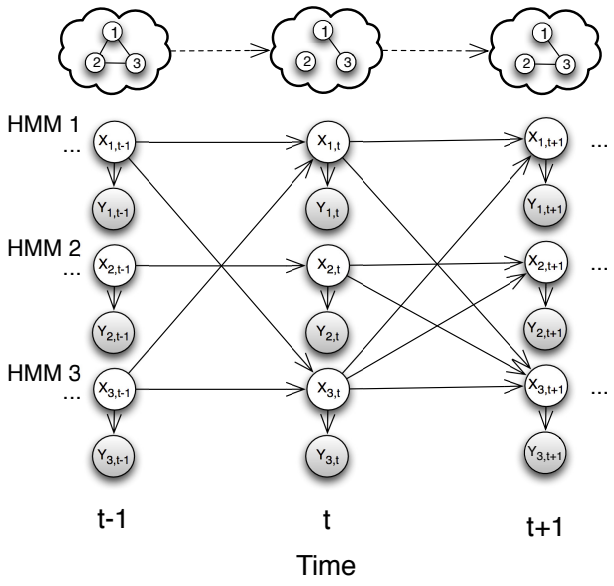

Figure 2: GCHMM graphical model

nections between latent variables, since these networks are typically sparse, and the incorporation of structure resulting from network-specific prior knowledge in H can also often be leveraged. For example, as in the epidemics model, H can become a simple function of a few parameters and sufficient statistics of connected states.

4 GCHMMS FOR MODELING INFECTION DYNAMICS

In this section, we show that the GCHMM can be used as a discrete-time multi-agent epidemic model, where the spread of infection is modeled on an individual level as opposed to the standard population-level models commonly used in epidemiology. In section 6, we show that the GCHMM can be applied to real-world data based on individual proximity and symptom reporting.

In particular, the GCHMM that we apply to epidemics can be seen as an individual-level version of the classic susceptible-infectious-susceptible (SIS) epidemiology model. The SIS model describes infection dynamics in which the infection does not confer long-lasting immunity, and so an individual becomes susceptible again once recovered (e.g., the common cold).

Using the GCHMM to model SIS dynamics identifies paths of infection based on individual-level interactions that are captured in our data.The classical differential equation and stochastic models of SIS dynamics work at the population level, and their variables are density and size of susceptible and infectious populations, respectively. The differential equation model $\dot{S} = -\beta \cdot SI + \gamma \cdot I$ and $\dot{I} = \beta \cdot SI - \gamma \cdot I$ for SIS specifies that the rate of change of infectious-population density is bilinear for both infectious-population density and susceptible-population density. In this system, any two individuals from the infectious population are treated as the same, as are any two individuals from the susceptible population, and therefore any two individuals from different populations have an equal chance of causing infection. The stochastic model $S + I \rightarrow 2I, rate = \beta' \cdot |S| \cdot |I|$ and $I \rightarrow S, rate = \gamma' \cdot |I|$ specifies that infection happens at a bilinear rate for both the infectious-population density and the susceptible-population density. This model enables us to reason about the randomness in the SIS system when the population size is small and randomness cannot be ignored.

The above models focus on the statistics of the spread of infection over a homogeneous population. However, we are instead interested in predicting the spread of infection on an individual level, given relevant information about each specific individual. Our goal is to explain symptom observations in a community with susceptible-infectious-susceptible dynamics at any given point in time. How likely is a person to be infectious at time t, given that his friends are reporting symptoms, reporting no symptoms, or not answering surveys, and given the infectious person's own survey responses and his recent proximity to his friends? Which nodes and links are critical in spreading infection in the community? How can we control infection in this community?

We use the GCHMM to address these questions, following the generative model given in section 3 and the details (state space, H, F, and so on) specified here.

$G_t = (N, E_t)$ is a dynamic network, where each node $n \in N$ represents a person in the network, and $E_t = \{(n_i, n_j)\}$ is a set of edges in G_t representing the fact that person n_i and person n_j have interacted or come into contact at time t. There are two possible latent states for each person n at each time t, $X_{n,t} \in \{0, 1\}$, where 0 represents the susceptible state and 1 the infectious state. There are six possible symptoms that can be displayed by a person at any given time, $Y_{n,t}$, which are runny nose, coughing, fever, feeling stressed, sadness, and diarrhea, and each symptom $Y_{n,t,i} \in \{0, 1\}$ represents the presence or absence of symptom i.

Our generative model is therefore as follows:

$$X_{n,t} \sim \text{Bernoulli}(\phi_{n, X_{e:\{n,\cdot\} \in G_t, t-1}}) \quad (9)$$

$$Y_{n,t,i} \sim \text{Bernoulli}_i(\theta_{X_{n,t}}) \quad (10)$$

$$\theta_{X_n} \sim \text{Beta}(h) \quad (11)$$

This is identical to the generative model from section 3 (the Bernoulli is the same as Categorical for 2 states), with F specified as a multivariate Bernoulli distribution. Here, h are given hyperparameters. The generative process for $\phi_{n,X_{e:\{n,\cdot\}\in G_t}}$ is a little more subtle, as it is defined using the interaction structure in the network, detailed below..

In keeping with the SIS model, we assume that there are certain transmission rates for the infection of one person by another, and likewise a recovery rate for an infected individual:

$$\mu = \begin{cases} \alpha \sim \text{Beta}(a, b) \\ \beta \sim \text{Beta}(a', b') \\ \gamma \sim \text{Beta}(a'', b'') \end{cases} \quad (12)$$

γ is the probability that a previously-infectious individual recovers and so again becomes susceptible ($p(X_{n,t+1} = 0|X_{n,t} = 1)$), β represents the probability that an infectious person infects a previously-susceptible person ($p(X_{n_i,t+1} = 1|X_{n_i,t} = 0, X_{n_j,t} = 1, \{n_i, n_j\} \in E_{t+1})$), and α represents the probability that an infectious person from outside the network infects a previously-susceptible person within the network. Each of these infection probabilities is assumed to be independent. It is also assumed that a person cannot be infected by more than one infectious persons at the same time. Here, $\{a, b, a', b', a'', b''\}$ are given hyperparameters.

Therefore, we can now compute transition matrix $\phi_{n,X_{e:\{n,\cdot\}\in G_t}}$ (and thus specify H from section 3) in terms of α, β, and γ:

$$\begin{aligned} & p(X_{n,t+1} = 0|X_{n,t} = 1) = \gamma & (13) \\ & P(X_{n,t+1} = 1|X_{n,t} = 0, X_{e:\{n,\cdot\}\in G_t}) & (14) \\ = \; & 1 - P(X_{n,t+1} = 0|X_{n,t} = 0, X_{e:\{n,\cdot\}\in G_t}) \\ = \; & 1 - (1-\alpha)(1-\beta)^{\sum_{e:\{n,\cdot\}\in G_t} X_{n',t}} \end{aligned}$$

Thus our H from equation 8 is now a simple function of parameters μ and sufficient statistics of connected states, $g(X)$, given by the summation term in the above equation. Intuitively, the probability of a susceptible person becoming infected is 1 minus the probability that no one, including someone from outside the network, or any of the people within the network with whom the susceptible person is known to have interacted, infected that individual. When the probability of infection is very small, it is approximately the sum of the probabilities from different sources ($P(X_{n,t+1} = 1|X_{n,t} = 0, X_{e:\{n,\cdot\}\in G_t}) \approx \alpha + \beta \cdot \sum_1^{|X_{e:\{n,\cdot\}\in G_t|}} X_{e:\{n,\cdot\}\in G_t,t}$), since the probability that more than one source contributed to infection is also small.

If this assumption is correct, then the probability of seeing an entire state sequence/matrix X is therefore as follows:

$$\begin{aligned} & P(X, \alpha, \beta, \gamma) \\ = \; & P(\alpha)P(\beta)P(\gamma)\prod_n P(X_{n,1}) \\ & \prod_{t,n} P(X_{n,t+1}|\{X_{n'\in N,t}\}, \alpha, \beta, \gamma) & (15) \\ = \; & P(\alpha)P(\beta)P(\gamma)\prod_n P(X_{n,1}) \\ & \prod_{t,n} \gamma^{1_{X_{n,t}=1}\cdot 1_{X_{n,t+1}=0}} \cdot (1-\gamma)^{1_{X_{n,t}=1}\cdot 1_{X_{n,t+1}=1}} \cdot \\ & (\alpha + \beta \cdot \sum_1^{|X_{e:\{n,\cdot\}\in G_t}|} X_{e:\{n,\cdot\}\in G_t,t})^{1_{X_{n,t}=0}\cdot 1_{X_{n,t+1}=1}} \cdot \\ & (1 - \alpha - \beta \cdot \sum_1^{|X_{e:\{n,\cdot\}\in G_t}|} X_{e:\{n,\cdot\}\in G_t,t})^{1_{X_{n,t}=0}\cdot 1_{X_{n,t+1}=0}} \end{aligned}$$

It is assumed that all people start off in the susceptible state, and that $1_\bullet$ in the above equation is the indicator function.

In general, we can often identify M types of events in agent-based models, sometimes by taking small enough time intervals in time-discretization to make first-order approximation sufficient, and count the different ways that events of type $m \in \{1, \ldots, M\}$ could change an agent's state from x' at time t to state $x \neq x'$ at time $t+1$, $g_m(X_{\bullet,t+1} = x, \{X_{n,t} : n, t\})$. The state transition matrix can then be defined as

$$\begin{aligned} & P(X_{n,t+1} = x|X_{n,t} \neq x, X_{e:\{n,\bullet\}\in G_t}) \approx & (16) \\ & \sum_{m=1}^{M} \mu_m \cdot g_m(X_{n,t+1} = x, X_{n,t}, X_{e:\{n,\bullet\}\in G_t}), \\ & \text{where } \mu_m \text{ is the success rate of event type } m. \end{aligned}$$

This formulation of the GCHMM enables us to fit a wide range of agent-based models to "big data" sets of networked people, by specifying the right ways of counting events [Castellano et al., 2009]. For example, in the Sznajd model of opinion dynamics [Sznajd-Weron, 2005], any pair of agents with the same opinion will have a small chance μ of convincing one of their neighbors to change to their opinion. The number of ways that an individual can be convinced by a pair of neighbors is then $g(X) = \binom{\sum_{(n',n)\in G_t} 1_{X_{n'}\neq X_n}}{2}$, and the chance that an agent is convinced is $\mu \cdot g(X)$. Sznajd's model captures the intuition that we might not pay

attention to a single person looking up, but we would look up if a group of people look up.

5 INFERENCE

In this section, we present an efficient inference algorithm for our GCHMM in order to describe and predict the spread of infection. We start by describing inference in the most general, worst case for GCHMMs, and progress from there to much more efficient inference for the epidemics model. The worst case inference algorithm for GCHMMs will be the same as for CHMMs (the case where the graph is complete). A Gibbs sampling algorithm for a particular CHMM with two chains is given in [Rezek et al., 2000], which we extend here to an unconstrained number of chains. The two sampling steps relevant to the extension to multiple chains become:

$$\begin{aligned} X_{n,t+1} &\sim \text{Categorical}([\frac{p(X_{n,t+1}=j, Y|\gamma,\phi)}{\sum_k p(X_{n,t+1}=k, Y|\gamma,\phi)}]) \\ \phi_{n,i} &\sim \text{Dirichlet}([\alpha_j + \\ &\qquad \sum_{\tau=1}^{T} 1(X_{n,\tau+1}=j \wedge X_{\bullet,\tau}=i)]) \end{aligned}$$

Here j and k are states of n, and i is the transition matrix row number corresponding to a combination of states for all nodes. We can see that this sampling procedure is not very efficient, particularly for a reasonably large number of chains.

Fortunately, in practice most social networks are sparse - far from complete. The number of parameters needed to be inferred will decrease dramatically for sparse networks (from $O(N^N)$ to $O(N^{n_{max}})$ where $n_{\max}$ is the maximum number of connections for node n). The parameters of the transition matrix can now be sampled conditioned on the network structure:

$$\begin{aligned} \phi_{n,i} \sim \text{Dirichlet}([\alpha_j + \\ \sum_{\tau=1}^{T} 1(X_{n,\tau+1}=j \wedge X_{e:\{n,\cdot\}\in G_{\tau+1},\tau}=i)]) \end{aligned} \tag{17}$$

Here i now corresponds to a combination of the states of nodes connected to n only. While significantly better than the full CHMM, this may still be intractable for large N or T. However, the interaction structure that we are interested in is also not typically governed by unrestricted transition matrices, ϕ. There is **structure** to interactions or behavior that we can leverage to drastically increase efficiency. One common example is that all agents may be subject to the same ϕ. Another is that interactions themselves have a structure which can be captured by an $H(\mu, g(X))$, where H is now a function parameterized by a reasonably small set of parameters μ and sufficient statistics of the current state space $g(X)$. This allows us to sample $p(\mu|g(X))$, and then compute ϕ, unlike in the algorithms above. This form of H applies to many multi-agent network models including the emergence of collaboration, the spread of rumors and the formation of culture. It similarly applies to our epidemics model, as described in section 4, where where $g(X)$ can be efficiently computed at each node, at each time step. We now describe the resulting inference method for the epidemics model, and then briefly discuss applying the same inference scheme to some more general, $g(X)$.

The epidemics inference algorithm learns the parameters of infection dynamics, including the rate of infection and rate of recovery. It then estimates the likelihood that an individual becomes infectious from the contact with other students based on the reported symptoms of others, and even when the individual's own symptom report is not available. Finally, the algorithm enables us to make useful predictions about the spread of infections within the community in general.

We employ a Gibbs sampler to iteratively sample the infectious/susceptible latent state sequences, to sample infection and recovery events conditioned on these state sequences, and to sample model parameters.

The Gibbs sampler for the GCHMM for epidemics is given in detail below.

The Gibbs sampler takes the following as its input:

$G = (N, E)$: a dynamic network where nodes $n \in N$ represent a person in the network, and $E_t = \{(n_i, n_j)\}$ is a set of edges in G_t representing that person n_i and person n_j have interacted or come into contact at time t.

Y: an observation matrix of symptoms indexed by time and node.

The Gibbs sampler gives the following output:

$\{X, \alpha, \beta, \gamma, \theta\}_s$: samples s. This includes several parameters: α, the base rate of infection; β, the rate of infection by each infectious neighbor in G_t; and γ, the rate of recovery. It includes the emission matrix θ, which expresses the probability of seeing each of the six symptoms given the infectious/susceptible latent state. It also includes the state matrix X of the epidemics GCHMM, which shows sequences of states 0 (susceptible) and 1 (infectious) for each individual over time.

We randomly initialize the model parameters and set the state matrix so that every individual in the network is in the susceptible state. The Gibbs sampler

then iterates through sampling the latent states:

$$X_{n,t+1}|\{X,Y\}\backslash X_{n,t+1};\alpha,\beta,\gamma \sim \text{Bernoulli}\left(\frac{P(X_{n,t+1}=1)}{\sum_{x=0,1}P(X_{n,t+1}=x)}\right) \quad (18)$$
$$P(X_{n,t+1}=1) = P(X|\alpha,\beta,\gamma)P(Y|X)$$

where $P(X|\alpha,\beta,\gamma)$, is the same as in equation 15 minus the priors on α, β, and γ. $P(Y|X)$ can be computed in a straightforward manner from the product of entries in the emissions matrix, θ, where $P(Y|X) = \prod_{n,t,i} P(Y_{i,n,t}|X_{n,t})$.

After sampling the latent states X, we sample infection events. Due to the interaction structure, and to ease sampling, we introduce the auxiliary variable $R_{n,t}$ to track the source of an infection (inside or outside the network) if an infection event occurs for person n at time $t+1$ (i.e., $X_{n,t}=0$ and $X_{n,t+1}=1$):

$$R_{n,t} \sim \text{Categorical}\left(\frac{\alpha,\beta,\ldots,\beta}{\alpha+\beta\sum_{n'}1_{(n',n)\in E_t\cap X_{n',t}=1}}\right) \quad (19)$$

Here $R_{n,t}$ takes the value 1 if the infection event originated outside the network, and $R_{n,t}>1$ if transmission came from someone within the network. Given the state sequences X and infection events R, we can sample the remaining parameters from their posteriors:

$$\alpha \sim \text{Beta}(a+\sum_{n,t}1_{\{R_{n,t}=1\}}, b+\sum_{n,t:X_{n,t}=0}1-\sum_{n,t}1_{\{R_{n,t}=1\}}), \quad (20)$$

$$\beta \sim \text{Beta}(a'+\sum_{n,t}1_{\{R_{n,t}>1\}}, b'+\sum_{n,t:X_{n,t}=0;n'}1_{(n',n)\in E_t\cap X_{n',t}=1}-\sum_{n,t}1_{\{R_{n,t}>1\}}), \quad (21)$$

$$\gamma \sim \text{Beta}(a''+\sum_{n,t:X_{n,t}=1}1_{\{X_{n,t+1}=0\}}, b''+\sum_{n,t:X_{n,t}=1}1-\sum_{n,t:X_{n,t}=1}1_{\{X_{n,t+1}=0\}}). \quad (22)$$

In the more general M state case, we can sample $X_{n,t+1}$ from its posterior categorical distribution similar to equation 18, sample events $R_{n,t}\in\{1,\ldots,M\}$ (reflecting which type of event caused the state change of $X_{n,t}$, c.f., equation 16) similar to equation 19, and sample the success rates of different types of events similar to equation 20.

$$X_{n,t+1}|\{X,Y\}\backslash X_{n,t+1};\mu \sim \text{Categorial}\left(\frac{P(X_{n,t+1})}{\sum_x P(X_{n,t+1}=x)}\right), \quad (23)$$

$$R_{n,t} \sim \text{Categorial}\left(\frac{\mu_1 g_1,\ldots,\mu_M g_M}{\sum_m \mu_m g_m}\right), \quad (24)$$

$$\mu_m \sim \text{Beta}(a_m+\sum_{n,t}1_{R_{n,t}=m}, b_m+\sum_{n,t}g_m-1_{R_{n,t}=m}) \quad (25)$$

6 EXPERIMENTAL RESULTS

In this section we describe the performance of the epidemics GCHMM in predicting missing data in multiple synthetic time series, comparing to a Support Vector Machine (SVM) and standard SIS model. We also fit our epidemics model to the hourly proximity records and self-reported symptoms in a real world Social Evolution data set.

6.1 CONTAGION IN THE SOCIAL EVOLUTION EXPERIMENT

To demonstrate the potential of GCHMMs and our epidemics model, we use it on the data collected in the Social Evolution experiment [Dong et al., 2011], part of which tracked common cold symptoms in a student residence hall from January 2009 to April 2009. This study monitored more than 80% of the residents of the hall through their mobile phones from October 2008 to May 2009, taking periodic surveys which included health-related issues and interactions, and tracked their locations. In particular students answered flu surveys, about the following symptoms: (1) runny nose, nasal congestion, and sneezing; (2) nausea, vomiting, and diarrhea; (3) frequent stress; (4) sadness and depression; and (5) fever. Altogether, 65 residents out of 84 answered the flu surveys.

Because of the symptom reports and proximity information, the Social Evolution data is a good test bed for fitting infection models to real-world data, and for inferring how friends infect one another: For almost all symptoms, a student with a symptom had 3-10 times higher odds of having friends with the same symptom, confirming that symptoms are probabilistically dependent on their friendship network. The durations of symptoms averaged two days, and fit an exponential distribution well, agreeing with the discussed epidemic models. The base probability of a subject reporting a symptom is approximately 0.01, and each individual had a 0.006˜0.035 increased chance of reporting

a symptom for each additional friend with the same symptom, in line with the assumption that the rate of contagion is proportional to the likelihood of contact with an infected individual.

6.2 CALIBRATING PERFORMANCE

We took several steps to calibrate the performances of our epidemics GCHMM and a support vector classifier on synthetic data. First, we synthesized 200 time series – each 128 days long – from the Bluetooth proximity pattern in the Social Evolution data and different parameterizations. Then, we randomly removed the infectious/susceptible data from 10% of the population, added noise to each time series, and then inferred the held-out data with each method, for each parameterization.

The different parameterizations were (1) $\alpha = 0.01$, $\beta = 0.02$, and $\gamma = 0.3$, with observation error 0.01; (2) $\alpha = 0.01$, $\beta = 0.02$, and $\gamma = 0.3$, with observation error 0.001; and (3) $\alpha = 0.005$, $\beta = 0.045$, and $\gamma = 0.3$, with observation error 0.01. Comparing performances between (1) and (2) enables us to see the effect of observation error on algorithm performance. Comparing performances between (1) and (3) enables us to see the effect of the network on algorithm performance. Comparing performances between methods enables us to see the difference between our model-based learning and the SVM or SIS model.

We ran Gibbs samplers for 10,000 iterations, including 1000 for burn-in. We trained the SVM on a 1000-day time series synthesized using the correct parameterization, and used the number of infectious contacts yesterday, today, and tomorrow as features. We assigned different weights to the "infected" class and the "susceptible" class to balance the true and false prediction rates.

All methods can easily identify 20% of infectious cases in the missing data with little error; however, the our model-based method consistently performs better than SIS and SVM. Less noise in symptoms observations and in the contact networks of individuals significantly improves the performance of inferring missing data, as shown in Figure 3. An ROC curve shows how different algorithms compare in terms of inferring infectious cases in the held out 10% of the data.

The SVM performs poorly – especially at identifying isolated infectious cases – because it assumes that cases are i.i.d and because properly incorporating the temporal structure of epidemic dynamics into the features is not easy. The SVM also assumes that we have enough training data. This assumption often cannot be satisfied for the kinds of problems we are interested in. Lastly, we also compare to the traditional

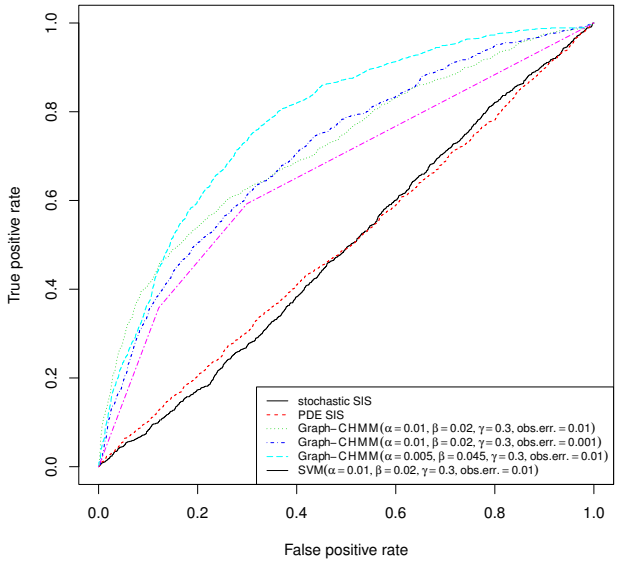

Figure 3: Less observation error (obs.err.=0.001) and better knowledge about the network ($\beta = 0.045$) result in a better trade-off between true positive rate (TPR) and false positive rate (FPR). Lack of knowledge about the network and assuming a compete graph structure result in poor trade-off between TPR and FPR. The support vector classifier has a worse trade-off between TPR and FPR than the epidemics GCHMM does.

SIS methods (both pde and stochastic). They do not predict well because they treat everyone in the population the same, regardless of individual interaction network information.

Observation noise makes inferring the individual states difficult, since it increases uncertainty in the parameters of the system. Knowledge of the dynamic contact network also affects the quality of parameter estimation and state inference. The more we know about who contacted whom, the more targeted we can be in locating the infectious cases.

6.3 INFERRING COLD FROM SYMPTOMS AND PROXIMITY

In this section, we report the results of our epidemics model on the Social Evoluation data. In order to infer infections we extracted an hour-by-hour proximity snapshot over the 107 days that we monitored symptoms, and interpolated hourly symptom reports from the daily symptom reports. We assumed that the symptoms are probabilistically independent given the common cold (infectious) state. We ran the Gibbs sampler for 10,000 iterations, with 1000 burn-in iterations.

We do not have the clinical certainty of common cold

diagnoses . However, the statistics that we discuss below give solid evidence that the epidemics model captures the structure of a infection process accompanying the symptom report.

Figure 4 shows the (marginal) likelihood of the daily common-cold states of individuals. Rows in this heat map are indexed by subjects, arranged so that friends go together, and then placed next to a dendrogram that organizes friends hierarchically into groups. Different colors on the leaves of the dendrogram represent different living sectors in the student residence hall. Columns in this heat map are indexed by date in 2009. Brightness of a heat-map entry indicates the likelihood of infectiousness - the brighter a cell, the more likely it is that the corresponding subject is infectious on the corresponding day. Sizes of black dots represent the number of reported symptoms. When a black dot doesn't exist on a table entry, the corresponding person didn't answer the survey that day.

This heat map shows clusters of common-cold infections. When larger clusters of interpersonal proximities occurred , symptom clusters lasted longer and involved more people. The heat map also tells us that subjects often submitted flu-symptom surveys daily when they were healthy, but would forget to submit surveys when in the infectious state. The Gibbs sampler nonetheless uses the data to determines that the individual was infectious for these days. Similarly, a subject sometimes reported isolated symptoms. The Gibbs sampler is able to conclude the he was most likely healthy, because the duration of the symptom reports didn't agree with the typical duration of a common cold, and because his symptom report was isolated in his contact network.

Inferred Infectious states normally last four days to two weeks. A student typically caught a cold 2-3 times during this time span. The bi-weekly searches of the keyword "flu" from January 2009 to April 2009 in Boston – as reported by Google Trends – correlated with these findings.

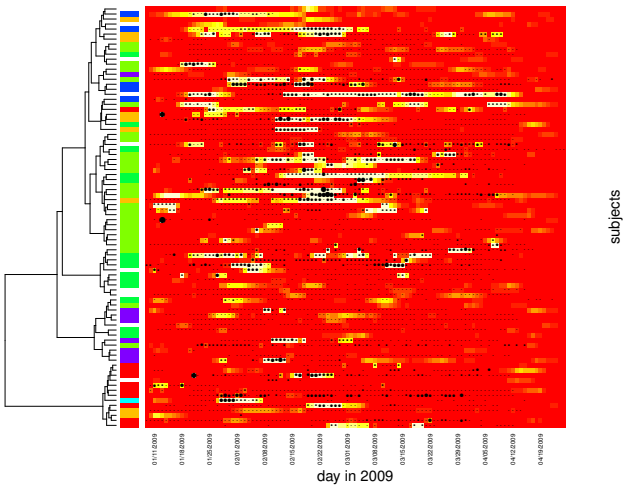

Figure 4: Our epidemics GCHMM can infer common cold state, and captures infection data from symptom self-reports and the proximity network. The size of black dots represents the number of symptoms reported, ranging from zero symptoms to all, and no black dot means no self-report.

7 CONCLUSIONS

We have presented the GCHMM for modeling discrete-time multi-agent dynamics when the agents are connected through a social network. We showed that the GCHMM can be used as an individual-level SIS model to successfully predict the spread of infection throughout a social network. In the future, it would be interesting to use the GCHMM to learn graph dynamics, or to predict missing links. It would also be interesting to try to use the GCHMM in applications with a more complex transition matrix structure.

The study of infection in small populations has important implications both for refining epidemic models and for advising individuals about their health. The spread of infection in this context is poorly understood because of the difficulty in closely tracking infection throughout a complete community. This paper showcases the spread of an infection centered on a student dormitory, with data based on daily symptom surveys over a period of four months and on proximity tracking through mobile phones. It also demonstrates that fitting a discrete-time multi-agent model of infection to real-world symptom self-reports and proximity observations gives us useful insights into infection paths and control.

Abstract

Particle Filter is an effective solution to track objects in video sequences in complex situations. Its key idea is to estimate the density over the possible states of the object using a weighted sample whose elements are called *particles*. One of its crucial step is a resampling step in which particles are resampled to avoid some degeneracy problem. In this paper, we introduce a new resampling method called *Combinatorial Resampling* that exploits some features of articulated objects to resample over an implicitly created sample of an exponential size better representing the density to estimate. We prove that it is sound and, through experimentations both on challenging synthetic and real video sequences, we show that it outperforms all classical resampling methods both in terms of the quality of its results and in terms of response times.

1 INTRODUCTION

Tracking articulated structures with accuracy and within a reasonable time is challenging due to the high complexity of the problem to solve. Actually, the state space of such a problem is inevitably high-dimensional and the estimation of the state of an object thus requires that of many parameters. When the dynamics of the objects is linear or linearizable and when the uncertainties about their position are Gaussian or mixtures of Gaussians, tracking can be performed analytically by Kalman-like Filters [Chen, 2003]. Unfortunately, in practice, such properties seldom hold and people often resort to sampling to approximate solutions of the tracking problem. The Particle Filter (PF) methodology [Gordon et al., 1993] is popular among these approaches and, in this paper, we focus on PF.

PF consists of estimating the density over the states of the tracked object using weighted samples whose elements are possible realizations of the object state and are called *particles*. PF and its variants, e.g., Partition Sampling (PS) [MacCormick and Blake, 1999], all use a resampling step to avoid a problem of degeneracy of the particles, i.e., the case when all but one of the particle's weights are close to zero [Douc et al., 2005]. Without this step, this problem would necessarily occur [Doucet et al., 2001].

A few resampling algorithms are classically used, e.g., Multinomial Resampling [Gordon et al., 1993], Residual Resampling [Liu and Chen, 1998], Stratified and Systematic Resampling [Kitagawa, 1996]. However, these methods have not been designed specifically to deal with articulated objects and, as such, they do not exploit their features. In this paper, we introduce *Combinatorial Resampling*, an algorithm that exploits them to produce better samples by resampling over an implicitly created sample of an exponential size. More precisely, in articulated object tracking, a particle may be thought of as a tuple of the realizations of each "part" of the object and it is often the case that swapping the realizations of a given part among several particles has no impact on the estimated distribution. For instance, in a human body tracking, it may be the case that swapping the positions of the left arm estimated by two particles does not alter the estimated distribution. Given a particle set, Combinatorial Resampling produces implicitly a new set of particles resulting from all such swappings and resamples from it. As such, this new set is of exponential size and acts as a much better description of the state space.

The paper is organized as follows. The next section recalls the basics of articulated object tracking and, in particular, Partitioned Sampling. It also recalls the fundamentals of dynamic Bayesian networks, as our resampling method relies on them. Section 3 presents a short overview of the aforementioned classical resampling approaches and the next one details our new resampling approach and its correctness. Section 5 shows some experimental results both on challenging synthetic and real video sequences. Those highlight the efficiency of our method both in terms of the quality of its results and in terms of response times. Finally, we give some concluding remarks and perspectives.

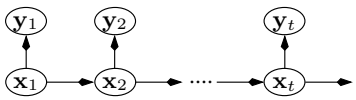

Figure 1: A Markov chain for object tracking.

2 ARTICULATED OBJECT TRACKING

In this paper, articulated object tracking consists of estimating a state sequence $\{\mathbf{x}_t\}_{t=1,\dots,T}$, whose evolution is given by equation $\mathbf{x}_t = \mathbf{f}_t(\mathbf{x}_{t-1}, \mathbf{n}_t^{\mathbf{x}})$, from observations $\{\mathbf{y}_t\}_{t=1,\dots,T}$ related to the states by $\mathbf{y}_t = \mathbf{h}_t(\mathbf{x}_t, \mathbf{n}_t^{\mathbf{y}})$. Usually, $\mathbf{f}_t$ and $\mathbf{h}_t$ are nonlinear functions, and $\mathbf{n}_t^{\mathbf{x}}$ and $\mathbf{n}_t^{\mathbf{y}}$ are i.i.d. noise sequences. From a probabilistic viewpoint, this problem can be represented by the Markov chain of Fig. 1 and it amounts to estimate, for any t, $p(\mathbf{x}_{1:t}|\mathbf{y}_{1:t})$ where $\mathbf{x}_{1:t}$ denotes the tuple $(\mathbf{x}_1, \dots, \mathbf{x}_t)$. This can be computed iteratively using Eq. (1) and (2), which are referred to as a *prediction step* and a *correction step* respectively.

$$p(\mathbf{x}_{1:t}|\mathbf{y}_{1:t-1}) = p(\mathbf{x}_t|\mathbf{x}_{t-1})p(\mathbf{x}_{1:t-1}|\mathbf{y}_{1:t-1}) \quad (1)$$

$$p(\mathbf{x}_{1:t}|\mathbf{y}_{1:t}) \propto p(\mathbf{y}_t|\mathbf{x}_t)p(\mathbf{x}_{1:t}|\mathbf{y}_{1:t-1}) \quad (2)$$

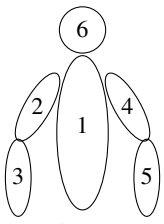
with $p(\mathbf{x}_t|\mathbf{x}_{t-1})$ the transition corresponding to $\mathbf{f}_t$ and $p(\mathbf{y}_t|\mathbf{x}_t)$ the likelihood corresponding to $\mathbf{h}_t$.

The PF framework [Gordon et al., 1993] approximates the above densities using weighted samples $\{\mathbf{x}_t^{(i)}, w_t^{(i)}\}$, $i = 1, \dots, N$, where each $\mathbf{x}_t^{(i)}$ is a possible realization of state $\mathbf{x}_t$ called a *particle*. In its prediction step (Eq. (1)), PF propagates the particle set $\{\mathbf{x}_{t-1}^{(i)}, w_{t-1}^{(i)}\}$ using a proposal function $q(\mathbf{x}_t|\mathbf{x}_{1:t-1}^{(i)},\mathbf{y}_t)$ which may differ from $p(\mathbf{x}_t|\mathbf{x}_{t-1}^{(i)})$ (but, for simplicity, we will assume they do not); in its correction step (2), PF weights the particles using a likelihood function, so that $w_t^{(i)} \propto w_{t-1}^{(i)} p(\mathbf{y}_t|\mathbf{x}_t^{(i)}) \frac{p(\mathbf{x}_t^{(i)}|\mathbf{x}_{t-1}^{(i)})}{q(\mathbf{x}_t^{(i)}|\mathbf{x}_{1:t-1}^{(i)},\mathbf{y}_t)}$, with $\sum_{i=1}^N w_t^{(i)} = 1$. The particles can then be resampled: those with the highest weights are duplicated while the others are eliminated. The estimation of the posterior density $p(\mathbf{x}_t|\mathbf{y}_{1:t})$ is then given by $\sum_{i=1}^N w_t^{(i)} \delta_{\mathbf{x}_t^{(i)}}(\mathbf{x}_t)$, where $\delta_{\mathbf{x}_t^{(i)}}$ are Dirac masses centered on particles $\mathbf{x}_t^{(i)}$.

As shown in [MacCormick and Isard, 2000], the number of particles necessary for a good estimation of the above densities grows exponentially with the dimension of the state space, hence making PF's basic scheme unusable in real-time for articulated object tracking. To cope with this problem, different variants of PF have been proposed, ranging from local search-based methods like the *Annealed Particle Filter* [Deutscher and Reid, 2005, Gall, 2005] and hierarchical-refining methods [Chang and Lin, 2010] to decomposition techniques like *Partitioned Sampling* (PS) [MacCormick and Blake, 1999] and its siblings [Rose et al., 2008, Besada-Portas et al., 2009]. Here, we focus on decomposition-based particle filters like PS.

PS's key idea is that the state and observation spaces $\mathcal{X}$ and $\mathcal{Y}$ can often be naturally decomposed as $\mathcal{X} = \mathcal{X}^1 \times \dots \times \mathcal{X}^P$ and $\mathcal{Y} = \mathcal{Y}^1 \times \dots \times \mathcal{Y}^P$ where each $\mathcal{X}^j$ represents some "part" of the object. For instance, on Fig. 2, a human body is decomposed as 6 parts (head, torso, etc.) numbered from 1 to 6. The state of the jth part at time t is denoted $\mathbf{x}_t^j$. Then, by exploiting conditional independences among different subspaces $(\mathcal{X}^j, \mathcal{Y}^j)$, PS estimates $p(\mathbf{x}_{1:t}|\mathbf{y}_{1:t})$ using only sequential applications of PF over $(\mathcal{X}^j, \mathcal{Y}^j)$. For instance, on Fig. 2, given the position of the torso, the left and right arm positions may be independent so, after applying PF on the torso, PS can apply it sequentially to the left and right arms and still compute a correct estimation of $p(\mathbf{x}_{1:t}|\mathbf{y}_{1:t})$. As the $(\mathcal{X}^j, \mathcal{Y}^j)$ subspaces are "smaller" than $(\mathcal{X}, \mathcal{Y})$, the distributions to estimate at each iteration of PF have fewer parameters than those defined on $(\mathcal{X}, \mathcal{Y})$, which significantly reduces the number of particles needed for their estimation and, thus, speeds up the computations.

The exploitation of the conditional independences among the $(\mathcal{X}^j, \mathcal{Y}^j)$ leads to generalizing the Markov chain of Fig. 1 by the Dynamic Bayesian Network (DBN) of Fig. 2



A human body: part 1 corresponds to the torso, parts 2 and 3 to the left arm, parts 4 and 5 to the right arm and part 6 to the head. On the right side of the figure, the corresponding DBN: to the jth part corresponds a pair of state and observation variables $\mathbf{x}_t^j, \mathbf{y}_t^j$. The arcs show the dependences between variables, including between different time slices.

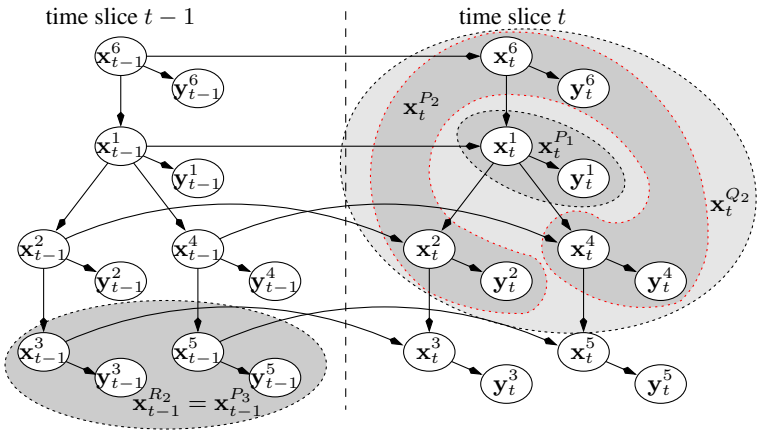


Figure 2: A Dynamic Bayesian Network.

[Murphy, 2002], in which the global state $\mathbf{x}_t$ of the object is more finely described as the set of states $\mathbf{x}_t^j$ of each part of the object. The semantics of DBNs is similar to that of Markov chains: the arcs correspond to probabilistic dependences and the joint distribution over all the nodes in the network is equal to the product of the distributions of each node conditionally to its parents in the graph.

The resampling scheme we introduce in this paper, i.e., Combinatorial Resampling, is designed to be part of PS-like algorithms and relies on DBNs. Therefore, we shall now formalize PS in terms of operations over DBNs. For this purpose, for any set $J = \{j_1, \ldots, j_k\}$, let $\mathbf{x}_t^J$ denote the tuple $(\mathbf{x}_t^{j_1}, \ldots, \mathbf{x}_t^{j_k})$, i.e., the tuple of the states of the object parts in J. For instance, on Fig. 2, if $J = \{2, 3\}$, then $\mathbf{x}_t^J$ represents the state of the whole left arm. Similarly, let $\mathbf{x}_t^{(i),J}$ denote the tuple of the parts in J of the ith particle. For instance, for $J = \{2, 3\}$, $\mathbf{x}_t^{(i),J}$ corresponds the state of left arm as represented by the ith particle. In the rest of the paper, we will assume that the object is composed of precisely P parts (in Fig. 2, $P = 6$). Now, we shall describe a slight generalization of PS where PF is iteratively applied on sets of object parts instead of just singletons like PS does. When PF is applied on a set, it is applied independently on all its elements. We need to distinguish at each step of such tracking algorithm the parts that were already processed by PF from those that were not yet. Thus, for any step j,

- let P_j denote the set of object parts being processed at the jth step (in the case of PS, $P_j = \{j\}$);
- let $Q_j = \sum_{h=1}^{j} P_h$ denote the set of all the object parts processed up to (including) the jth step;
- let $R_j = \sum_{h=j+1}^{P} P_h$ denote the set of the object parts yet to process after the jth step is completed.

Fig. 2 illustrates these notations: here, $P_1 = \{1\}$, i.e., PF is first applied only on the torso; $P_2 = \{2, 4, 6\}$, i.e., at its 2nd step, the tracking algorithm applies PF in parallel on parts 2, 4 and 6. Therefore, at the 2nd step, parts $Q_2 = \{1, 2, 4, 6\}$ have been processed and there remains to process parts $R_2 = \{3, 5\}$. Thus, if PF has propagated all the parts in Q_2 from time $t-1$ to t, in the particles, the parts in R_2 still refer to time $t-1$ (see Fig. 2). Let K denote the number of steps of the tracking algorithm, i.e., the number of sets P_j (for PS, $K = P$). To simplify the proofs in the rest of the paper, we shall fix $Q_0 = R_K = \emptyset$. Now, PS can be described in Algorithm 1. In [MacCormick and Isard, 2000], it is showed that this algorithm is mathematically sound when its resampling method is a *weighted resampling* using a g function corresponding to $p(\mathbf{y}_t|\mathbf{x}_t)$ (see the next section).

Input: A particle set $\{\mathbf{x}_{t-1}^{(i)}, w_{t-1}^{(i)}\}$ at time $t-1$, an image $\mathcal{I}$
Output: A particle set $\{\mathbf{x}_t^{(i)}, w_t^{(i)}\}$ at time t
$Q \leftarrow \emptyset$; $R \leftarrow \{1, \ldots, P\}$
for $j = 1$ **to** K **do**
  foreach k **in** P_j **do**
    $Q' \leftarrow Q \cup \{k\}$; $R' \leftarrow R \backslash \{k\}$
    $\{(\mathbf{x}_t^{(i),Q'}, \mathbf{x}_{t-1}^{(i),R'})\} \leftarrow$ propagate $(\{\mathbf{x}_t^{(i),Q}, \mathbf{x}_{t-1}^{(i),R}\})$
    $\{(w_t^{(i),Q'}, w_{t-1}^{(i),R'})\} \leftarrow$
      correct $(\{(\mathbf{x}_t^{(i),Q'}, \mathbf{x}_{t-1}^{(i),R'}), (w_t^{(i),Q}, w_{t-1}^{(i),R})\}, \mathcal{I})$
    $Q \leftarrow Q'$; $R \leftarrow R'$
  $\{(\mathbf{x}_t^{(i),Q}, \mathbf{x}_{t-1}^{(i),R}), (w_t^{(i),Q}, w_{t-1}^{(i),R})\} \leftarrow$
    resample $(\{(\mathbf{x}_t^{(i),Q}, \mathbf{x}_{t-1}^{(i),R}), (w_t^{(i),Q}, w_{t-1}^{(i),R})\})$
return $\{\mathbf{x}_t^{(i)}, w_t^{(i)}\}$

Algorithm 1: Partitioned Sampling PS.

3 RESAMPLING METHODS

Several resampling schemes are classically used, that we shall review briefly now. Comparisons of their pros and cons can be found in [Douc et al., 2005].

Multinomial resampling consists of selecting N numbers k_i, $i = 1, \ldots, N$, w.r.t. a uniform distribution $U((0, 1])$ on $(0, 1]$. Then, sample $\mathcal{S} = \{\mathbf{x}_t^{(i)}, w_t^{(i)}\}$ is substituted by a new sample $\mathcal{S}' = \{\mathbf{x}_t^{(D(k_i))}, \frac{1}{N}\}$ where $D(k_i)$ is the unique integer j such that $\sum_{h=1}^{j-1} w_t^{(h)} < k_i \leq \sum_{h=1}^{j} w_t^{(h)}$. If $(n_1, \ldots, n_N)$ denote the number of times each of the particles in $\mathcal{S}$ are duplicated, then $(n_1, \ldots, n_N)$ is distributed w.r.t. the multinomial distribution Mult$(N; w_t^{(1)}, \ldots, w_t^{(N)})$. *Stratified resampling* differs from multinomial resampling by selecting randomly the k_i's w.r.t. the uniform distribution $U((\frac{i-1}{N}, \frac{i}{N}])$. In *systematic resampling*, some number k is drawn w.r.t. $U((0, \frac{1}{N}])$ and, then, the k_i's are defined as $k_i = \frac{i-1}{N} + k$.

Residual resampling [Liu and Chen, 1998] is a method very efficient for decreasing the variance of the particle set induced by the resampling step. It is performed in two steps. First, for every $i \in \{1, \ldots, N\}$, $n'_i = \lfloor N w_t^{(i)} \rfloor$ duplicates of particle $\mathbf{x}_t^{(i)}$ of $\mathcal{S}$ are inserted into $\mathcal{S}'$. The $N - \sum_{i=1}^{n} n'_i$ particles still needed to complete the N-sample $\mathcal{S}'$ are drawn randomly using the multinomial distribution Mult$(N - \sum_{i=1}^{n} n'_i; N w_t^{(1)} - n'_1, \ldots, N w_t^{(N)} - n'_N)$, for instance using the multinomial resampling algorithm. The weights assigned to all the particles in $\mathcal{S}'$ are $1/N$.

Finally, *weighted resampling* is defined as follows: let $g : \mathcal{X} \mapsto \mathbb{R}$ be any strictly positive continuous function, where $\mathcal{X}$ denotes the state space. Weighted resampling proceeds as follows: let ρ_t be defined as $\rho_t(i) = g(\mathbf{x}_t^{(i)}) / \sum_{j=1}^{N} g(\mathbf{x}_t^{(j)})$ for $i = 1, \ldots, N$. Select independently indices $k_1, \ldots, k_N$ according to probability ρ_t. Finally, construct the new set of particles $\mathcal{S}' = \{\mathbf{x}_t^{(k_i)}, w_t^{(k_i)} / \rho_t(k_i)\}_{i=1}^{N}$. [MacCormick, 2000] shows that $\mathcal{S}'$ represents the same probability distribution as $\mathcal{S}$ while

focusing the particles on the peaks of g. Note however that, unlike the other resampling methods described above, weighted resampling does not assign equal weights $(1/N)$ to all the particles. In the rest of the paper, we will need this "equal weight" feature, so whenever weighted resampling will be used, it will be implicitly followed by one of the other above resampling methods.

In the next section, we will propose a new resampling method that exploits the structure within articulated objects to improve the efficiency of particle filtering.

4 DBN-BASED COMBINATORIAL RESAMPLING

Our resampling scheme is suitable for particle filters as described in Algo. 1. More precisely, we will show in Subsection 4.1 that, in articulated object tracking, the set $\{1,\ldots,P\}$ of parts of the objects to track can be partitioned into some sets $\{P_1,\ldots,P_K\}$ such that those parts in each P_j are all independent conditionally to $\cup_{h<j}P_h$. For instance, in Fig. 2, $P=6$ and $K=3$, $P_1=\{1\}$ corresponds to the torso, $P_2=\{2,4,6\}$ to the head and both arms, and $P_3=\{3,5\}$ to the forearms. In addition, given the position of the torso (P_1), those of the head and the arms (P_2) are independent. In Subsection 4.2, these independences will be exploited to justify that permutations of some particles' parts do not alter the estimation of $p(\mathbf{x}_{1:t}|\mathbf{y}_{1:t})$. Then, our resampling scheme, which will be described in Subsection 4.3, will exploit these permutations to construct implicitly some new exponential-size sample from which it will resample new high-quality samples.

4.1 IDENTIFYING SETS $P_1,\ldots,P_K$

To be sound, i.e., to not alter the estimation of $p(\mathbf{x}_{1:t}|\mathbf{y}_{1:t})$, Combinatorial Resampling exploits conditional independences among the different parts of the object. The partition into sets $P_1,\ldots,P_K$ precisely accounts for these independences and thus naturally results from a d-separation analysis, the independence property at the core of DBNs:

Definition 1 (*d*-separation [Pearl, 1988]) *Two nodes $\mathbf{x}_t^i$ and $\mathbf{x}_s^j$ of a DBN are dependent conditionally to a set of nodes $\mathbf{Z}$ if and only if there exists a chain, i.e., an undirected path, $\{\mathbf{c}_1=\mathbf{x}_t^i,\ldots,\mathbf{c}_n=\mathbf{x}_s^j\}$ linking $\mathbf{x}_t^i$ and $\mathbf{x}_s^j$ in the DBN such that the following two conditions hold:*

1. *for every node $\mathbf{c}_k$ such that the arcs are $\mathbf{c}_{k-1}\rightarrow\mathbf{c}_k\leftarrow\mathbf{c}_{k+1}$, either $\mathbf{c}_k$ or one of its descendants is in $\mathbf{Z}$;*
2. *none of the other nodes $\mathbf{c}_k$ belongs to $\mathbf{Z}$.*

Such a chain is called active *(else it is* blocked*). If there exists an active chain linking two nodes, these nodes are dependent and are called d-connected, otherwise they are independent conditionally to $\mathbf{Z}$ and are called d-separated.*

In Fig. 2, conditionally to the position of the torso up to time t, both arms are thus independent.

In the rest of the paper, we will assume that, *within each time slice*, the DBN structure is a directed tree, i.e., there do not exist nodes $\mathbf{x}_t^i,\mathbf{x}_t^j,\mathbf{x}_t^k$ such that $\mathbf{x}_t^i\rightarrow\mathbf{x}_t^j\leftarrow\mathbf{x}_t^k$. We will also assume that arcs across time slices link similar nodes, i.e., there exist no arc $\mathbf{x}_{t-1}^i\rightarrow\mathbf{x}_t^j$ with $j\neq i$. Finally, we will assume that nodes $\mathbf{y}_t^j$ have only one parent $\mathbf{x}_t^j$ and no children. For articulated object tracking, these requirements are rather mild and Fig. 2 satisfies all of them.

Now, we can construct sets $P_1,\ldots,P_K$: for any node, say X_t, in time slice t of the DBN, let $\mathbf{Pa}(X_t)$ and $\mathbf{Pa}_t(X_t)$ denote the set of parents of X_t in the DBN in all time slices and in time slice t only respectively. For instance, in Fig. 2, $\mathbf{Pa}(\mathbf{x}_t^2)=\{\mathbf{x}_t^1,\mathbf{x}_{t-1}^2\}$ and $\mathbf{Pa}_t(\mathbf{x}_t^2)=\{\mathbf{x}_t^1\}$. Let $\{P_1,\ldots,P_K\}$ be a partition of $\{1,\ldots,P\}$ defined by:

- $P_1=\{k\in\{1,\ldots,P\}:\mathbf{Pa}_t(\mathbf{x}_t^k)=\emptyset\}$;
- for any $j>1$, $P_j=\{k\in\{1,\ldots,P\}\backslash\bigcup_{h=1}^{j-1}P_h:\mathbf{Pa}_t(\mathbf{x}_t^k)\subseteq\bigcup_{h=1}^{j-1}\bigcup_{r\in P_h}\{\mathbf{x}_t^r\}\}$.

On Fig. 2, this results in $P_1=\{1\}$, $P_2=\{2,4,6\}$ and $P_3=\{3,5\}$. It turns out that the way we constructed the P_j's, all the $\mathbf{x}_t^k\in P_j$ can be processed independently by PF because they are independent conditionally to $\mathbf{Pa}(\mathbf{x}_t^k)$, and this is precisely this independence property which is needed to enable a sound object part swapping within Combinatorial Resampling:

Proposition 1 *The particle set resulting from Algorithm 1, with P_j defined as in the preceding paragraph, $Q_j=\sum_{h=1}^{j}P_h$ and $R_j=\sum_{h=j+1}^{K}P_h$, represents $p(\mathbf{x}_t|\mathbf{y}_{1:t})$.*

Proof: By induction on j. Assume that, before processing parts P_j, particles estimate $p(\mathbf{x}_t^{Q_{j-1}},\mathbf{x}_{t-1}^{R_{j-1}}|\mathbf{y}_{1:t-1},\mathbf{y}_t^{Q_{j-1}})$. This is clearly the case for P_1 since P_1 are the first parts processed. Remember that P_j,Q_j,R_j are the set of parts processed at the jth step, up to the jth step and still to process respectively. We will now examine sequentially the distributions estimated by the particle set after applying in parallel PF's prediction step over the parts in P_j, then after applying PF's correction step and, finally, after resampling.

1. Let us show that after the parallel propagations of the parts in P_j (prediction step), the particle set represents density $p(\mathbf{x}_t^{Q_j},\mathbf{x}_{t-1}^{R_j}|\mathbf{y}_{1:t-1},\mathbf{y}_t^{Q_{j-1}})$. For instance, on Fig. 2, this means that, after propagating the parts in P_2, the particle set estimates $p(\mathbf{x}_t^{1,2,4,6},\mathbf{x}_{t-1}^{3,5}|\mathbf{y}_{1:t-1},\mathbf{y}_t^1)$, i.e., only the positions of the forearms still refer to time $t-1$ and the only observation taken into account at time t is the position of the torso (not yet those of the head and arms). All these

parallel operations correspond to computing:

$$\int p(\mathbf{x}_t^{Q_{j-1}}, \mathbf{x}_{t-1}^{R_{j-1}} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}}) \prod_{k \in P_j} p(\mathbf{x}_t^k | \mathbf{Pa}(\mathbf{x}_t^k)) \, d\mathbf{x}_{t-1}^{P_j}.$$

By d-separation, a node is independent of all of its non descendants conditionally to its parents. Hence, for every $k \in P_j$, $\mathbf{x}_t^k$ is independent of $\mathbf{x}_t^{P_j \setminus \{k\}} \cup \mathbf{x}_t^{Q_{j-1}} \cup \mathbf{x}_{t-1}^{R_{j-1}} \cup \mathbf{y}_{1:t-1} \cup \mathbf{y}_t^{Q_{j-1}}$ conditionally to $\mathbf{Pa}(\mathbf{x}_t^k)$ (see Fig. 3.a where $\mathbf{x}_t^k$ is the doubly-circled node, $\mathbf{Pa}(\mathbf{x}_t^k)$ are the striped nodes and the black and shaded nodes correspond to the independent observation and state nodes respectively). Consequently, the above integral is equivalent to:

$$\begin{aligned} &\int p(\mathbf{x}_t^{Q_{j-1}}, \mathbf{x}_{t-1}^{R_{j-1}} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}}) \\ &\quad p(\mathbf{x}_t^{P_j} | \mathbf{x}_t^{Q_{j-1}}, \mathbf{x}_{t-1}^{R_{j-1}}, \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}}) \, d\mathbf{x}_{t-1}^{P_j} \\ &= \int p(\mathbf{x}_t^{P_j}, \mathbf{x}_t^{Q_{j-1}}, \mathbf{x}_{t-1}^{R_{j-1}} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}}) \, d\mathbf{x}_{t-1}^{P_j}. \end{aligned}$$

As $Q_j = Q_{j-1} \cup P_j$ and $R_{j-1} = P_j \cup R_j$, the above equation is equivalent to $p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}})$.

2. Let us show that after the parallel corrections of the P_j parts, the particle set estimates $p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_j})$. These operations correspond to computing, up to a constant, distribution $p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}}) \times \prod_{k \in P_j} p(\mathbf{y}_t^k | \mathbf{x}_t^k)$. By d-separation, nodes $\mathbf{y}_t^k$ are independent of the rest of the DBN conditionally to $\mathbf{x}_t^k$, so $p(\mathbf{y}_t^{P_j} | \mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j}, \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}}) = \prod_{k \in P_j} p(\mathbf{y}_t^k | \mathbf{x}_t^k)$. After the corrections over P_j, the particle set thus estimates $p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j}, \mathbf{y}_t^{P_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}})$, which, when normalized, is equal to $p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_{j-1}}, \mathbf{y}_t^{P_j}) = p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_j})$. As resamplings do not alter densities, at the end of the algorithm, the particle set estimates $p(\mathbf{x}_t^{Q_K}, \mathbf{x}_{t-1}^{R_K} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_K}) = p(\mathbf{x}_t | \mathbf{y}_{1:t})$. □

4.2 SUBSTATE PERMUTATIONS

The advantage of using the P_j's as defined above instead of singletons as the classical PS does is that this enables to improve by permutations the particle set without altering the joint posterior density. Those permutations are the core of Combinatorial Resampling as the latter creates implicitly new particle sets resulting from all the possible permutations. The next proposition determines the permutations that guarantee the distributions are not altered. Intuitively, it asserts that whenever two particles are such that they have the same states on some nodes $\mathbf{Pa}_s(\mathbf{x}_s^k)$, then swapping their states on $\mathbf{x}_s^k$ and its descendants cannot alter the density estimated by the particle set. For instance, on Fig. 3.b, if two particles have the same value for the striped nodes $\mathbf{Pa}_s(\mathbf{x}_s^k)$, their values on the shaded node $\mathbf{x}_s^k$ and the black one ($\mathbf{x}_s^k$'s descendant) can be safely swapped.

Proposition 2 *Let $\{(\mathbf{x}_t^{(i),Q_j}, \mathbf{x}_{t-1}^{(i),R_j})\}$ be the particle set at the jth step of Algo. 1. Let $k \in P_j$ and let $\mathbf{Desc}_t(\mathbf{x}_t^k)$ be the set of descendants of $\mathbf{x}_t^k$ in time slice t. Let $\sigma : \{1, \ldots, N\} \mapsto \{1, \ldots, N\}$ be any permutation such that $\mathbf{x}_s^{(i),h} = \mathbf{x}_s^{(\sigma(i)),h}$ for all the nodes $\mathbf{x}_s^h \in \cup_{s=1}^t \mathbf{Pa}_s(\mathbf{x}_s^k)$. Then, the particle set resulting from the application of σ on the parts of $\{(\mathbf{x}_t^{(i),Q_j}, \mathbf{x}_{t-1}^{(i),R_j})\}$ corresponding to $\{\mathbf{x}_t^k\} \cup \mathbf{Desc}_{t-1}(\mathbf{x}_{t-1}^k)$ still estimates $p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_j})$.*

Proof: If $j = 1$, the proposition trivially holds since σ is applied to all the nodes of the connected component of $\mathbf{x}_t^k$. Assume now that $j \neq 1$. We shall now partition the object parts as described on Fig. 3.c to highlight which parts shall be permuted, which ones shall be identical to enable permutations and which parts are unconcerned: let $\mathbf{x}_{t-1}^D = \mathbf{Desc}_{t-1}(\mathbf{x}_{t-1}^k)$, $\mathbf{x}_t^{k'} = \mathbf{Pa}_t(\mathbf{x}_t^k)$, $\mathbf{x}_t^V = \mathbf{x}_t^{Q_j} \setminus (\{\mathbf{x}_t^k, \mathbf{x}_t^{k'}\})$ and $\mathbf{x}_{t-1}^W = \mathbf{x}_{t-1}^{R_j} \setminus \mathbf{x}_{t-1}^D$. Thus, the permuted parts are $\mathbf{x}_t^k \cup \mathbf{x}_{t-1}^D$ (see Fig. 3.c), the identical part is $\mathbf{x}_t^{k'}$, and the unconcerned parts are $\mathbf{x}_t^V \cup \mathbf{x}_{t-1}^W$.

$$\begin{aligned} p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_j}) &\propto p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j}, \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_j}) \\ &= p(\mathbf{x}_t^{\{k,k'\} \cup V}, \mathbf{x}_{t-1}^{D \cup W}, \mathbf{y}_{1:t}^{\{k,k'\} \cup V}, \mathbf{y}_{1:t-1}^{D \cup W}) \\ &= \int p(\mathbf{x}_t^{\{k\} \cup V}, \mathbf{x}_{1:t}^{k'}, \mathbf{x}_{t-1}^{D \cup W}, \mathbf{y}_{1:t}^{\{k,k'\} \cup V}, \mathbf{y}_{1:t-1}^{D \cup W}) d\mathbf{x}_{1:t-1}^{k'} \end{aligned}$$

Conditionally to $\{\mathbf{x}_{1:t}^{k'}\}$, $S = \{\mathbf{x}_t^k\} \cup \mathbf{x}_{t-1}^D \cup \mathbf{y}_{1:t}^k \cup \mathbf{y}_{1:t-1}^D$ is independent of the rest of the DBN because, by Definition 1, no active chain can pass through an arc outgoing from a node in a conditioning set and, removing from the DBN the arcs outgoing from $\{\mathbf{x}_{1:t}^{k'}\}$, S is not connected anymore to the rest of the DBN. For the same reason,

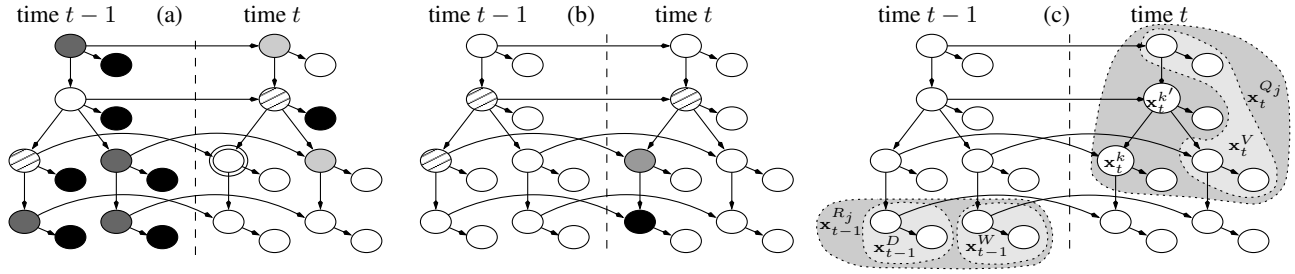

Figure 3: d-separation analysis.

$\mathbf{x}_t^V \cup \mathbf{x}_{t-1}^W \cup \mathbf{y}_{1:t}^V \cup \mathbf{y}_{1:t-1}^W$ is independent of the rest of the DBN conditionally to $\{\mathbf{x}_{1:t}^{k'}\}$. Therefore, the above integral is equal to:

$$\int p(\mathbf{x}_{1:t}^{k'}, \mathbf{y}_{1:t}^{k'})\, p(\mathbf{x}_t^k, \mathbf{x}_{t-1}^D, \mathbf{y}_{1:t}^k, \mathbf{y}_{1:t-1}^D | \mathbf{x}_{1:t}^{k'}) \; p(\mathbf{x}_t^V, \mathbf{x}_{t-1}^W, \mathbf{y}_{1:t}^V, \mathbf{y}_{1:t-1}^W | \mathbf{x}_{1:t}^{k'})\, d\mathbf{x}_{1:t-1}^{k'}. \quad (3)$$

Permuting particles over parts $\{\mathbf{x}_t^k\} \cup \mathbf{x}_{t-1}^D$ for fixed values of $\mathbf{x}_{1:t}^{k'}$ cannot change the estimation of density $p(\mathbf{x}_t^k, \mathbf{x}_{t-1}^D, \mathbf{y}_{1:t}^k, \mathbf{y}_{1:t-1}^D | \mathbf{x}_{1:t}^{k'})$ because estimations by samples are insensitive to the order of the elements in the samples. Moreover, it can neither affect the estimation of density $p(\mathbf{x}_t^V, \mathbf{x}_{t-1}^W, \mathbf{y}_{1:t}^V, \mathbf{y}_{1:t-1}^W | \mathbf{x}_{1:t}^{k'})$ since $\mathbf{x}_t^V \cup \mathbf{x}_{t-1}^W \cup \mathbf{y}_{1:t}^V \cup \mathbf{y}_{1:t-1}^W$ is independent of $\{\mathbf{x}_t^k\} \cup \mathbf{x}_{t-1}^D$ conditionally to $\{\mathbf{x}_{1:t}^{k'}\}$. Consequently, applying permutation σ on parts $\{\mathbf{x}_t^k\} \cup \mathbf{x}_{t-1}^D$ does not change the estimation of Eq. (3) and, therefore, of $p(\mathbf{x}_t^{Q_j}, \mathbf{x}_{t-1}^{R_j} | \mathbf{y}_{1:t-1}, \mathbf{y}_t^{Q_j})$. □

As shown in the next subsection, these permutations can be exploited at the resampling level to improve samples.

4.3 OUR RESAMPLING APPROACH

All the permutations satisfying Proposition 2 can be applied to the particle set without altering the estimation of the posterior density. For instance, let $\mathbf{x}_t^{(1)}$ and $\mathbf{x}_t^{(2)}$ be two particles whose torso positions are identical, then swapping their left arm and forearm positions $(\mathbf{x}_t^2, \mathbf{x}_{t-1}^3)$ cannot alter the density estimation. Similarly, the latter is unaffected by duplications of all the particles within a particle set. This leads to Combinatorial Resampling:

Definition 2 (Combinatorial Resampling) *Let S be the particle set at the jth step of Algo. 1. For any $k \in P_j$, let Σ_k be the set of permutations satisfying Proposition 2. Let $\Sigma = \prod_{k \in P_j} \Sigma_k$. Let $S' = \cup_{\sigma \in \Sigma}\{$particle set resulting from the application of σ to $S\}$. Combinatorial resampling consists of applying any resampling algorithm over the combinatorial set S' instead of S.*

On the example of Fig. 2, let $\mathbf{x}_t^{(1)} = \langle 1, 2, 3, 4, 5, 6\rangle$, $\mathbf{x}_t^{(2)} = \langle 1, 2', 3', 4', 5', 6'\rangle$ and $\mathbf{x}_t^{(3)} = \langle 1'', 2'', 3'', 4'', 5'', 6''\rangle$ be three particles, where each number, $1, 1'', 2, 2', 2''$, etc., corresponds to the state of a part in Fig. 2. Assume that $S = \{\mathbf{x}_t^{(1)}, \mathbf{x}_t^{(2)}, \mathbf{x}_t^{(3)}\}$ at the 2nd step of Algo. 1, i.e., the object parts just processed are $P_2 = \{2, 4, 6\}$. Parts $\{2, 3\}$, $\{4, 5\}$ and $\{6\}$ can be permuted in $\mathbf{x}_t^{(1)}$ and $\mathbf{x}_t^{(2)}$ because their torso, i.e. 1, are identical, hence S' is the union of the result of all such permutations over S and is thus equal to:

$\langle 1,2\ ,3\ ,4\ ,5\ ,6\ \rangle\ \langle 1,2',3',4',5',6'\rangle\ \langle 1'',2'',3'',4'',5'',6''\rangle$
$\langle 1,2\ ,3\ ,4\ ,5\ ,6'\rangle\ \langle 1,2',3',4',5',6\ \rangle\ \langle 1'',2'',3'',4'',5'',6''\rangle$
$\langle 1,2\ ,3\ ,4',5',6\ \rangle\ \langle 1,2',3',4\ ,5\ ,6'\rangle\ \langle 1'',2'',3'',4'',5'',6''\rangle$
$\langle 1,2\ ,3\ ,4',5',6'\rangle\ \langle 1,2',3',4\ ,5\ ,6\ \rangle\ \langle 1'',2'',3'',4'',5'',6''\rangle$
$\langle 1,2',3',4\ ,5\ ,6\ \rangle\ \langle 1,2\ ,3\ ,4',5',6'\rangle\ \langle 1'',2'',3'',4'',5'',6''\rangle$
$\langle 1,2',3',4\ ,5\ ,6'\rangle\ \langle 1,2\ ,3\ ,4',5',6\ \rangle\ \langle 1'',2'',3'',4'',5'',6''\rangle$
$\langle 1,2',3',4',5',6\ \rangle\ \langle 1,2\ ,3\ ,4\ ,5\ ,6'\rangle\ \langle 1'',2'',3'',4'',5'',6''\rangle$
$\langle 1,2',3',4',5',6'\rangle\ \langle 1,2\ ,3\ ,4\ ,5\ ,6\ \rangle\ \langle 1'',2'',3'',4'',5'',6''\rangle$

Constructing S' in extension is impossible in practice because $|\Sigma|$ grows exponentially with N, the number of particles. Fortunately, we can sample over S' without actually constructing it. We shall explain the idea on the particle set S illustrated on Fig. 4, which corresponds to the object of Fig. 2 in which we omitted the head part for clarity reasons. Assume that parts $P_j = \{3, 5\}$, i.e., the forearms, have just been processed and we wish to sample over combinatorial sample S' induced by S. To construct a new particle, the idea is to first select a value for the parts in Q_{j-1}, i.e., those processed at previous steps by PF and in which no permutation will occur. Here, $Q_{j-1} = \{1, 2, 4\}$. We thus first determine the different values of $\mathbf{x}_t^{Q_{j-1}}$ in S and partition S into sets $S_1, \ldots, S_R$ such that all the particles in each set S_h have the same value for $\mathbf{x}_t^{Q_{j-1}}$ (see Fig. 4). In this figure, S_1 thus contains the first two particles since their values on $\mathbf{x}_t^{Q_{j-1}}$ are both $\langle 1, 0, 3\rangle$. To each such set S_h is assigned a weight W_h defined below so that picking the value of $\mathbf{x}_t^{Q_{j-1}}$ in S_h w.r.t. weight W_h results in a particle set estimating the same distribution as that of S. Once the value of $\mathbf{x}_t^{Q_{j-1}}$ has been chosen, there just remains to pick independently values for each $\mathbf{x}_t^k$ and their descendants, $k \in P_j$, that are compatible with that chosen for $\mathbf{x}_t^{Q_{j-1}}$. Thus, for any $h \in \{1, \ldots, R\}$, let S_h^k denote the set of particles in S whose kth part value is compatible with the value of $\mathbf{x}_t^{Q_{j-1}}$ in S_h. By Proposition 2, S_h^k is the set of particles in S that have the same value of $\mathbf{Pa}_t(\mathbf{x}_t^k)$ as those in S_h. For instance, in Fig. 4, S_1^3 is the set of the first 3 particles because all of them have value 1 on part 2.

Now, to determine the aforementioned weights W_h, there just needs to count how many times the combinatorial set has duplicated S_h. So, let $N_1, \ldots, N_R$ and $N_1^k, \ldots, N_R^k$ denote the sizes of $S_1, \ldots, S_R$ and $S_1^k, \ldots, S_R^k$ respectively. Finally, let $N^k = \max\{N_1^k, \ldots, N_R^k\}$ and, for any $h \in \{1, \ldots, R\}$, let W_h^k denote the sum of the weights assigned to the kth part of the particles in S_h^k, i.e., $W_h^k = \sum_{\mathbf{x}_t^{(i)} \in S_h^k} w^{(i),k}$. Then, as proved below, for any h,

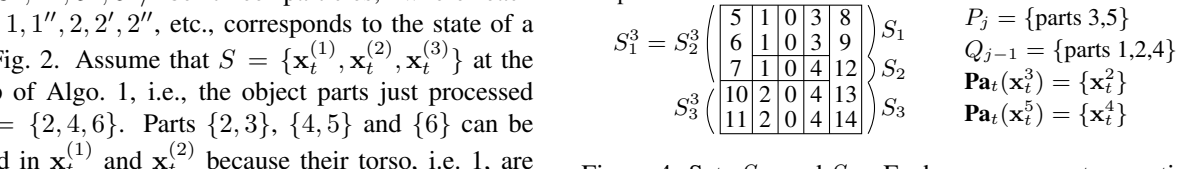

Figure 4: Sets $S_{\mathbf{i}_h}$ and $S_{\mathbf{i}_h^k}$. Each row represents a particle $\mathbf{x}_t^{(i)}$ and each number a value $\mathbf{x}_t^{(i),j}$ of part j of the particle.

Input: A particle set $\{(\mathbf{x}_t^{(i),Q_j}, \mathbf{x}_{t-1}^{(i),R_j}), w_t^{(i)}\}_{i=1}^N$

Output: A new particle set $\{(\mathbf{x}_t^{\prime\prime(i),Q_j}, \mathbf{x}_{t-1}^{\prime\prime(i),R_j}), w_t^{\prime\prime(i)}\}_{i=1}^N$

1 **for** $i = 1$ **to** N **do**
2 $\quad h \leftarrow$ sample $\{1, \ldots, R\}$ w.r.t. weights $W_1, \ldots, W_R$
3 $\quad \mathbf{x}_t^{\prime\prime(i),Q_{j-1}} \leftarrow \mathbf{x}_t^{(z),Q_{j-1}}$ where $\mathbf{x}_t^{(z)}$ is any element in S_h
4 $\quad w_t^{\prime\prime(i)} \leftarrow 1$
5 $\quad$ **foreach** k **in** P_j **do**
6 $\quad\quad \mathbf{x}_t^{(r)} \leftarrow$ sample from S_h^k w.r.t. weights $\{w_t^{(r),k}\}_{\mathbf{x}_t^r \in S_h^k}$
7 $\quad\quad \mathbf{x}_t^{\prime\prime(i),k} \leftarrow \mathbf{x}_t^{(r),k}$; $\quad w_t^{\prime\prime(i)} \leftarrow w_t^{\prime\prime(i)} \times w_t^{(r),k}$
8 $\quad\quad \mathbf{x}_{t-1}^{\prime\prime(i),\mathbf{Desc}_{t-1}(\mathbf{x}_{t-1}^k)} \leftarrow \mathbf{x}_{t-1}^{(r),\mathbf{Desc}_{t-1}(\mathbf{x}_{t-1}^k)}$
9 **return** $\{\mathbf{x}_t^{\prime\prime(i)}, w^{\prime\prime(i)}\}_{i=1}^N$

Algorithm 2: Efficient resampling over S'.

$$W_h = N_h \times \prod_{k \in P_j} \frac{N^k!}{A_{N_h^k}^{N_h}} \times A_{N_h^k - 1}^{N_h - 1} \times W_h^k, \qquad (4)$$

where $A_n^k = n!/(n-k)!$ stands for the number of k-permutations out of n elements. Resampling over S' can thus be performed efficiently as in Algo. 2. To scale-up to large particle sets, $\log(W_h)$ should be computed instead of W_h and the weights used in line 2 of Algo. 2 should be $\exp(\log W_h - \log W)$, where $W = \max\{W_1, \ldots, W_R\}$.

Proposition 3 *Algorithm 2 produces a particle set estimating the same density as that given in input.*

Proof: Let $S = \{(\mathbf{x}_t^{(i),Q_j}, \mathbf{x}_{t-1}^{(i),R_j})\}_{i=1}^N$ and S' its combinatorial set (see Def. 2). In lines 2–3, Algo. 2 selects which central part Q_{j-1} particle $\mathbf{x}_t''$ should have. By definition, this amounts to selecting one set S_h w.r.t. the sum of the weights of the particles in S' having the same central part as those in S_h. Let us show that this is achieved using the weights described in Eq. (4).

In Definition 2, Σ_k is the set of all the possible permutations of the kth part of the particles in S. Clearly, within each set S_h^k, all the $N_h^k!$ permutations of the kth part of the particles of this set are admissible. They form the cycles within the permutations of Σ_k and, as such, a given permutation σ over S_h^k shall appear many times within Σ_k. There is no need to count precisely how many times σ is repeated, what is important is that the repeated sets of particles estimate the same density as S. To do so, remark that $N^k = \max\{N_1^k, \ldots, N_R^k\}$ is the size of the biggest set $S_1^k, \ldots, S_R^k$. Applying all the permutations over this set multiplies its size by $N^k!$, so the size of all the other sets should be multiplied by the same amount. Duplicating $N^k!/N_h^k!$ permutation σ guarantees that all the Q_{j-1}-central parts of the particles in S are duplicated the same number of times. Now, the particles in S_h also belong to S_h^k. As $|S_h| = N_h$, there are $A_{N_h^k}^{N_h}$ different possibilities to assign some k-part of S_h^k to the particles of S_h. The number of times these permutations are repeated within those over S_h^k is thus $N_h^k!/A_{N_h^k}^{N_h}$. Hence, duplicating $(N^k!/N_h^k!) \times (N_h^k!/A_{N_h^k}^{N_h}) = N^k!/A_{N_h^k}^{N_h}$ times the permutations over S_h ensures that the particle set estimates the same density as S. The same applies to all the other parts in P_j, hence the product in Eq. (4).

Now, let us compute the sum of the weights of the particles resulting from all the permutations over S_h. Each such permutation generates a new set of N_h particles. By symmetry, if $\mathbf{W}$ is the sum of the weights of the first particle in each set, call it $\mathbf{x}_t^{(i)}$, then the overall sum we look for is $N_h \times \mathbf{W}$. As permutations over the parts in P_j are independent, $\mathbf{W}$ is equal to the product over parts $k \in P_j$ of the sum $\mathbf{W}^k$ of the weights induced by all the permutations over the kth part, i.e., the permutations over S_h^k. By symmetry, any weight in S_h^k can be assigned to $\mathbf{x}_t^{(i)}$, hence $\mathbf{W}^k$ is equal to the sum of all these weights, W_h^k, times the number $\mathbf{O}$ of occurrences of each weight induced by all the permutations over S_h^k. For instance, if there are 3 weights 1,2,3, then there are $\mathbf{O} = 2$ permutations where the first particle as a weight of 1: $\langle 1, 2, 3\rangle$ and $\langle 1, 3, 2\rangle$. Once particle $\mathbf{x}_t^{(i)}$ has been assigned a weight, there remains $N_h - 1$ weights to assign to the other particles from a set of $N_h^k - 1$ weights, hence there are $\mathbf{O} = A_{N_h^k - 1}^{N_h - 1}$ possibilities. Overall, $\mathbf{W}^k$ is thus equal to $W_h^k \times A_{N_h^k - 1}^{N_h - 1}$ and we get Eq. (4).

So, lines 2–3 select correctly the Q_{j-1} part. Once this is done, by d-separation, all the parts in P_j are independent and should be sampled w.r.t. $p(\mathbf{x}_t^k | \mathbf{Pa}_t(\mathbf{x}_t^k))$, which is done in lines 5–8 since $p(\mathbf{x}_t^k | \mathbf{Pa}_t(\mathbf{x}_t^k)) \propto w_t^{(i),k}$. □

We shall now provide some experiments highlighting the efficiency of our resampling scheme.

5 EXPERIMENTATIONS

We performed experiments on synthetic data in order to create sequences varying the criteria whose impact on our algorithm's efficiency are the most important, i.e. the number of parts processed in parallel and the length of the object's arms. As such, this resulted in a fine picture of the behaviors of our algorithm. These results are given in Subsection 5.1. Of course, our algorithm is also effective on real sequences. This is illustrated in Subsection 5.2.

For both cases, articulated objects are modeled by a set of P polygonal parts (or regions): a central one P_1 (containing only one polygon) to which are linked $|P_j|, j > 1$, arms of length $K - 1$ (see Fig. 5 for some examples). The polygons are manually positioned in the first frame. State vectors contain the parameters describing all the parts and are defined by $\mathbf{x}_t = \{\mathbf{x}_t^1, \ldots, \mathbf{x}_t^P\}$, with $\mathbf{x}_t^k = \{x_t^k, y_t^k, \theta_t^k\}$, where (x_t^k, y_t^k) is the center of part k, and θ_t^k is its orientation, $k = 1, \ldots, P$. We thus have $|\mathcal{X}| = 3P$. A particle $\mathbf{x}_t^{(i)} = \{\mathbf{x}_t^{(i),1}, \ldots, \mathbf{x}_t^{(i),P}\}$, $i = 1, \ldots, N$, is a possible spatial configuration, i.e., a realization, of the ar-

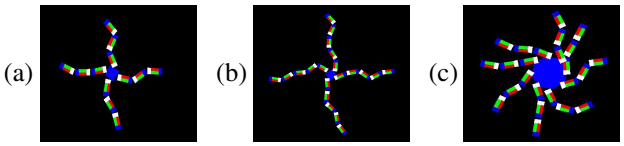
ticulated object. Particles are propagated using a random walk whose variances σ_x, σ_y and σ_θ have been empirically fixed. Particle weights are computed by measuring the similarity between the distribution of pixels in the region of the estimated part of the object and that of the corresponding reference region using the Bhattacharyya distance [Bhattacharyya, 1943]. The particle weights are then computed by $w_{t+1}^{(i)} = w_t^{(i)} p(\mathbf{y}_{t+1}|\mathbf{x}_{t+1}^{(i)}) \propto w_t^{(i)} e^{-\lambda \mathbf{d}^2}$, with, in our tests, $\lambda = 50$ and $\mathbf{d}$ the Bhattacharyya distance between the target (prior) and the reference (previously estimated) 8-bin histograms. The articulated object's distribution is estimated starting from its central part P_1.

5.1 TESTS ON SYNTHETIC VIDEO SEQUENCES

We have generated our own video sequences composed of 300 frames of 800×640 pixels. Each video displays an articulated object randomly moving and deforming over time, subject to either weak or strong motions. Some examples are given in Fig. 5. With various numbers of parts, the articulated objects are designed to test the ability of resampling to deal with high-dimensional state spaces.

We compare six different resampling approaches. The first five (multinomial, systematic, stratified, residual and weighted resampling) are integrated into PS. PS propagates and corrects particles polygon after polygon to derive a global estimation of the object. For combinatorial resampling, the object's arms are considered independent conditionally to the central part and, thus, the P_j parts, $j > 1$, correspond to the jth joints of all the arms. For weighted resampling, function g is set empirically to $g(w) = e^{20w}$ to favor the selection of high-weighted particles over low-weighted ones. Results are compared w.r.t. two criteria: computation times and estimation errors, defined as the sum of the Euclidean distances between each corner of the estimated parts and its sibling in the ground truth. For all these tests, we fixed $\sigma_x = \sigma_y = 1$ pixel and $\sigma_\theta = 0.025$ rad. All the results presented are a mean over 30 runs performed on a MacBook Pro with a 2.66 GHz Intel Core i7.

We first compared the estimation errors. Fig 6.(a-c) show a convergence study of the resampling methods depending on the number N of particles for the 3 objects of Fig. 5. For



(a) $K = 4, |P_j| = 4$, $P = 13, |\mathcal{X}| = 39$ (b) $K = 6, |P_j| = 4$, $P = 21, |\mathcal{X}| = 63$ (c) $K = 4, |P_j| = 8$, $P = 25, |\mathcal{X}| = 125$

Figure 5: Excerpts of frames from our synthetic video sequences, and the features of the corresponding articulated objects (number of arms $|P_j|$, $j > 1$, length of arms $K - 1$, total number of parts P, and dimension of state space $\mathcal{X}$).

all these tests, combinatorial resampling (CR) outperforms all the other methods: i) it converges faster (about only $N = 100$ particles are necessary to do so) when the other methods often require 300 particles to converge; ii) CR's error at convergence is much lower than that of the other methods. For instance, in Fig.6(a), CR reaches the convergence error of the other methods (about 230 pixels) with only $N = 20$ particles and, with 100 particles, its error decreases to 112 pixels. When the length of the arms (given by K) increases (Fig 6(b)), CR stays robust, whereas multinomial, systematic, stratified and residual resampling tend to fail (estimation errors twice higher). Weighted resampling seems more stable, but gives estimation errors 25% higher than those of CR. Finally, when the number of parts treated in parallel increases (Fig 6(c)), CR stays stable: with only $N = 20$ particles, its estimation error is 2.5 to 3 times lower than the one of other resampling approaches.

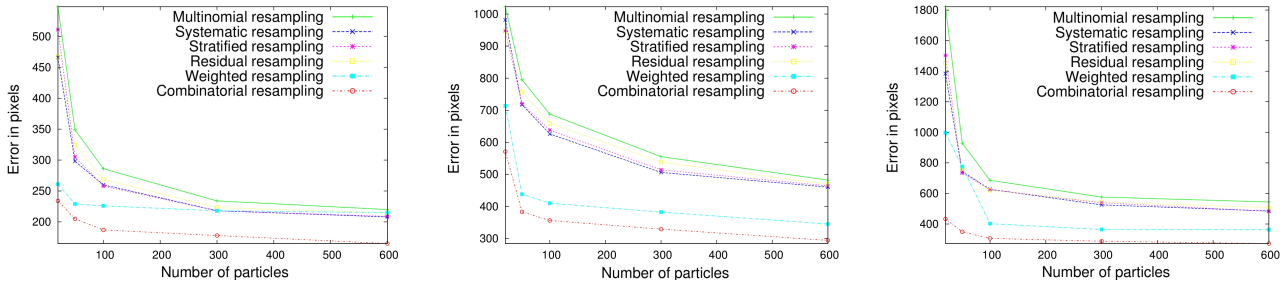
Finally, resampling times (in seconds) over the whole sequences, are reported in Table 1 for the estimation of the densities of the objects of Fig. 5(a-c) with $N = \{100, 600\}$ particles. The first four resampling approaches have similar behaviors. Due to its additional step ensuring that weights are equal to $1/N$, which is required by Algo. 1, weighted resampling is longer. The best approach is CR when the number of particles is high (600) and when the size of the P_j's is high. For instance, when tracking the object of Fig. 5(c) (8 parts processed simultaneously), the resampling times are considerably lower with CR than with the other methods. This is due to the fact that, by processing several object parts simultaneously, the number of resamplings performed is significantly reduced. Hence, even if performing CR once is longer than performing another method, overall, CR is globally faster. Note also that CR's response times increase more slowly with N than the other methods. Finally, when K increases (Fig. 5(b)), our approach also provides significantly smaller resampling times when N becomes high.

5.2 TESTS ON REAL VIDEO SEQUENCES

We tested our approach on sequences from the UCF50 dataset (http://server.cs.ucf.edu/∼vision/data/UCF50.rar), to demonstrate the efficiency of our combinatorial resampling to make the particle set better focus on the modes

Table 1: Resampling times (in seconds) for the estimation of the density of different objects, with $N = \{100, 600\}$.

	Fig. 5.a		Fig. 5.b		Fig. 5.c	
	100	600	100	600	100	600
Multinomial	0.5	17.1	1.3	46.9	1.8	79.6
Systematic	0.5	19.8	1.2	53.6	1.7	80.5
Stratified	0.5	16.9	1.3	44.8	1.7	74.9
Residual	0.5	20.3	1.3	55.7	1.8	83.4
Weighted	1.0	33.0	2.5	90.1	3.5	157.8
Combinatorial	0.7	10.6	1.5	26.3	1.5	22.3



(a) (b) (c)

Figure 6: Comparison of convergence for different resampling approaches: errors of estimation of the density of objects depending on N: (a) with $|P_i| = 4$, $K = 4$ (object of Fig. 5.(a)), (b) with $|P_i| = 4$, $K = 6$ (object of Fig. 5.(b)) and (c) with $|P_i| = 8$, $K = 4$ (object of Fig. 5.(c)).

Figure 7: Tracking results on `JumpRope` sequence with $N = 500$ particles (frames 10, 50, 121 and 234). First line, using residual resampling, last line, using our combinatorial resampling.

of the densities to estimate. This feature holds even when there are wide movements over time and when images have a low resolution. Qualitative results are given by superimposing on the frames of the sequences a red articulated object corresponding to the estimation derived from the weighted sum of the particles. For this test, we fixed $\sigma_x = \sigma_y = 2$ pixels and $\sigma_\theta = 0.08$ rad.

Figure 7 shows tracking results on the `JumpRope` sequence (containing 290 frames of 320×240 pixels) with $N = 500$ particles. In this sequence, a person is quickly moving from left to right while jumping, and crossing/uncrossing his arms and legs. For this test, we defined an articulated object with $P = 12$ parts, hence $|\mathcal{X}| = 36$, and we compared the estimations resulting from PS with a residual resampling (top line) with those resulting from our proposed resampling approach (bottom line). As can be observed, our approach produces better results: its estimations are more stable along the sequence. For example, on the images of the 2nd and 3rd columns, we can see the estimation of the articulated object fails with residual resampling but is correct with our combinatorial resampling. For this sequence, on average over 20 runs, our method needed 16 seconds while residual resampling needed 22. In addition, our algorithm proved to be more robust and provided more accurate results. As for synthetic sequences, our tests show that the higher the number of particles, the more our algorithm outperforms residual resampling in terms of response time. It is also always more accurate.

6 CONCLUSION

In this paper, we have introduced a new resampling method called *Combinatorial Resampling*. From a given sample S, this algorithm constructs implicitly a new sample S' exponentially larger than S. By construction, S' is more representative than S of the density over the whole state space and resampling from S' rather than S produces much better results, as confirmed by our experiments. We proved the mathematical correctness of the method and showed that it is effective for real time tracking. For future researches, there remains to exhibit theoretical convergence results for PS combined with this new resampling scheme.

Abstract

We present and prove properties of a new offline policy evaluator for an exploration learning setting which is superior to previous evaluators. In particular, it simultaneously and correctly incorporates techniques from importance weighting, doubly robust evaluation, and nonstationary policy evaluation approaches. In addition, our approach allows generating longer histories by careful control of a bias-variance tradeoff, and further decreases variance by incorporating information about randomness of the target policy. Empirical evidence from synthetic and real-world exploration learning problems shows the new evaluator successfully unifies previous approaches and uses information an order of magnitude more efficiently.

1 Introduction

We are interested in the "contextual bandit" setting, where on each round:

1. A vector of features (or "context") $x \in \mathcal{X}$ is revealed.
2. An action (or arm) a is chosen from a given set $\mathcal{A}$.
3. A reward $r \in [0,1]$ for the action a is revealed, but the rewards of other actions are not. In general, the reward may depend stochastically on x and a.

This setting is extremely natural, because we commonly make decisions based on some contextual information and get feedback about that decision, but not about other decisions. Prominent examples are the ad display problems at Internet advertising engines [15, 7], content recommendation on Web portals [18], as well as adaptive medical treatments. Despite a similar need for exploration, this setting is notably simpler than full reinforcement learning [25], because there is no temporal credit assignment problem—each reward depends on the current context and action only, not on previous ones.

The goal in this setting is to develop a good *policy* for choosing actions. In this paper, we are mainly concerned with *nonstationary* policies which map the current context and a history of past rounds to an action (or a distribution of actions). Note that as a special case we cover also *stationary* policies, whose actions depend on the currently observed context alone. While stationary policies are often sufficient in supervised learning, in situations with partial feedback, the most successful policies need to remember the past, i.e., they are nonstationary.

The gold standard of performance here is deploying a policy and seeing how well it actually performs. This standard can be very expensive in industrial settings and often impossible in academic settings. These observations motivate us to construct methods for scoring policies *offline* using recorded information from previously deployed policies. As a result, we can dramatically reduce the cost of deploying a new policy while at the same time rapidly speeding up the development phase through the use of benchmarks, similar to supervised learning (e.g., the UCI repository [1]) and *off-policy* reinforcement learning [21]. We would like our method to be as general and rigorous as possible, so that it could be applied to a broad range of policies.

An offline policy evaluator is usually only useful when the future behaves like the past, so we make an IID assumption: the contexts are drawn IID from an unknown distribution $D(x)$, and the conditional distribution of rewards $D(r|x,a)$ does not change over time (but is unknown). In our intended applications like medical treatments or Internet advertising, this is a reasonable assumption.

Below, we identify a few desiderata for an offline evaluator:

- *Low estimation error.* This is the first and foremost desideratum. The error typically comes from two sources—bias (due to covariate shift and/or insufficient expressivity) and variance (insufficient number of samples). Successful methods allow optimization

[*]This work was done while MD, JL, and LL were at Yahoo! Research.

of the tradeoff between these two components.

- *Incorporation of a prior reward estimator.* The evaluator should be able to take advantage of a reasonable reward estimator whenever it is available.
- *Incorporation of "scavenged exploration."* The evaluator should be able to take advantage of *ad hoc* past deployment data, with the quality of such data determining the bias introduced.

Existing Methods. Several prior evaluators have been proposed. We are going to improve on all of them.

- The direct method (DM) first builds a reward estimator $\hat{r}(x, a)$ from logged data that predicts the average reward of choosing action a in context x, and then evaluates a policy against the estimator. This straightforward approach is flexible enough to evaluate any policy, but its evaluation quality relies critically on the accuracy of the reward estimator. In practice, learning a highly accurate reward estimator is extremely challenging, rendering high bias in the evaluation results.
- Inverse Propensity Scoring (IPS) [11] and importance weighting require the log of past deployment that includes for each action the probability p with which it was chosen. The expected reward of policy π is estimated by $\frac{rI(\pi(x)=a)}{p}$, where $I(\cdot)$ is the indicator function. This formula comes up in many contexts and is built into several algorithms for learning in this setting such as EXP4 [3]. The IPS evaluator can take advantage of scavenged exploration through replacing p by an estimator $\hat{p}$ [16, 24], but it does not allow evaluation of nonstationary policies and does not take advantage of a reward estimator.
- Doubly Robust (DR) Policy Evaluation [6, 23, 22, 20, 13, 7, 8] incorporates a (possibly biased) reward estimator in the IPS approach according to:

$$(r - \hat{r}(x, a))I(\pi(x) = a)/p + \hat{r}(x, \pi(x)) \ , \quad (1.1)$$

  where $\hat{r}(x, a)$ is the estimator of the expected reward for context x and action a. The DR evaluator remains unbiased (for arbitrary reward estimator), and usually improves on IPS [8]. However, similar to IPS, it does not allow evaluation of nonstationary policies.
- Nonstationary Policy Evaluation [18, 19] uses rejection sampling (RS) to construct an unbiased history of interactions between the policy and the world. While this approach is unbiased, it may discard a large fraction of data through stringent rejection sampling, especially when the actions in the log are chosen from a highly non-uniform distribution. This can result in unacceptably large variance.

Contributions. In this paper, we propose a new policy evaluator that takes advantage of all good properties from the above approaches, while avoiding their drawbacks. As fundamental building blocks we use DR estimation, which is extremely efficacious in stationary settings, and rejection sampling, which tackles nonstationarity. We introduce two additional strategies for variance control:

- In DR, we harness the knowledge of the randomness in the evaluated policy ("revealed randomness"). Randomization is the preferred tool for handling the exploration/exploitation tradeoff and if not properly incorporated into DR, it would yield an increase in the variance. We avoid this increase without impacting bias.
- We substatially improve sample use (i.e., acceptance rate) in rejection sampling by modestly increasing the bias. Our approach allows an easy control of the bias/variance tradeoff.

As a result, we obtain an evaluator of nonstationary policies, which is extremely sample-efficient while taking advantage of reward estimators and scavenged exploration through incorporation into DR. Our incorporation of revealed randomness yields a favorable bonus: when the past data is generated by the same (or very similar) policy as the one evaluated, we accept all (or almost all) samples—a property called "idempotent self-evaluation."

After introducing our approach in Sec. 2, we analyze its bias and variance in Sec. 3, and finally present an extensive empirical evaluation in Sec. 4.

Algorithm 1 DR-ns(π, $\{(x_k, a_k, r_k, p_k)\}$, q, $c_{\max}$)

1. $h_0 \leftarrow \emptyset$, $t \leftarrow 1$, $c_1 \leftarrow c_{\max}$
   $R \leftarrow 0$, $C \leftarrow 0$, $Q \leftarrow \emptyset$
2. For $k = 1, 2, \ldots$ consider event (x_k, a_k, r_k, p_k)
   (a) $R_k \leftarrow \sum_{a'} \pi(a'|x_k, h_{t-1})\hat{r}(x_k, a') + \frac{\pi(a_k|x_k, h_{t-1})}{p_k} \cdot (r_k - \hat{r}(x_k, a_k))$
   (b) $R \leftarrow R + c_t R_k$
   (c) $C \leftarrow C + c_t$
   (d) $Q \leftarrow Q \cup \left\{ \frac{p_k}{\pi(a_k|x_k, h_{t-1})} \right\}$
   (e) Let $u_k \sim \text{Uniform}[0, 1]$
   (f) If $u_k \leq \frac{c_t \pi(a_k|x_k, h_{t-1})}{p_k}$
      i. $h_t \leftarrow h_{t-1} + (x_k, a_k, r_k)$
      ii. $t \leftarrow t + 1$
      iii. $c_t \leftarrow \min\{c_{\max}, \ q\text{-th quantile of } Q\}$
3. Return R/C

2 A New Policy Evaluator

Algorithm 1 describes our new policy evaluator DR-ns (for "doubly robust nonstationary"). Over the run of the algorithm, we process the past deployment data (exploration samples) and run rejection sampling (Steps 2e–2f) to create a simulated history h_t of the interaction between the

target policy and the environment. The algorithm returns the expected reward estimate R/C.

The algorithm takes as input a target policy to evaluate, exploration samples, and two scalars q and $c_{\max}$ which control the tradeoff between the length of h_t and bias. On each exploration sample, we use a modified DR to estimate $\mathbf{E}_\pi[r_t|x_t = x_k, h_{t-1}]$ (Step 2a). Compared with Eq. (1.1), we take advantage of revealed randomness.

The rate of acceptance in rejection sampling is controlled by the variable c_t that depends on two parameters: $c_{\max}$, controlling the maximum allowed acceptance rate, and q, which allows adaptive (policy-specific) adjustment of the acceptance rate. The meaning of q is motivated by unbiased estimation as follows: to obtain no bias, the value of c_t should never exceed the ratio $p_k/\pi(a_k|x_k, h_{t-1})$ (i.e., the right-hand side in Step 2f should never exceed one). During the run of the algorithm we keep track of the observed ratios (in Q), and q determines the quantile of the empirical distribution in Q, which we use as an upper bound for c_t. Setting $q = 0$, we obtain the unbiased case (in the limit). By using larger values of q, we increase the bias, but get longer sequences through increased acceptance rate. Similar effect is obtained by varying the value of $c_{\max}$, but the control is cruder, since it ignores the evaluated policy.

In reward estimation, we weigh the current DR estimate by the current acceptance rate, c_t (Step 2b). In unbiased case, for each simulated step t, we expect to accumulate multiple samples with the total weight of 1 in expectation. To obtain better scaling (similar to importance weighted methods), we also accumulate the sum of weights c_t in the variable C, and use them to renormalize the final estimate as R/C.

As a quick observation, if we let $c_{\max} = 1$ and evaluate a (possibly randomized nonstationary) policy on data that this policy generated, every event is accepted into the history regardless of q. Note that such aggressive all-accept strategy is unbiased for this specific "self-evaluation" setting and makes the maximal use of data. Outside self-evaluation, q has an effect on acceptance rate (stronger if exploration and target policy are more different). In our experiments, we set $c_{\max} = 1$ and rely on q to control the acceptance rate.

3 Analysis

We start with basic definitions and then proceed to analysis.

3.1 Definitions and Notation

Let $D(x)$ and $D(r|x, a)$ denote the unknown (conditional) distributions over contexts and over rewards. To simplify notation (and avoid delving into measure theory), we assume that rewards and contexts are taken from some countable sets, but our theory extends to arbitrary measurable context spaces $\mathcal{X}$ and arbitrary measurable rewards in $[0, 1]$. We assume that actions are chosen from a finite set $\mathcal{A}$ (this is a critical assumption). Our algorithm also uses an estimator of expected conditional reward $\hat{r}(x, a)$, but we do not require that this estimator be accurate. For example, one can define $\hat{r}(x, a)$ as a constant function for some value in $[0, 1]$; often the constant may be chosen 0.5 as the minimax optimum [4]. However, if $\hat{r}(x, a) \approx \mathbf{E}_D[r|x, a]$, then our value estimator will have a lower variance but unchanged bias [8]. In our analysis, we assume that $\hat{r}$ is fixed and determined before we see the data (e.g., by initially splitting the input dataset).

We assume that the input data is generated by some past (possibly nonstationary) policy, which we refer to as the "exploration policy." Contexts, actions, and rewards observed by the exploration policy are indexed by timesteps $k = 1, 2, \ldots$. The input data consists of tuples (x_k, a_k, r_k, p_k), where contexts and rewards are sampled according to D, and p_k is the logged probability with which the action a_k was chosen. In particular, we will *not* need to evaluate probabilities of choosing actions $a' \neq a_k$, nor require the full knowledge of the past policy, substantially reducing logging efforts.

Our algorithm augments tuples (x_k, a_k, r_k, p_k) by independent samples u_k from the uniform distribution over $[0, 1]$. A history up to the k-th step is denoted

$$z_k = (x_1, a_1, r_1, p_1, u_1, \ldots, x_k, a_k, r_k, p_k, u_k) \ ,$$

and an infinite history $(x_k, a_k, r_k, p_k, u_k)_{k=1}^{\infty}$ is denoted z. In our analysis, we view histories z as samples from a distribution μ. Our assumptions about data generation then translate into the assumption about factoring of μ as

$$\begin{aligned}\mu(x_k, a_k, r_k, p_k, u_k|z_{k-1}) \\ = D(x_k)\mu(a_k|x_k, z_{k-1})D(r_k|x_k, a_k) \\ I\left(p_k = \mu(a_k|x_k, z_{k-1})\right) U(u_k)\end{aligned}$$

where U is the uniform distribution over $[0, 1]$. Note that apart from the unknown distribution D, the only degree of freedom above is $\mu(a_k|x_k, z_{k-1})$, i.e., the unknown exploration policy.

When z_{k-1} is clear from the context, we use a shorthand μ_k for the distribution over the k-th tuple

$$\begin{aligned}&\mu_k(x, a, r, p, u) \\ &= \mu\left(x_k = x,\, a_k = a,\, r_k = r,\, p_k = p,\, u_k = u \;\middle|\; z_{k-1}\right) \ .\end{aligned}$$

We also write $\mathbf{P}_k^\mu$ and $\mathbf{E}_k^\mu$ for $\mathbf{P}_\mu[\cdot|z_{k-1}]$ and $\mathbf{E}_\mu[\cdot|z_{k-1}]$.

For the target policy π, we index contexts, actions, and rewards by t. Finite histories of this policy are denoted as

$$h_t = (x_1, a_1, r_1, \ldots, x_t, a_t, r_t)$$

and the infinite history is denoted h. Nonstationary policies depend on a history as well as the current context, and

hence can be viewed as describing conditional probability distributions $\pi(a_t|x_t, h_{t-1})$ for $t = 1, 2, \ldots$. In our analysis, we extend the nonstationary target policy π into a probability distribution over h defined by the factoring

$$\pi(x_t, a_t, r_t|h_{t-1}) = D(x_t)\pi(a_t|x_t, h_{t-1})D(r_t|x_t, a_t) \ .$$

Similarly to μ, we define shorthands $\pi_t(x, a, r)$, $\mathbf{P}_t^\pi$, $\mathbf{E}_t^\pi$.

We assume a continuous running of our algorithm on an infinite history z. For $t \geq 1$, let $\kappa(t)$ be the index of the t-th sample accepted in Step 2f; thus, κ converts an index in the target history into an index in the exploration history. We set $\kappa(0) = 0$ and define $\kappa(t) = \infty$ if fewer than t samples are accepted. Note that κ is a deterministic function of the history z. For simplicity, we assume that for every t, $\mathbf{P}_\mu[\kappa(t) = \infty] = 0$. This means that the algorithm generates a distribution over histories h, we denote this distribution $\hat{\pi}$.

Let $B(t) = \{\kappa(t-1)+1, \kappa(t-1)+2, \ldots, \kappa(t)\}$ for $t \geq 1$ denote the set of sample indices between the $(t-1)$-st acceptance and the t-th acceptance. This set of samples is called the t-th block. The inverse operator identifying the block of the k-th sample is $\tau(k) = t$ such that $k \in B(t)$. The contribution of the t-th block to the value estimator is denoted $R_{B(t)} = \sum_{k \in B(t)} R_k$. In our analysis, we assume a completion of T blocks, and consider both normalized and unnormalized estimators:

$$R = \sum_{t=1}^{T} c_t R_{B(t)} \ , \quad \tilde{R}^{\text{avg}} = \frac{\sum_{t=1}^{T} c_t R_{B(t)}}{\sum_{t=1}^{T} c_t |B(t)|} \ .$$

3.2 Bias Analysis

Our goal is to develop an accurate estimator. Ideally, we would like to bound the error as a function of an increasing number of exploration samples. For nonstationary policy, it can be easily shown that a single simulation trace of a policy can yield reward that is bounded away by 0.5 from the expected reward regardless of the length of simulation (see, e.g., Example 3 in [19]). Hence, even for unbiased methods, we cannot accurately estimate the expected reward from a single trace.

A simple (but wasteful) approach is to divide the exploration samples into several parts, run the algorithm separately on each part, obtaining estimates $R^{(1)}, \ldots, R^{(m)}$, and return the average $\sum_{i=1}^{m} R^{(i)}/m$. (We only consider the unnormalized estimator in this section. We assume that the division into parts is done sequentially, so that each estimate is based on the same number of blocks T.) Using standard concentration inequalities, we can then show that the average is within $O(1/\sqrt{m})$ of the expectation $\mathbf{E}_\mu[R]$. The remaining piece is then bounding the bias term $\mathbf{E}_\mu[R] - \mathbf{E}_\pi\left[\sum_{t=1}^{T} r_t\right]$.

Recall that $R = \sum_{t=1}^{T} c_t R_{B(t)}$. The source of bias are events when c_t is not small enough to guarantee that $c_t\pi(a_k|x_k, h_{t-1})/p_k$ is a probability. In this case, the probability that the k-th exploration sample is accepted is

$$p_k \min\left\{1, \tfrac{c_t\pi(a_k|x_k,h_{t-1})}{p_k}\right\} = \min\left\{p_k, c_t\pi(a_k|x_k, h_{t-1})\right\},$$

which violates the unbiasedness requirement that the probability of acceptance be proportional to $\pi(a_k|x_k, h_{t-1})$.

Let $\mathcal{E}_k$ denote this "bad" event (conditioned on z_{k-1} and the induced target history h_{t-1}):

$$\mathcal{E}_k = \{(x, a) : c_t\pi_t(a|x) > \mu_k(a|x)\} \ .$$

Associated with this event is the "bias mass" ε_k:

$$\varepsilon_k = \mathop{\mathbf{P}}_{(x,a)\sim\pi_t}[\mathcal{E}_k] - \mathop{\mathbf{P}}_{(x,a)\sim\mu_k}[\mathcal{E}_k]/c_t \ .$$

Notice that from the definition of $\mathcal{E}_k$, this mass is nonnegative. Since the first term is a probability, this mass is at most 1. We assume that this mass is bounded away from 1, i.e., that there exists ε such that for all k and z_{k-1} we have the bound $0 \leq \varepsilon_k \leq \varepsilon < 1$.

The following theorem analyzes how much bias is introduced in the worst case, as a function of ε. Its purpose is to identify the key quantities that contribute to the bias, and to provide insights of what to optimize in practice.

Theorem 1. *For $T \geq 1$,*

$$\left|\mathbf{E}_\mu\left[\sum_{t=1}^{T} c_t R_{B(t)}\right] - \mathbf{E}_\pi\left[\sum_{t=1}^{T} r_t\right]\right| \leq \frac{T(T+1)}{2} \cdot \frac{\varepsilon}{1-\varepsilon} \ .$$

Intuitively, this theorem says that if a bias of ε is introduced in round t, its effect on the sum of rewards can be felt for $T - t$ rounds. Summing over rounds, we expect to get an $O(\varepsilon T^2)$ effect on the unnormalized bias in the worst case or equivalently a bias of $O(\varepsilon T)$ on the average reward. In general a very slight bias can result in a significantly better acceptance rate, and hence longer histories (or more replicates $R^{(i)}$).

This theorem is the first of this sort for policy evaluators, although the mechanics of proving correctness are related to the proofs for model-based reinforcement-learning agents in MDPs (e.g., [14]). A key difference here is that we depend on a context with unbounded complexity rather than a finite state space.

Before proving Theorem 1, we state two technical lemmas (for proofs see Appendix B). Recall that $\hat{\pi}$ denotes the distribution over target histories generated by our algorithm.

Lemma 1. *Let $t \geq 1$, $k \geq 1$ and let z_{k-1} be such that $\kappa(t-1) = k-1$. Let h_{t-1} and c_t be the target history and acceptance ratio induced by z_{k-1}. Then:*

$$\sum_{x,a} \left|\mathbf{P}_k^\mu[x_{\kappa(t)} = x, a_{\kappa(t)} = a] - \pi_t(x, a)\right| \leq \frac{2\varepsilon}{1-\varepsilon} \ ,$$

$$\left|c_t\mathbf{E}_k^\mu[R_{B(t)}] - \mathbf{E}_t^\pi[r_t]\right| \leq \frac{\varepsilon}{1-\varepsilon} \ .$$

Lemma 2. $\sum_{h_T} |\hat{\pi}(h_T) - \pi(h_T)| \leq (2\varepsilon T) / (1-\varepsilon)$.

Proof of Theorem 1. We first bound a single term $|\mathbf{E}_{z\sim\mu}[c_t R_{B(t)}] - \mathbf{E}_{h\sim\pi}[r_t]|$ using the previous two lemmas, the triangle inequality and Hölder's inequality:

$$\begin{aligned}
&\left|\mathbf{E}_{z\sim\mu}[c_t R_{B(t)}] - \mathbf{E}_{h\sim\pi}[r_t]\right| \\
&= \left|\mathbf{E}_{z\sim\mu}\left[c_t \mathbf{E}^{\mu}_{\kappa(t)}[R_{B(t)}]\right] - \mathbf{E}_{h\sim\pi}[r_t]\right| \\
&\leq \left|\mathbf{E}_{z\sim\mu}\left[\mathbf{E}^{\pi}_t[r_t]\right] - \mathbf{E}_{h\sim\pi}\left[\mathbf{E}^{\pi}_t[r_t]\right]\right| + \frac{\varepsilon}{1-\varepsilon} \\
&= \left|\mathop{\mathbf{E}}_{h_{t-1}\sim\hat{\pi}}\left[\mathbf{E}^{\pi}_t\left[r-\frac{1}{2}\right]\right] - \mathop{\mathbf{E}}_{h_{t-1}\sim\pi}\left[\mathbf{E}^{\pi}_t\left[r-\frac{1}{2}\right]\right]\right| + \frac{\varepsilon}{1-\varepsilon} \\
&\leq \frac{1}{2}\sum_{h_{t-1}}\left|\hat{\pi}(h_{t-1}) - \pi(h_{t-1})\right| + \frac{\varepsilon}{1-\varepsilon} \\
&\leq \frac{1}{2}\cdot\frac{2\varepsilon(t-1)}{1-\varepsilon} + \frac{\varepsilon}{1-\varepsilon} = \frac{\varepsilon t}{1-\varepsilon} \ .
\end{aligned}$$

The theorem now follows by summing over t and using the triangle inequality. □

3.3 Progressive Validation

While the bias analysis in the previous section qualitatively captures the bias-variance tradeoff, it cannot be used to construct an explicit error bound. The second and perhaps more severe problem is that even if we had access to a more explicit bias bound, in order to obtain *deviation* bounds, we would need to decrease the length of generated histories by a significant factor (at least according to the simple approach discussed at the beginning of the previous section).

In this section, we show how we can use a single run of our algorithm to construct a stationary policy, whose value is estimated with an error $O(1/\sqrt{n})$ where n is the number of original exploration samples. Thus, in this case we get explicit error bound and much better sample efficiency.

Assume that the algorithm terminates after fully generating T blocks. We will show that the value R/C returned by our algorithm is an unbiased estimate of the expected reward of the randomized stationary policy π_{PV} defined by:

$$\pi_{\text{PV}}(a|x) = \sum_{t=1}^{T} \frac{c_t|B(t)|}{C}\pi(a|x, h_{t-1}) \ .$$

Conceptually, this policy first picks among the histories h_0, $\ldots$, h_{T-1} with probabilities $c_1|B(1)|/C, \ldots, c_t|B(T)|/C$, and then executes the policy π given the chosen history. We extend π_{PV} to a distribution over triples

$$\pi_{\text{PV}}(x, a, r) = D(x)\pi_{\text{PV}}(a|x)D(r|x, a) \ .$$

To analyze our estimator, we need to assume that during the run of the algorithm, the ratio $\pi_t(a_k|x_k)/\mu_k(a_k|x_k)$ is bounded, i.e., we assume there exists $M < \infty$ such that

$$\forall z,\ \forall t \geq 1,\ \forall k \in B(t): \quad \frac{\pi_t(a_k|x_k)}{\mu_k(a_k|x_k)} \leq M \ .$$

Next, fix z_{k-1} and let $t = \tau(k)$ (note that $\tau(k)$ is a deterministic function of z_{k-1}). It is not too difficult to show that R_k is an unbiased estimator of $\mathbf{E}_{r\sim\pi_t}[r]$, and to bound its range and variance (for proofs see Appendices B and C):

Lemma 3. $\mathbf{E}^{\mu}_k[R_k] = \mathbf{E}_{r\sim\pi_t}[r]$.

Lemma 4. $|R_k| \leq 1 + M$.

Lemma 5. $\mathbf{E}^{\mu}_k[R^2_k] \leq 3 + M$.

Now we are ready to show that R/C converges to the expected reward of the policy π_{PV}:

Theorem 2. *Let n be the number of exploration samples used to generate T blocks, i.e., $n = \sum_{t=1}^{T}|B(t)|$. With probability at least $1-\delta$,*

$$\left|R/C - \mathop{\mathbf{E}}_{r\sim\pi_{\text{PV}}}[r]\right| \leq \frac{nc_{\max}}{C}\cdot 2\max\left\{\frac{(1+M)\ln(2/\delta)}{n}, \sqrt{\frac{(3+M)\ln(2/\delta)}{n}}\right\}.$$

Proof. The proof follows by Freedman's inequality (Theorem 3 in Appendix A), applied to random variables $c_t R_k$, whose range and variance can be bounded using Lemmas 4 and 5 and the bound $c_t \leq c_{\max}$. □

4 Experiments

We conduct experiments on two problems, the first is a public supervised learning dataset converted into an exploration learning dataset, and the second is a real-world proprietary dataset.

4.1 Classification with Bandit Feedback

In the first set of experiments, we illustrate the benefits of DR-ns (Algorithm 1) over naive rejection sampling using the public dataset `rcv1` [17]. Since `rcv1` is a multi-label dataset, an example has the form (x, c), where x is the feature and c is the set of corresponding labels. Following the construction of previous work [4, 8], an example (x, c) in a K-class classification problem may be interpreted as a bandit event with context x, action $a \in [K] := \{1, \ldots, K\}$, and loss $l_a := I(a \notin c)$, and a classifier as an arm-selection policy whose expected loss is its classification error. In this section, we aim at evaluating average policy loss, which can be understood as negative reward. For our experiments, we only use the $K = 4$ top-level classes in `rcv1`, namely $\{C, E, G, M\}$; a random selection of $40K$ data from the whole dataset were used. Call this dataset D.

Data Conversion. To construct a partially labeled exploration data set, we choose actions non-uniformly in the following manner. For an example (x, c), a uniformly random

score $s_a \in [0.1, 1]$ is assigned to arm $a \in [K]$, and the probability of action a is

$$\mu(a|x) = \frac{0.3 \times s_a}{\sum_{a'} s_{a'}} + \frac{0.7 \times I(a \in c)}{|c|}.$$

This kind of sampling ensures two useful properties. First, every action has a non-zero probability, so such a dataset suffices to provide an unbiased offline evaluation of any policy. Second, actions corresponding to correct labels have higher observation probabilities, emulating the typical setting where a baseline system already has a good understanding of which actions are likely best.

We now consider the two tasks of evaluating a static policy and an adaptive policy. The first serves as a sanity check to see how well the evaluator works in the degenerate case of static policies. In each task, a one-vs-all reduction is used to induce a multi-class classifier from either fully or partially labeled data. In fully labeled data, each example is included in data sets of all base binary classifiers. In partially labeled data, an example is included only in the data set corresponding to the action chosen. We use the LIBLINEAR [9] implementation of logistic regression. Given a classifier that predicts the most likely label a^*, our policy follows an ε-greedy strategy with ε fixed to 0.1; that is, with probability 0.9 it chooses a^*, otherwise a random label $a \in [K]$. The reward estimator $\hat{r}$ is directly obtained from the probabilistic output of LIBLINEAR (using the "`-b 1`" option). The scaling parameter is fixed to the default value 1 (namely, "`-c 1`").

Static Policy Evaluation. In this task, we first chose a random 10% of D and trained a policy π_0 on this fully labeled data. From the remainder, we picked a random "evaluation set" containing 50% of D. The average loss of π_0 on the evaluation set served as the ground truth. A partially labeled version of the evaluation set was generated by the conversion described above; call the resulting dataset D'. Finally, various offline evaluators of π_0 were compared against each other on D'.[1] We repeated the generation of evaluation set in 300 trials to measure the bias and standard deviation of each evaluator.

Adaptive Policy Evaluation. In this task, we wanted to evaluate the average online loss of the following adaptive policy π. The policy is initialized as a specific "offline" policy calculated on random 400 fully observed examples (1% of D). Then the "online" partial-feedback phase starts (the one which we are interested in evaluating). We update the policy after every 15 examples, until 300 examples are observed. On policy update, we simply use an enlarged training set containing the initial 400 fully labeled and additional partially labeled examples. The offline training set was fixed in all trials. The remaining data was split into two portions, the first containing a random 80% of D for evaluation, the second containing 19% of D to determine the ground truth. The evaluation set was randomly permuted and then transformed into a partially labeled set D' on which evaluators were compared. The generation of D' was repeated in 50 trials, from which bias and standard deviation of each evaluator were obtained. To estimate the ground-truth value of π, we simulated π on the randomly shuffled (fully labeled) 19% of ground-truth data 2 000 times to compute its average online loss.

[1] To avoid risks of overfitting, for evaluators that estimate $\hat{r}$ (all except RS), we split D' into two equal halves, one for training $\hat{r}$, the other for running the evaluator. The same approach was taken in the adaptive policy evaluation task.

Compared Evaluators. We compared the following evaluators described earlier: DM for direct method, RS for the unbiased evaluator in [19] combined with rejection sampling, and DR-ns as in Algorithm 1 (with $c_{\max} = 1$). We also tested a variant of DR-ns, which does not monitor the quantile, but instead uses c_t equal to $\min_D \mu(a|x)$; we call it WC since it uses the worst-case (most conservative) value of c_t that ensures unbiasedness of rejection sampling.

Results. Tables 1 and 2 summarize the accuracy of different evaluators in the two tasks, including rmse (root mean squared error), bias (the absolute difference between evaluation mean and the ground truth), and stdev (standard deviation of the evaluation results in different runs). It should be noted that, given the relatively small number of trials, the measurement of bias is not statistically significant. So for instance, it cannot be inferred in a statistically significant way from Table 1 that WC enjoys a lower bias than RS. However, the tables provide 95% confidence interval for the rmse that allows a meaningful comparison.

It is clear from both tables that although rejection sampling is guaranteed to be unbiased, its variance usually is the dominating source of rmse. At the other extreme is the direct method, which has the smallest variance but often suffers high bias. In contrast, our method DR-ns is able to find a good balance between these extremes and, with proper choice of q, is able to yield much more accurate evaluation results. Furthermore, compared to the unbiased variant WC, DR-ns's bias appears to be modest.

It is also clear that the main benefit of DR-ns is its low variance, which stems from the adaptive choice of c_t values. By slightly violating the unbiasedness guarantee, it increases the effective data size significantly, hence reducing the variance of its evaluation. In particular, in the first task of evaluating a static policy, rejection sampling was able to use only 264 examples (out of the 20K data in D') since the minimum value of $\mu(a|x)$ in the exploration data was very small; in contrast, DR-ns was able to use 523, 3 375, 4 279, and 4 375 examples for $q \in \{0, 0.01, 0.05, 0.1\}$, respectively. Similarly, in the adaptive policy evaluation task, with DR-ns($q > 0$), we could extract many more online tra-

Table 1: Static policy evaluation results.

evaluator	rmse ($\pm 95\%$ C.I.)	bias	stdev
DM	0.0151 ± 0.0002	0.0150	0.0017
RS	0.0191 ± 0.0021	0.0032	0.0189
WC	$\mathbf{0.0055 \pm 0.0006}$	0.0001	0.0055
DR-ns($q = 0$)	0.0093 ± 0.0010	0.0032	0.0189
DR-ns($q = 0.01$)	0.0057 ± 0.0006	0.0021	0.0053
DR-ns($q = 0.05$)	$\mathbf{0.0055 \pm 0.0006}$	0.0022	0.0051
DR-ns($q = 0.1$)	0.0058 ± 0.0006	0.0017	0.0055

Table 2: Adaptive policy evaluation results.

evaluator	rmse ($\pm 95\%$ C.I.)	bias	stdev
DM	0.0329 ± 0.0007	0.0328	0.0027
RS	0.0179 ± 0.0050	0.0007	0.0181
WC	0.0156 ± 0.0037	0.0086	0.0132
DR-ns($q = 0$)	0.0129 ± 0.0034	0.0046	0.0122
DR-ns($q = 0.01$)	$\mathbf{0.0089} \pm 0.0017$	0.0065	0.0062
DR-ns($q = 0.05$)	0.0123 ± 0.0017	0.0107	0.0061
DR-ns($q = 0.1$)	0.0946 ± 0.0015	0.0946	0.0053

jectories of length 300 for evaluating π, while RS and WC were able to find only one such trajectory out of the evaluation set. In fact, if we increased the trajectory length of π from 300 to 500, neither RS or WC could construct a full trajectory of length 500 and failed the task completely.

4.2 Content Slotting in Response to User Queries

In this set of experiments, we evaluate two policies on a proprietary real-world dataset consisting of web search queries, various content that is displayed on the web page in response to these queries, and the feedback that we get from the user (as measured by clicks) in response to the presentation of this content. Formally, this partially labeled data consists of tuples (x_k, a_k, r_k, p_k), where x_k is a query and corresponding features, $a_k \in \{$web-link,news,movie$\}$ (the content shown at slot 1 on the results page), r_k is a so-called click-skip reward ($+1$ if the result was clicked, -1 if a result at a *lower* slot was clicked), and p_k is the recorded probability with which the exploration policy chose the given action.

The page views corresponding to these tuples represent a small percentage of traffic for a major website; any given page view had a small chance of being part of this experimental bucket. Data was collected over a span of several days during July 2011. It consists of 1.2 million tuples, out of which the first 1 million were used for estimating $\hat{r}$ with the remainder used for policy evaluation. For estimating the variance of the compared methods, the latter set was divided into 10 independent test subsets of equal size.

Two policies were compared in this setting: *argmax* and *self-evaluation* of the exploration policy. For *argmax* policy, we first obtained a linear estimator $r'(x, a) = w_a \cdot x$ by importance-weighted linear regression (with importance weights $1/p_k$). The *argmax* policy chooses the action with the largest predicted reward $r'(x, a)$. Note that both $\hat{r}$ and r' are linear estimators obtained from the training set, but $\hat{r}$ was computed without importance weights (and we therefore expect it to be more biased). *Self-evaluation* of the exploration policy was performed by simply executing the exploration policy on the evaluation data.

Table 3: Estimated rewards reported by different policy evaluators on two policies for a real-world exploration problem. In the first column results are normalized by the (known) expected reward of the deployed policy. In the second column results are normalized by the reward reported by IPS. All $\pm$ are computed standard deviations over results on 10 disjoint test sets.

evaluator	*self-evaluation*	*argmax* policy
RS	0.986 ± 0.060	0.990 ± 0.048
IPS	0.995 ± 0.041	1.000 ± 0.027
DM	1.213 ± 0.010	1.211 ± 0.002
DR	0.967 ± 0.042	0.991 ± 0.026
DR-ns	0.974 ± 0.039	0.993 ± 0.024

Table 3 compares RS [19], IPS, DM, DR [8], and DR-ns($c_{\max} = 1$, $q = 0.1$). For business reasons, we do not report the estimated reward directly, but normalize to either the empirical average reward (for *self-evaluation*) or the IPS estimate (for the *argmax* policy evaluation).

In both cases, the RS estimate has a much larger variance than the other estimators. Note that the minimum observed p_k equals $1/13$, which indicates that a naive rejection sampling approach would suffer from the data efficiency problem. Indeed, out of approximately 20 000 samples per evaluation subset, about 900 are added to the history for the *argmax* policy. In contrast, the DR-ns method adds about 13 000 samples, a factor of 14 improvement.

The experimental results are generally in line with theory. The variance is smallest for DR-ns, although IPS does surprisingly well on this data, presumably because values $\hat{r}$ in DR and DR-ns are relatively close to zero, so the benefit of $\hat{r}$ is diminished. The Direct Method (DM) has an unsurprisingly huge bias, while DR and DR-ns appear to have a very slight bias, which we believe may be due to imperfect logging. In any case, DR-ns dominates RS in terms of variance as it was designed to do, and has smaller bias and variance than DR.

5 Conclusion and Future Work

We have unified best-performing stationary policy evaluators and rejection sampling by carefully preserving their best parts and eliminating the drawbacks. To our knowl-

edge, the resulting approach yields the best evaluation method for nonstationary and randomized policies, especially when reward predictors are available.

Yet, there are definitely opportunities for further improvement. For example, consider nonstationary policies which can devolve into a round-robin action choices when the rewards are constant (such as UCB1 [2]). A policy which cycles through actions has an expected reward equivalent to a randomized policy which picks actions uniformly at random. However, for such a policy, our policy evaluator will only accept on average a fraction of $1/K$ uniform random exploration events. An open problem is to build a more data-efficient policy evaluator for this kind of situations.

Abstract

We consider the problem of sampling from solutions defined by a set of hard constraints on a combinatorial space. We propose a new sampling technique that, while enforcing a uniform exploration of the search space, leverages the reasoning power of a systematic constraint solver in a black-box scheme. We present a series of challenging domains, such as energy barriers and highly asymmetric spaces, that reveal the difficulties introduced by hard constraints. We demonstrate that standard approaches such as Simulated Annealing and Gibbs Sampling are greatly affected, while our new technique can overcome many of these difficulties. Finally, we show that our sampling scheme naturally defines a new approximate model counting technique, which we empirically show to be very accurate on a range of benchmark problems.

1 Introduction

In recent years, we have seen significant interest in probabilistic reasoning approaches that combine both hard, logical constraints and probabilistic information through soft, weighted constraints. Markov Logic Networks [1] are a prominent example of such a modeling language. The hard constraints are used to capture definitional and other irrefutable relationships in the underlying domain, while soft constraints capture less categorical information, generally better for modeling real-world data and dependencies.

Markov Chain Monte Carlo (MCMC) methods, such as Simulated Annealing (SA) and Gibbs Sampling [2], are among the most prominent approaches to probabilistic reasoning, especially when exact inference is beyond reach. In fact, they are guaranteed to asymptotically converge to a stationary distribution that can theoretically provide uniform samples. However, sampling from the solutions of a set of hard constraints is believed to be very hard in worst case, as it is closely related to #-P complete problems such as model counting [3, 4, 5, 6, 7]. In particular, the time required for a Markov Chain to reach the stationary distribution (mixing time) is often exponential in the number of problem variables when hard constraints are present. These difficulties led to the introduction of alternate sampling strategies. For example, in the SampleSAT approach [8], a Markov Chain is constructed that combines moves proposed according to a Simulated Annealing Markov Chain with so-called WalkSAT moves, inspired by local search constraint solvers. The SampleSAT method provides a significant advance, since SA sampling on constraint problems of practical interest generally does not reach any solutions or, at best, only a small subset of all possible solutions. SampleSAT was subsequently incorporated into MC-SAT in the Alchemy package for reasoning and learning for Markov Logic Networks [9]. A key limitation of SampleSAT is that it is not guaranteed to converge to the uniform distribution on the solution set. In fact, one can create examples where the stationary distribution of SampleSAT is arbitrarily biased (non-uniform) in terms of solution samples. Still, this does not negate the value of SampleSAT in many practical settings. For, although SA-like sampling does sample in the limit from the uniform stationary distribution on the solution set, reaching the stationary distribution often requires exponential time, making the SA strategy of little use in practice.

In this paper, we revisit the question of how to devise practical methods for sampling from solutions defined by a set of hard constraints on a combinatorial space. We present a series of challenging domains that reveal the difficulties introduced by such constraints. These include high energy[1] barriers, large energy plateaus ("golf-course" like energy landscapes), and highly asymmetric sampling spaces. We present data demonstrating that SA, Gibbs sampling, and SampleSAT [8] are all greatly affected by these problems.

*This work was supported by NSF Grant 0832782.

[1] Energy is defined as the number of violated constraints.

However, we also show that highly structured energy landscapes can actually present new opportunities for solution samplers. Combinatorially defined energy functions have a rich structure embedded, but traditional MCMC methods are very general and therefore treat the energy as a "black-box", effectively ignoring the underlying structure. On the other hand, modern day constraint solvers use clever heuristic to exploit constraint structure as much as possible, and can solve very large structured industrial problems with millions of variables [10]. However, these solvers cannot be used directly as solution samplers because they tend to oversample certain solutions, as they are designed just to find one satisfying assignment but not to be uniform [8].

In this paper, we propose a novel sampling scheme called `SearchTreeSampler`, which leverages the reasoning power of a systematic constraint solver while enforcing a uniform exploration of the search space. Constraint solvers have been previously applied by SampleSearch [11, 12, 13] in the context of importance sampling, a framework where the performance is known to heavily depend on the choice of the proposal distribution. In contrast, `SearchTreeSampler` introduces a new way of exploring the search space that does not rely on a heuristically chosen proposal distribution, and directly provides (approximately) uniform samples. The constraint solver is used as a black-box, so that any systematic solver can be plugged in, with no modifications required. We empirically demonstrate that by leveraging constraint structure, `SearchTreeSampler` can overcome many of the difficulties encountered by other solution samplers. In particular, we show it can be orders of magnitude faster than competing methods, while providing more uniform samples at the same time. Further, we show that our sampling scheme naturally defines a new technique for approximately counting the number of distinct solutions (model counting), that we empirically show to be very accurate on a range of benchmark problems.

2 Problem Definition

We consider the problem of sampling from a combinatorial search space defined by n Boolean variables and m constraints specified by a Boolean formula F in conjunctive normal form (CNF). A constraint or *clause* C is a logical disjunction of a set of (possibly negated) variables. A formula F is said to be in CNF form if it is a logical conjunction of a set of clauses $\mathcal{C}$.

We define V to be the set of propositional variables in the formula, where $|V| = n$. A variable assignment $\sigma : V \to \{0, 1\}$ is a function that assigns a value in $\{0, 1\}$ to each variable in V. As usual, the value 0 is interpreted as FALSE and the value 1 as TRUE. Let F be a formula in CNF over the set V of variables with $m = |\mathcal{C}|$ clauses and let σ be a variable or truth assignment. We say that σ satisfies a clause C if at least one signed variable of C is TRUE. We say that a truth assignment σ is a satisfying assignment for F (also called a model or a solution) if σ satisfies all the clauses $C \in \mathcal{C}$. Let $\mathcal{S}_F$ be the set of solutions of F, and let $Z = |\mathcal{S}_F|$ be the number of distinct solutions.

Given a Boolean formula F, we define a discrete probability distribution D over the set of all possible truth assignments $\{0, 1\}^n$ such that

$$D(\sigma) = \begin{cases} 1/Z & \text{if } \sigma \in \mathcal{S}_F \text{ (i.e., } \sigma \text{ is a solution)} \\ 0 & \text{otherwise} \end{cases}$$

In this paper we consider the problem of sampling from D. This problem is very hard and in fact simply deciding whether or not the support of D is empty is NP-complete (the CNF-SAT problem). Sampling is however believed to be even harder, as it is closely related to $\#$-P complete problems such as inference and model counting [3, 4]. For instance, SAT solvers cannot be directly used as solution samplers because they tend to oversample certain solutions, as they are designed just to find one satisfying assignment but not to be uniform [8].

3 Background on Solution Sampling

In this section, we briefly describe the main techniques for solution sampling.

3.1 Simulated Annealing

Simulated Annealing is a MCMC algorithm that defines a reversible Markov Chain on the space of truth assignments $\{0, 1\}^n$ to sample from a Boltzmann distribution [14]. The transition probabilities (and the steady state probability distribution) depend only on a property of the truth assignments called "energy". The energy $E : \{0, 1\}^n \to \mathbb{N}$ gives the number of clauses violated by a truth assignment σ and is defined as follows

$$E(\sigma) = |\{c \in \mathcal{C} | \sigma \text{ does not satisfy } c\}|.$$

The Boltzmann steady state probability distribution is given by

$$P_T(\sigma) = \frac{1}{Z(T)} e^{-\frac{E(\sigma)}{T}},$$

where T is a formal parameter called "temperature", and $Z(T)$ is the normalization constant. Notice that P_T assigns the same probability to all solutions, i.e. $P_T(\sigma) = \alpha$ for all $\sigma \in \mathcal{S}_F$, but is not necessarily zero for non-solutions. Given an algorithm $\mathcal{A}$ that produces samples from P_T, we can construct an algorithm $\mathcal{B}$ that samples from D (i.e. uniformly from the solution set) using rejection sampling. More specifically, we take samples s produced by $\mathcal{A}$ and we discard all the ones such that $s \notin \mathcal{S}_F$. The fundamental tradeoff involved is that we want the probability distribution P_T to be easier to sample from (compared to D), but

at the same time the probability mass should be concentrated on satisfying assignments (i.e. P_T should be close enough to D) so that we don't generate too many unwanted samples (i.e. non-solutions). Closely related to Simulated Annealing (SA) is the Gibbs Sampler for the Boltzmann distribution, that defines a similar Markov Chain with the same steady state probability distribution [2]. In our analysis below, we consider a fixed temperature annealing where T is fixed during the run of the Markov Chain.

3.2 SampleSAT

In [8] Wei et al. propose the use of an hybrid approach where they interleave SA moves with moves based on a focused random walk procedure (inspired by local search SAT solvers [15]). This approach is based on a result by Papadimitriou [16] proving that a random walk procedure for SAT will find a solution to any satisfiable 2CNF formula in $O(n^2)$ time, where n is the number of variables in the formula. While the role of focused random walk moves is to find solution "clusters", the role of SA moves is to heuristically provide some level of uniformity of the sampling. The drawback of this approach is that it does not maintain any detailed balance equation so there is no control on the resulting steady state probability distribution. SampleSAT therefore loses all the theoretical guarantees on the uniformity of the sampling provided by SA, and as we show below in the experimental section, it can lead to poor uniformity also in practice.

3.3 SampleSearch

SampleSearch [11, 12, 13] is an importance sampling technique that draws samples from the so-called *backtrack-free distribution*. Although it is not a uniform sampler, these samples can be used to compute expectations (using importance sampling) by correcting for the non uniformity of the *backtrack-free distribution*. The support of the *backtrack-free distribution* corresponds exactly to the set of solutions, and this greatly reduces the number of rejected samples. However, as other importance sampling schemes, the performance is highly dependent on the choice of the proposal distribution, which is usually precomputed using a generalized belief propagation scheme [11]. Sampling from the *backtrack-free distribution* can be achieved either by using a complete solver as a black-box, or by using the SampleSearch scheme, which integrates backtracking search with sampling [12]. Our approach is similar in the sense that we also use a complete solver as an oracle as we explore the search tree. However, the search tree is explored is a very different way. Specifically, our *recursive* approach aims at uniformly exploring of the search tree level by level, and directly provides (approximately) uniform samples without need for a heuristically chosen proposal distribution (e.g., using variational methods). We will compare the performance of the two methods for model counting below.

4 Black-Box Sampling

Modern day SAT solvers are very effective at finding *a solution*, but they explore the search space in a highly non-uniform way. This is because they use heuristics such assigning "Pure literals" (e.g., if a variable only appears with positive sign in a formula, then it can be safely set to true) that heavily bias the search towards certain parts of the search space.

Modifying a pure DPLL-style algorithm to produce uniform samples is a challenging task. Suppose the choice of the ordering in which variables are set is chosen uniformly at random, and the polarity (whether to assign true or false to a variable during search) is also chosen uniformly at random. Then in general the first solution found is not a uniform sample from S_F. A simple counterexample is the formula $x_1 \vee x_2$, where it can be seen that the solution $x_1 = x_2 = 1$ is less likely to be found in both possible variables orderings. In order to obtain uniform samples, one could choose the polarity of the variables according to their marginal probabilities (with respect to D), but this would defy the purpose of sampling, since we often want to obtain samples precisely to estimate quantities such as marginals.

Instead of modifying an existing search procedure to produce uniform samples, we introduce a novel recursive sampling scheme that aims at enforcing a level by level uniform exploration of the search tree, while leveraging the reasoning power of a complete SAT solver.

4.1 A Recursive Sampling Strategy

Our method is based on the notion of *pseudosolution*, defined as follows:

Definition 1. *Let π be an ordering of the variables. A* pseudosolution *of level i is a truth assignment to the first i variables that can be completed to form a solution (i.e. a node in the search tree at level i that has a solution as a descendant). We denote S_i the set of* pseudosolutions *of level i.*

Our recursive strategy (Algorithm 1) is based on the idea of dividing the search tree into L levels, and recursively sampling *pseudosolutions* using previously generated samples of *pseudosolutions* of a higher level (see Figure 1). In other words, we assume to have access to uniform samples of ancestors of solutions at level i, and we generate samples of ancestors of solutions at level $i + \ell$ using Algorithm 2. The procedure is initialized with a pseudosolution of level 0, i.e. an empty variable assignment. Note that generating samples from *pseudosolutions* of level n (if there are n variables) is equivalent to the original problem of sampling solutions from S_F.

A complete SAT solver is used in Algorithm 2 to generate

Algorithm 1 SearchTreeSampler(F, k, M)

Input: Formula F with n vars. Parameters k, $M = 2^\ell$
Output: A set S of solutions of F
if F is not satisfiable **then**
  return $\emptyset$
else
  Let $\Phi_0 = \{\top\}$ // True, empty variable assignment
  Let $L = \lceil \frac{n}{\ell} \rceil$ // number of levels
  for $i = 1, \cdots, L$ **do**
    $\Phi_i \leftarrow$ BlackBoxSampler(Φ_{i-1}, k, ℓ)
  end for
  return Φ_L
end if

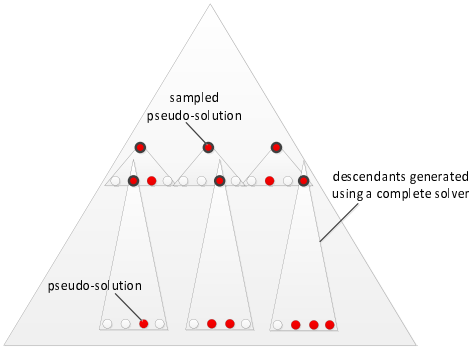

Figure 1: Representation of how Algorithm 1 explores the search tree.

$D(s_j)$, the set of all pseudosolutions of level $i + \ell$ with s_j as ancestor. This is accomplished by repeatedly checking the satisfiability of $F \wedge s_j \bigwedge_{d \in D} \neg d$ until it is provably unsatisfiable, adding a *pseudosolution* d to D each time one is found. Completeness is required in order to enumerate all elements of $D(s_j)$, i.e. to prove unsatisfiability when all elements have been found.

4.2 Analysis

It is easy to verify by induction that the sets Φ_i in Algorithm 1 satisfy the property $|\Phi_i| \geq \min\{k, |S_i|\}$. The key property of Algorithm 2 is that the set S returned is such that sampling from S is approximately equivalent to sampling from $S_{i+\ell}$, the set of *pseudosolutions* of level $i + \ell$. The parameter $k > 1$ controls the uniformity of the sampling. This is formalized by the following Theorem:

Theorem 1. *Let S be the output of Algorithm 2 with input Φ such that $|\Phi| \geq \min\{k, |S_i|\}$, and $s, s' \in S_{i+\ell}$ be any two pseudosolutions of level $i + \ell$. We have*

$$\frac{k}{M + k - 1} \leq \frac{P(s)}{P(s')} \leq \frac{M + k - 1}{k}, \qquad (1)$$

where $M = 2^\ell$ and $P(s)$ is the probability that a uniformly sampled element from S is equal to s.

Algorithm 2 BlackBoxSampler(Φ,k,ℓ)

Input: A set Φ of uniformly sampled pseudosolutions of level i. Parameters k, ℓ
Output: A set S of pseudosolutions of level $i + \ell$ (approximately uniformly sampled) with $2^\ell |\Phi| \geq |S| \geq |\Phi|$
$S = \emptyset$
for $j = 1, \cdots, \min\{k, |\Phi|\}$ **do**
  Sample s_j from Φ without replacement
  Generate $D(s_j)$, the set of all pseudosolutions of level $i+\ell$ with s_j as ancestor (using a complete SAT solver)
  $S = S \cup D(s_j)$
end for
return S

Proof. Suppose $k \leq |\Phi|$ (otherwise, it means that Φ contains all pseudosolutions of level i, hence by definition $S = S_{i+\ell}$ and therefore $P(s) = P(s')$), and that $\Phi \subseteq S_i$ is a set of uniformly sampled pseudosolutions of level i. We can think of each pseudosolution $s \in \Phi$ as an urn, that contains a certain number $1 \leq |D(s)| \leq M = 2^\ell$ of pseudosolutions at a lower level $i + \ell$ (its descendants). Let $|S_i| = N \geq |\Phi|$ be the total number of pseudosolutions of level i.

Since Φ contains uniform samples, $s_1, \cdots, s_k$ in Algorithm 2 are also uniform samples of *pseudosolutions* of level i. Let S as in Algorithm 2 (the union of the contents of the k urns selected). Let $s \in S_{i+\ell}$ be a pseudosolution of level $i + \ell$, and let $a(s) \in S_i$ be its unique ancestor at level i. Clearly, the probability that $s \in S$ is $P[s \in S] = \frac{\binom{N-1}{k-1}}{\binom{N}{k}}$ that is equal to the probability of selecting the ancestor $a(s)$ of s on level i. Let e be a randomly selected element of S. Ideally, we would like the probability $P(s) \triangleq P[e = s]$ to be a constant independent of s (uniform sampling). However, intuitively this is not exactly constant because there is a bias towards elements such that $|D(a(s))|$ is small. Specifically,

$$P(s) = \frac{1}{\binom{N}{k}} \sum_{\ell_1 \cdots \ell_{k-1}} \frac{1}{|D(a(s)) \cup D(s_{\ell_1}) \cdots \cup D(s_{\ell_{k-1}})|}.$$

Since the sets are disjoint,

$$P[e = s] = P(s) = \frac{\binom{N-1}{k-1}}{\binom{N}{k}} \sum_{t=1}^{\binom{N-1}{k-1}} \frac{1}{\binom{N-1}{k-1}} \frac{1}{|D(a(s))| + z_t},$$

where $z_t = |D(s_{\ell_1}) \cup \cdots \cup D(s_{\ell_{k-1}})| \geq k - 1$. Let $s' \in S_{i+\ell}$ be another pseudosolution of level $i + \ell$. We rewrite $P(s)$ as

$$\frac{1}{\binom{N}{k}} \left(\sum_{t=1}^{\binom{N-2}{k-2}} \frac{1}{|D(a(s))| + a_t + |D(a(s'))|} + \sum_{t=1}^{\binom{N-2}{k-1}} \frac{1}{|D(a(s))| + b_t} \right).$$

Suppose wlog that $|D(a(s))| \geq |D(a(s'))|$. Then,

$$\frac{1}{|D(a(s'))| + b_t} \leq \frac{|D(a(s))| + k - 1}{|D(a(s'))| + k - 1} \frac{1}{|D(a(s))| + b_t}$$

by Lemma 1, and using the fact that $1 \leq |D(a(s))| \leq M$,

$$\frac{1}{|D(a(s'))| + b_t} \leq \frac{M + k - 1}{k} \frac{1}{|D(a(s))| + b_t}.$$

Hence,

$$\sum_{t=1}^{\binom{N-2}{k-1}} \frac{1}{|D(a(s'))| + b_t} \leq \frac{M + k - 1}{k} \sum_{t=1}^{\binom{N-2}{k-1}} \frac{1}{|D(a(s))| + b_t}$$

and finally,

$$\left(\sum_{t=1}^{\binom{N-2}{k-2}} \frac{1}{|D(a(s))| + a_t + |D(a(s'))|} + \sum_{t=1}^{\binom{N-2}{k-1}} \frac{1}{|D(a(s'))| + b_t} \right) \leq$$

$$\frac{M + k - 1}{k} \left(\sum_{t=1}^{\binom{N-2}{k-2}} \frac{1}{|D(a(s))| + a_t + |D(a(s'))|} + \sum_{t=1}^{\binom{N-2}{k-1}} \frac{1}{|D(a(s))| + b_t} \right)$$

that gives

$$\frac{P(s')}{P(s)} \leq \frac{M + k - 1}{k}.$$

□

Lemma 1. *Given $d \geq c$ and a finite sequence $\{b_j\}_1^T$ such that $0 < k - 1 \leq b_j$ for all j, we have*

$$\frac{\sum_j \frac{1}{c + b_j}}{\sum_j \frac{1}{d + b_j}} \leq \frac{d + k - 1}{c + k - 1}.$$

Proof. Notice that for any j we have $\frac{\frac{1}{c+b_j}}{\frac{1}{d+b_j}} \leq \frac{1/(c+k-1)}{1/(d+k-1)}$ because when $c \leq d$ it is a monotonically decreasing function of b_j. The desired result follows by summing up both sides over j and dividing. □

Equation (1) shows that the sampling becomes more uniform as $k \to \infty$, and allows us to bound the uniformity of the output of Algorithm 2 as a function of k (a pseudosolution cannot be much more likely than another one). For instance, when $M = 2$ and $k = 100$, a pseudosolution cannot be more than 1% more likely to be sampled than another one. Notice that larger values of k would both improve the uniformity of the sampling and at the same time increase the number of output samples (sampling is without replacement). However, larger values of k would also require more calls to the SAT solver.

Remark: When Algorithm 2 is used recursively as in Algorithm 1, the samples received as input are usually not truly uniform unless k is larger than the total number of solutions[2]. Even though in general the sets Φ_i in Algorithm 1 do not meet the assumptions of Theorem 1, they tend to satisfy them as $k \to \infty$. The effect of rather small, practical values of k is investigated empirically below, where we evaluate the statistical properties of the output samples Φ_L.

[2]Uniformity is also guaranteed for the first b levels, until $|S_b| < k$.

4.3 Complexity

If n is the number of variables of the input formula F, Algorithm 1 requires $O(\lceil \frac{n}{\log M} \rceil Mk)$ calls to the SAT solver to get at least $\min\{\#\text{solutions of F}, k\}$ samples. Larger values M require more calls to the SAT solver, but intuitively also improve the uniformity of the sampling by reducing the number of recursions. In particular, in the extreme (impractical) case $M = 2^n$ we obtain truly uniform sampling because it corresponds to exact model counting (explicitly enumerating all solutions). Notice also that although in our experiments we use constant values for k and M, they could be chosen as a function of the level i.

5 Evaluating Sampling Methods

It can be verified that Simulated Annealing (SA) is ergodic for all "temperatures" $T > 0$ when new configurations are generated by randomly flipping a variable chosen uniformly at random (so that the chains are irreducible [2]). Since according to the steady state probability distribution all satisfying assignments have the same probability, in principle SA will provide uniform samples if we are willing to wait until the stationary distribution is reached. However, the amount of time we have to wait until the chain reaches its steady state and between two consecutive samples is of paramount importance for any practical application. On the other hand, SampleSAT is often much faster at finding solutions because of the focused random walk component, but it does not provide any guarantee on the uniformity of the sampling. To evaluate the practical utility of these methods it is therefore important to quantitatively measure the uniformity of the samples provided after finite amounts of time.

The experiments are run on a set of formulas F for which we know (analytically or using exact model counters [17]) that the number of distinct solutions $|S_F|$ is relatively small (≤ 1000). Therefore, by taking a sufficiently large number of samples, we are able to check the uniformity of the methods. In particular, let N_i be the number of times the ith solution has been sampled, for $i = 1, \ldots, |S_F|$. Given P samples from a truly uniform solution sampler, we expect N_i to be close to $P/|S_F|$ (since for the law of large numbers N_i/P converges to $1/|S_F|$ in probability as $P \to \infty$). To quantitatively measure the uniformity of the sampler, we use the Pearson's χ^2 statistic defined as

$$\chi^2 = \frac{1}{P/|S_F|} \sum_i (N_i - P/|S_F|)^2,$$

where $P/|S_F|$ is the expected theoretical frequency under

the hypothesis that the distribution is truly uniform. The χ^2 value can be used to test a null hypothesis stating that the frequencies N_i observed are consistent with a uniform distribution. In particular, the null hypothesis is rejected if the χ^2 value is larger than a cutoff value that depends on the number of distinct solutions $|S_F|$ (specifying the number of degrees of freedom of the distribution) and on the statistical significance desired (e.g., 0.05).

For our experiments, we use MiniSAT 2.2 [18] as a complete solver in Algorithm 1. Pseudosolutions are defined according to lexicographical variable ordering π_{LX}. For efficiency, all the experiments are run with $M = 2$. When we wish to obtain P samples, we keep running `SearchTreeSampler` with a parameter $k < |S_F| < P$ until we obtain at least P samples (taking exactly k samples without replacement from S_F per run), and we report the total running time. Note that choosing $k \geq |S_F|$ (e.g., $k = P$) wouldn't let us evaluate the performance of the method as an approximately uniform sampler, because it would correspond to enumerating all solutions (hence perfectly uniform sampling).

SA is evaluated as follows. We run the chain from a random initial truth assignment, discarding all the samples for the first 10^7 steps (burn-in phase). After the burn-in phase, we assume that the Markov Chain has reached its steady state distribution and we start taking samples. Every K steps, the current truth assignment σ_t is taken as a sample from the steady state distribution. We wait for K steps to ensure that consecutive samples are sufficiently independent. If the sample σ_t is a solution ($\sigma_t \in S_F$), we output it, otherwise we discard it. This process is carried out until we find a prescribed number of solutions P (non necessarily all distinct). SampleSAT is executed with default parameters, and all methods are run on the same 3GHz machine with 4Gb of memory.

6 Challenging Sample Spaces

6.1 Golf-Course energy landscape

We first consider a class of instances from [8] which we call $plateau(b)$, defined as

$$(x_1 \vee y_1) \wedge (x_1 \vee y_2) \wedge \cdots \wedge (x_1 \vee y_b) \wedge (\neg x_1 \vee z_1) \wedge (\neg x_1 \vee \neg z_1).$$

This class of instances is hard for local search methods such as SA because it has a very large plateau of truth assignments (of size at least 2^{b+1}) with energy $E(\sigma) = 1$, corresponding to assignments with $x_1 = 1$. The effect of the last two clauses is to enforce $x_1 = 0$, so that there are only two distinct solutions. Intuitively, this instance is difficult for SA because in order to reach one of the solutions, SA needs to set $x_1 = 0$. Setting $x_1 = 0$ is likely to violate several of the first b clauses, making the uphill move unlikely to be accepted. Formally, in [8] it is shown (Theorem 1) that SA at fixed temperature with probability going to 1 takes time exponential (in b) to find a satisfying assignment.

As shown in [8], SampleSAT is not affected by energy plateaus because it uses focused moves to quickly reach solutions. Since it is not based on local information, `SearchTreeSampler` is not affected by energy plateaus. In fact, since $plateau(b)$ instances belong to 2-CNF (formulas with at most 2 variables per clause) and has two solutions, we can use the following result:

Theorem 2. *Algorithm 1 provides uniform samples in polynomial time for 2-CNF instances F such that $S_F \leq k$.*

Proof. Follows from the fact that 2-SAT is solvable in polynomial time. Uniformity follows from the fact that Algorithm 1 will output all solutions when $S_F \leq k$. □

6.2 Energy barriers

We define an energy barrier between two variable assignments $\sigma, \sigma' \in \{0,1\}^n$ as the minimum over the set of all possible paths on the Boolean hypercube $\{0,1\}^n$ between σ and σ' of the maximum energy of the configurations in each path. Simulated Annealing is designed to deal with energy barriers (such as the ones encountered around a local minimum) by allowing occasional uphill moves (stochastic hill climbing), i.e. moves that lead to an increase of the energy function. In particular, larger values of the temperature parameter T make the acceptance of uphill moves more likely.

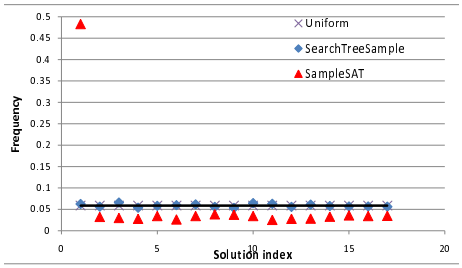
In this section, we will show that SA can only deal with relatively low energy barriers if we want to maintain a reasonable efficiency in the rejection sampling scheme. Consider the following CNF formula that we call $XORBarrier(b)$:

$$(x_1 \Rightarrow y_1) \wedge (x_1 \Rightarrow y_2) \wedge \cdots \wedge (x_1 \Rightarrow y_b) \wedge (\neg x_1 \Rightarrow \neg y_1) \wedge (\neg x_1 \Rightarrow \neg y_2) \wedge \cdots \wedge (\neg x_1 \Rightarrow \neg y_b).$$

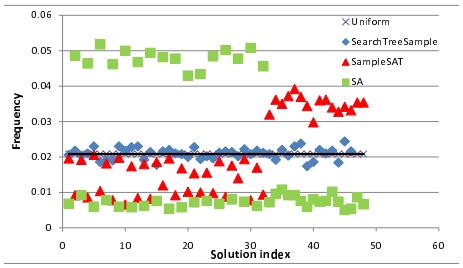
We use the term $XORBarrier(b)$ because it is equivalent to a conjunction of XOR constraints of the form $\neg(x_1\ XOR\ y_1) \wedge \cdots \wedge \neg(x_1\ XOR\ y_b)$. It is easy to see that for any value of b, these instances have only two solutions $(x_1, y_1, \cdots, y_b) = (0 \ldots 0)$ and $(x_1, y_1, \cdots, y_b) = (1 \cdots 1)$. It can be seen that $d(i) = |\{\sigma \in \{0,1\}^n | E(\sigma) = i\}| = 2\binom{b}{i}$. For any value of the temperature parameter T, the steady state probability of having SA in a configuration with energy i is

$$\mathbb{P}[E(\sigma) = i] = \sum_{\sigma | E(\sigma) = i} P_T(\sigma) \propto n(i) e^{-\frac{i}{T}} = 2\binom{b}{i} e^{-\frac{i}{T}}.$$

The key feature of this type of instances is the following. Since Simulated Annealing (and Gibbs Sampling) flips only one variable at a time, it is easy to see that any path in the Markov Chain graph that brings from one solution to



(a) Asymmetric space with energy barrier.



(b) Random formula with energy barrier.

Figure 2: Uniformity of sampling. Frequency each solution is sampled by different methods.

the other one will contain a configuration that violates $b/2$ constraints. Therefore we conclude that there is an energy barrier of "height" $b/2$ between the two solutions.

For large values of b, one cannot find a temperature T that provides both high enough $P_T(0)$ (i.e. small number of flips per solution) and $P_T(b/2)$ (i.e. probability of "jumping" over the barrier) to obtain a practical sampler. For instance, for $b = 80$, to get $P_T(40) > 10^{-9}$ (i.e. climbing the barrier on average once in about a billion samples) SA needs a temperature $T > 0.75$, but $P_{0.75}(0) = 7.4 \times 10^{-9}$ (which means that on average we need more than 10^8 samples to get a single solution). Similar results are obtained when using Gibbs sampling. This is because a Gibbs sampler has the same Boltzmann steady state probability distribution and it also proceeds by flipping a single variable at a time, so it cannot "jump" over the barrier with a single move.

Since instances in $XORBarrier(b)$ belong to 2-SAT and have 2 solutions, from Theorem 2 Algorithm 1 provides uniform samples in polynomial time.

A common strategy to partially overcome the ergodicity problems of Gibbs sampling and Simulated Annealing is the use of multiple parallel chains [9] or restarts [8]. These approaches can be quite effective and, for instance, are capable of producing uniform samples for the $XORBarrier(b)$ class of instances presented above. Intuitively, this is because on average 50% of the random initial assignments will be on one side of the barrier (i.e., the half-hypercube with $x_1 = 0$) and the other 50% on the other side (i.e., $x_1 = 1$).

6.3 Asymmetric spaces with energy barriers

These approaches are however not sufficient to sample from distributions where there are "solution clusters" (i.e., groups of solutions that are close in Hamming distance) of different sizes that are separated by energy barriers. Consider for instance the following class of instances that we call $AsymXORbarrier(b, \ell)$:

$$XORBarrier(b) \wedge (x_1 \vee z_1) \wedge (x_1 \vee z_2) \wedge \cdots \wedge (x_1 \vee z_\ell)\,.$$

The effect of the additional clauses $(x_1 \vee z_i)$ is to create a cluster of 2^ℓ solutions on one side of the barrier ($x_1 = 1$), while there exist only one solution with $x_1 = 0$.

As shown in Figure 2a and Table 1 (bottom rows), `SearchTreeSampler` provides a much more uniform sampling compared to SampleSAT on this type of instances. Specifically, the uniformity of sampling hypothesis is rejected for SampleSAT according to the χ^2-test. This is because SampleSAT employs restarts and therefore samples the first solution in Figure 2a (corresponding to the isolated solution with all variables set to 0) too often, i.e. about 50% of the times. Similarly biased results are obtained using a Gibbs Sampler with multiple parallel chains (as implemented in the Alchemy system [9]), while plain SA or Gibbs is not able to cross the barrier in a reasonable amount of time. Further, we see from Table 1 (4th column) that thanks to MiniSAT's reasoning power, `SearchTreeSampler` is about 3 orders of magnitude faster than SampleSAT.

6.4 Embedded energy barriers

In Table 1 (top rows), we evaluate the performance of the methods considered on three types of instances: a logistic one generated by SATPlan [19] (*logistic*, with 110 variables, 461 clauses, and 512 solutions), a graph Coloring problem from SatLib [20](*coloring*, with 90 variables, 300 clauses, and 900 solutions), and a random 3-SAT formula (*random*, with 75 variables, 315 clauses, and 48 solutions). We collect respectively $P = 50000$, $P = 200000$, and $P = 5000$ samples for each instance. We also artificially introduce an energy barrier in each of these instances by choosing a variable z such that there are roughly half solutions with $z = 1$ and half solutions with $z = 0$ in the original formula. We then introduce a new set clauses defined by $XORbarrier(40)$ where we substitute z to x_1 and $y_1, \ldots, y_{40}$ are fresh variables. Note that this does not change the number of solutions.

We experimented with several values of k and T and we provide a summary of the best results obtained in Table 1, both for the original formulas and the ones with an embedded energy barrier. By carefully choosing the tempera-

Method	Instance	Parameter	Time (s)	χ^2	P-value

SearchTreeSampler	AsymXORBarrier(80,8)	k=50	1.6	197.17	**0.99**

Table 1: Uniformity of sampling for instances with and without embedded energy barriers. P-value is the probability of observing an event at least as extreme under the null hypothesis (uniform sampling). In bold null hypothesis is not rejected.

ture parameter T, SA can provide uniform samples for the original formulas. However, it is very slow compared to the other methods (smaller T would make it faster, but the samples would not be uniform). On the other hand, SampleSAT is generally much faster, but the samples provided are far less uniform. SearchTreeSampler is superior to both SA and SampleSAT, both in terms of running time (at least 2 orders of magnitude faster) and uniformity. As expected, increasing k improves the uniformity and it does not affect the running time because it also produces more samples per run.

As expected, the introduction of energy barriers severely limits the ergodicity of SA, as shown in the last column of Table 1 and in Figure 2. As a result, both SA and SampleSAT fail to provide uniform samples (according to the χ^2 test) for the instances with embedded energy barriers. On the other hand, the uniformity of SearchTreeSampler is not affected, although the runtime increases (because the search tree is deeper with the introduced fresh variables).

7 A New Model Counting Technique

A typical way [21, 22] to estimate the number of solutions $|S_F| = Z$ (model count) of a formula F using a sample approximation is to estimate a series of multipliers

$$\frac{Z}{Z(x_1 = a_1)} \frac{Z(x_1 = a_1)}{Z(x_1 = a, x_2 = a_2)} \cdots \frac{Z(x_1 = a_1, \cdots, x_{n-1} = a_{n-1})}{1}.$$

For instance, $\frac{Z(x_1=a_1)}{Z}$ is given by the fraction of solutions that have $x_1 = a_1$ (the number of solutions in the green vs. yellow part of the search tree in Figure 3), and so on. This can be a challenging task because one has to heuristically select a "good" variable ordering and polarities $a_1, \cdots, a_n$ to condition on, and solve multiple sampling tasks with some of the variables clamped [22].

Algorithm 1 provides a new direct way of estimating the number of solutions. Let S_i be the set of pseudosolutions of level i. Suppose $Z = |S_n| > 0$ (the formula is satisfiable), and for simplicity let $M = 2^\ell = 2$. Then, we have

$$Z = |S_n| = \frac{|S_n|}{|S_{n-1}|} \frac{|S_{n-1}|}{|S_{n-2}|} \frac{|S_{n-2}|}{|S_{n-3}|} \cdots \frac{|S_1|}{1}$$

(see right panel of Figure 3), where we can estimate each multiplier using the relation

$$\frac{|S_i|}{|S_{i-1}|} = \frac{1}{|S_{i-1}|} \sum_{s \in S_{i-1}} |D(s)| \approx \frac{1}{|\Phi_{i-1}|} \sum_{\widetilde{s} \in \Phi_{i-1}} |D(\widetilde{s})|,$$

where elements $\widetilde{s} \in \Phi_{i-1}$ provided by Algorithm 1 are (approximately) uniformly sampled elements of S_{i-1}. Note that each multiplier corresponds to the average number of descendants at a given level i of the search tree, and we can estimate all of them in a single run of SearchTreeSampler (i.e. no need to solve multiple sampling tasks as in [22]).

7.1 Experimental Results

We compare our new counting method with SampleSearch [23], currently the best model counter based on (importance) sampling [12], on several large instances (with known ground truth) from a standard model counting benchmark [3]. In Figure 4 we plot the estimated model count over time (as more samples are being collected) for the two methods, for 4 representative instances (encodings of Latin Squares and Langford's problems). Note that both methods rely on MiniSAT as internal constraint solver. Both methods are run on the same 3GHz machine, `SearchTreeSampler` with $k = 500$ and SampleSearch with parameters as in [23].

Our empirical results show that `SearchTreeSampler` converges faster and provides more accurate estimates. Similar results are obtained for other instances in the benchmark (not reported for space reasons). Note that these instances have a rather large number of solutions so it is difficult to evaluate the uniformity of the sampling using a χ^2 test. In this case, the accuracy of the estimates of Z is an indication of the of the quality of the sampling scheme.

8 Conclusions

We presented `SearchTreeSampler`, a new method to sample solutions of Boolean formulas and to estimate their count. Our method uses a constraint solver as a black-box, and can therefore leverage the reasoning power of state-of-the-art constraint solving technology, while maintaining an approximately uniform exploration of the search tree. We presented several challenging domains, such as energy barriers and asymmetric search spaces, that reveal the difficulties of sampling. We presented data demonstrating that standard methods such as Simulated Annealing, Gibbs Sampling, and SampleSAT seriously suffer from these difficulties in terms of runtime and uniformity of the sampling. Our results also demonstrate that `SearchTreeSampler` can overcome many of these difficulties and is considerably faster on a set of benchmark problems. Further, we show that the intermediate samples of pseudosolutions provided by our method can be used in a new model counting technique, which is shown to be very effective in practice.

Abstract

Generative models for graphs have been typically committed to strong prior assumptions concerning the form of the modeled distributions. Moreover, the vast majority of currently available models are either only suitable for characterizing some particular network properties (such as degree distribution or clustering coefficient), or they are aimed at estimating joint probability distributions, which is often intractable in large-scale networks. In this paper, we first propose a novel network statistic, based on the Laplacian spectrum of graphs, which allows to dispense with any parametric assumption concerning the modeled network properties. Second, we use the defined statistic to develop the *Fiedler random graph* model, switching the focus from the estimation of joint probability distributions to a more tractable conditional estimation setting. After analyzing the dependence structure characterizing Fiedler random graphs, we evaluate them experimentally in edge prediction over several real-world networks, showing that they allow to reach a much higher prediction accuracy than various alternative statistical models.

1 INTRODUCTION

Arising from domains as diverse as bioinformatics and web mining, large-scale data exhibiting network structure are becoming increasingly available. Network models are commonly used to represent the relations among data units and their structural interactions. Recent studies, especially targeted at social network modeling, have focused on random graph models of those networks. In the simplest form, a social network is a configuration of binary random variables X_{uv} such that the value of X_{uv} stands for the presence or absence of a link between nodes u and v in the network. The general idea underlying random graph modeling is that network configurations are generated by a stochastic process governed by specific probability laws, so that different models correspond to different families of distributions over graphs.

The simplest random graph model is the Erdős-Rényi (ER) model [Erdős and Rényi, 1959], which assumes that the probability of observing a link between two nodes in a given graph is constant for any pair of nodes in that graph, and it is independent of which other edges are being observed. In preferential attachment models [Barabási and Albert, 1999], the probability of linking to any specified node is proportional to the degree of the node in the graph, leading to "rich get richer" effects. Small-world models [Watts and Strogatz, 1998] try to capture instead some phenomena often observed in real networks such as high clustering coefficients and small diameters [Newman, 2010]. A sophisticated attempt to model complex dependences between edges in the form of Gibbs-Boltzmann distributions is made by exponential random graph (ERG) models [Snijders et al., 2006], which subsume the ER model as a special case. Finally, a recent attempt at modeling real networks through a stochastic generative process is made by Kronecker graphs [Leskovec et al., 2010], which try to capture phenomena such as heavy-tailed degree distributions and shrinking diameter properties while paying attention to the temporal dynamics of network growth.

While some of these models behave better than others in terms of computational tractability, one basic limitation affecting all of them is what we may call a *parametric assumption* concerning the probability laws underlying the observed network properties. In other words, currently available models of network structure assume that the probability distribution gener-

*Université Charles de Gaulle – Lille 3, Villeneuve d'Ascq (France).

ating the network can be expressed through a particular parametric form $P(\mathcal{G}|\,\boldsymbol{\theta})$, where $\mathcal{G}$ is the observed graph and $\boldsymbol{\theta}$ is a parameter vector. For example, typical formulations of exponential random graph models assume that the building blocks of real networks are given by such structures as k-stars and k-triangles, with different weights assigned to different structures, whereas Kronecker graphs assume that the number of edges and the number of nodes in a given network are related by a densification power law with a suitable densification parameter. In such frameworks, estimating the model from data reduces to fitting the model parameters, whereas the model structure remains fixed from the very beginning. The problem is that, in order for a parametric model to deliver an accurate estimate of the distribution at hand, its prior assumption concerning the form of the modeled distribution must be satisfied by the given data, which is something that we can rarely assess a priori. To date, the knowledge we have concerning real-world network phenomena does not allow to assume that any particular parametric assumption is really capturing in depth any network-generating law, although some observed properties may happen to be modeled fairly well.

The aim of this paper is twofold. On the one hand, we take a first step toward *nonparametric* modeling of random networks by developing a novel network statistic, which we call the *Fiedler delta* statistic. The Fiedler delta function allows to model different graph properties at once in an extremely compact form. This statistic is based on the spectral analysis of the graph Laplacian. In particular, it is based on the smallest non-zero eigenvalue of the Laplacian matrix, which is known as Fiedler value [Fiedler, 1973, Mohar, 1991]. On the other hand, we systematically adopt a *conditional* approach to random graph modeling, i.e. we focus on the conditional distribution of edges given some neighboring portion of the network, while setting aside the problem of estimating joint distributions. The resulting conditional random graph model is what we call *Fiedler random graph* (FRG). Roughly speaking, to model the conditional distribution of an edge variable X_{uv} with respect to its neighborhood, we compute the difference in Fiedler values for the vicinity subgraph including or excluding the edge $\{u, v\}$. The underlying intuition is that the variations encapsulated in the Fiedler delta for each particular edge will give a measure of the role of that edge in determining the algebraic connectivity of its neighborhood. As part of our contributions, we theoretically prove that FRGs capture edge dependencies at any distance within a given neighborhood, hence defining a fairly general class of conditional probability distributions over graphs.

Experiments on the estimation of (conditional) link distributions in large-scale networks show that FRGs are well suited for estimation problems on very large networks, especially small-world and scale-free networks. Our results reveal that the FRG model supersedes other approaches in terms of edge prediction accuracy, while allowing for efficient computation in the large-scale setting. In particular, it is known that the computation of the Fiedler delta scales polynomially in the size of the analyzed neighborhood [Bai et al., 2000]. And the experiments show that even for small sizes of neighborhoods (which allow for extremely fast computation), our model regularly outperforms the alternative ones—which we reformulate here in terms of conditional models so as to allow for transparent comparison.

The paper is organized as follows. Sec. 2 reviews some preliminary notions concerning the Laplacian spectrum of graphs. The FRG model is presented in Sec. 3, where we also show how to estimate FRGs from data, and we analyze the dependence structures involved in FRGs. In Sec. 4 we review (and to some extent develop) a few alternative conditional approaches to random graph estimation, starting from some well-known generative models. All considered models are then evaluated experimentally in Sec. 5, while Sec. 6 draws some conclusions and sketches a few directions for further work.

2 GRAPHS, LAPLACIANS, AND EIGENVALUES

Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be an undirected graph with n nodes. In the following we assume that the graph is unweighted with adjacency matrix $\mathbf{A}$. For each (unordered) pair of nodes $\{u, v\}$ such that $u \neq v$, we take X_{uv} to denote a binary random variable such that $X_{uv} = 1$ if $\{u, v\} \in \mathcal{E}$, and $X_{uv} = 0$ otherwise. Since the graph is undirected, $X_{uv} = X_{vu}$.

The degree d_u of a node $u \in \mathcal{V}$ is defined as the number of connections of u to other nodes, that is $d_u = |\{v : \{u, v\} \in \mathcal{E}\}|$. Accordingly, the degree matrix $\mathbf{D}$ of a graph $\mathcal{G}$ corresponds to the diagonal matrix with the vertex degrees $d_1, \ldots, d_n$ on the diagonal. The main tools exploited by the random graph model proposed here are the graph Laplacian matrices. Different graph Laplacians have been identified in the literature [von Luxburg, 2007]. In this paper, we use consistently the *unnormalized graph Laplacian*, defined as $\mathbf{L} = \mathbf{D} - \mathbf{A}$. The basic facts related to the unnormalized Laplacian matrix can be summarized as follows:

Proposition 1 (Mohar [1991])**.** *The unnormalized graph Laplacian* $\mathbf{L}$ *of an undirected graph* $\mathcal{G}$ *with* n

nodes has the following properties: (i) $\mathbf{L}$ *is symmetric and positive semi-definite; (ii)* $\mathbf{L}$ *has* n *non-negative, real-valued eigenvalues* $0 = \lambda_1(\mathcal{G}) \leq \ldots \leq \lambda_n(\mathcal{G})$*; (iii) the multiplicity of the eigenvalue 0 of* $\mathbf{L}$ *equals the number of connected components in the graph, that is,* $\lambda_2(\mathcal{G}) > 0$ *if and only if* $\mathcal{G}$ *is connected.*

In the following, the (algebraic) multiplicity of an eigenvalue λ will be denoted by $M(\lambda, \mathcal{G})$. If the graph has one single connected component, then $M(0, \mathcal{G}) = 1$, and the second smallest eigenvalue $\lambda_2(\mathcal{G}) > 0$ is called *Fiedler eigenvalue*. The Fiedler eigenvalue provides insight into several graph properties: when there is a nontrivial spectral gap, i.e. $\lambda_2(\mathcal{G})$ is clearly separated from 0, the graph has good expansion properties, stronger connectivity, and rapid convergence of random walks in the graph [Mohar, 1991]. For example, it is known that $\lambda_2(\mathcal{G}) \leq \mu(\mathcal{G})$, where $\mu(\mathcal{G})$ is the edge connectivity of the graph (i.e. the size of the smallest edge cut whose removal makes the graph disconnected). Notice that if the graph has more than one connected component, then $\lambda_2(\mathcal{G})$ will be also equal to zero, thus implying that the graph is not connected. Without loss of generality, we abuse the term Fiedler eigenvalue to denote the smallest eigenvalue different from zero, regardless of the number of connected components. In this paper, by Fiedler value we will mean the eigenvalue $\lambda_{k+1}(\mathcal{G})$, where $k = M(0, \mathcal{G})$.

For any pair of nodes u and v in a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, we define two corresponding graphs $\mathcal{G}^+$ and $\mathcal{G}^-$ in the following way: $\mathcal{G}^+ = (\mathcal{V}, \mathcal{E} \cup \{\{u, v\}\})$, and $\mathcal{G}^- = (\mathcal{V}, \mathcal{E} \setminus \{\{u, v\}\})$. Clearly, we have that either $\mathcal{G}^+ = \mathcal{G}$ or $\mathcal{G}^- = \mathcal{G}$. A basic property concerning the Laplacian eigenvalues of $\mathcal{G}^+$ and $\mathcal{G}^-$ is the following [Mohar, 1991, Anderson and Morley, 1985, Cvetković et al., 1979]:

Lemma 1. *If* $\mathcal{G}^+$ *and* $\mathcal{G}^-$ *are two graphs with* n *nodes, such that* $\{u, v\} \subseteq \mathcal{V}$*,* $\mathcal{G}^+ = (\mathcal{V}, \mathcal{E} \cup \{\{u, v\}\})$*, and* $\mathcal{G}^- = (\mathcal{V}, \mathcal{E} \setminus \{\{u, v\}\})$*, then we have that:*

1. $\sum_{i=1}^{n} \lambda_i(\mathcal{G}^+) - \lambda_i(\mathcal{G}^-) = 2$*;*
2. $\lambda_i(\mathcal{G}^+) \leq \lambda_i(\mathcal{G}^-)$ *for any* i *such that* $1 \leq i \leq n$*.*

3 FIEDLER RANDOM GRAPHS

Fiedler random graphs are defined in Sec. 3.1, while in Secs. 3.2 and 3.3 we deal with the problems of estimating them from data and characterizing their statistical dependence structure respectively.

3.1 CONDITIONAL DISTRIBUTIONS

Given the notions reviewed above, we introduce the Fiedler delta function $\Delta\lambda_2$, which is defined as follows. Let $k = M(0, \mathcal{G}^+)$. Then,

$$\Delta\lambda_2(u, v, \mathcal{G}) = \lambda_{k+1}(\mathcal{G}^+) - \lambda_{k+1}(\mathcal{G}^-) \qquad (1)$$

In other words, for any pair of nodes u and v in graph $\mathcal{G}$, the Fiedler delta value of the pair $\{u, v\}$ in $\mathcal{G}$ is the (absolute) variation in the Fiedler eigenvalue of the graph Laplacian that would result from removing edge $\{u, v\}$ from $\mathcal{G}^+$.

Lemma 1 immediately implies the following proposition:

Proposition 2. *For any graph* $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ *and any pair of nodes* u *and* v *such that* $\{u, v\} \in \mathcal{E}$*, we have that* $0 \leq \Delta\lambda_2(u, v, \mathcal{G}) \leq 2$*.*

Proof. Let $\mathcal{G}^- = (\mathcal{V}, \mathcal{E} \setminus \{\{u, v\}\})$ and $k = M(0, \mathcal{G})$. The theorem follows straightforwardly from Lemma 1, given that $\Delta\lambda_2(u, v, \mathcal{G}) = \lambda_{k+1}(\mathcal{G}) - \lambda_{k+1}(\mathcal{G}^-)$. □

Using the Fiedler delta statistic, we can proceed to define a Fiedler random graph. Given $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, let $\mathcal{X}(\mathcal{G})$ denote the set of random variables defined on $\mathcal{G}$, that is $\mathcal{X}(\mathcal{G}) = \{X_{uv} \colon u \neq v \wedge \{u, v\} \subseteq \mathcal{V}\}$. Then:

Definition 1. *Given a graph* $\mathcal{G} = (\mathcal{V}, \mathcal{E})$*, suppose we associate a subgraph* $\mathcal{G}_{uv}$ *of* $\mathcal{G}$ *to each variable* $X_{uv} \in \mathcal{X}(\mathcal{G})$*. We say that* $\mathcal{G}$ *is a* Fiedler random graph *if, for any* $X_{uv} \in \mathcal{X}(\mathcal{G})$*, we have that* $P(X_{uv} | \, \mathcal{X}(\mathcal{G}_{uv}) \setminus \{X_{uv}\}) = P(X_{uv} | \, \Delta\lambda_2(u, v, \mathcal{G}_{uv}))$*.*

Concerning Definition 1, we stress the importance of two points. First, the key intuition motivating FRGs is to treat the Fiedler delta function as a real-valued random variable defined over graph configurations, and to exploit this random variable as a compact representation of those configurations. Second, FRGs are *conditional* models, i.e. they only define conditional distributions of edges in a random graph given the possible configurations of other edges. The model definition does not specify whether and how the considered conditional distributions can be combined to obtain a consistent factorization of the joint distribution of $\mathcal{X}(\mathcal{G})$. In order to obtain that result, the model should take into account the global dependence structure of $\mathcal{X}(\mathcal{G})$, but this goal is not pursued by FRG modeling. Two interesting questions that can be raised on the nature of the FRG model are then the following. First, how does the Fiedler delta statistic behave with respect to the Markov dependence property [Besag, 1974, Frank and Strauss, 1986]? Second, how useful can be the information enclosed in the Fiedler delta statistic for learning and mining applications over large-scale networks? One basic result related to the first question is presented in Sec. 3.3, whereas Sec. 5 will address the second point.

3.2 MODEL ESTIMATION

The goal of estimating a FRG from data is to obtain an estimate of the conditional distribution $P(X_{uv}|\,\mathcal{X}(\mathcal{G}_{uv}) \setminus \{X_{uv}\})$, defined over subgraphs $\mathcal{G}_{uv}$ of $\mathcal{G}$. Starting from Definition 1, this quantity can be manipulated as follows:

$$\begin{aligned} P(X_{uv}|\,\mathcal{X}(\mathcal{G}_{uv}) \setminus \{X_{uv}\}) &= P(X_{uv}|\,\Delta\lambda_2(u,v,\mathcal{G}_{uv})) \\ &= \frac{p(\Delta\lambda_2(u,v,\mathcal{G}_{uv})|\,X_{uv})P(X_{uv})}{p(\Delta\lambda_2(u,v,\mathcal{G}_{uv}))} \\ &= \frac{p(\Delta\lambda_2(u,v,\mathcal{G}_{uv})|\,X_{uv})P(X_{uv})}{\sum\limits_{x_{uv}} p(\Delta\lambda_2(u,v,\mathcal{G}_{uv})|\,x_{uv})P(x_{uv})} \end{aligned} \tag{2}$$

In Eq. 2, $P(X_{uv})$ is the prior probability of observing an edge between any two nodes u and v, whereas $p(\Delta\lambda_2(u,v,\mathcal{G}_{uv})|\,X_{uv})$ is the conditional density of the Fiedler delta $\Delta\lambda_2(u,v,\mathcal{G}_{uv})$ given the value of X_{uv}. Suppose we have a network $\mathcal{G} = (\mathcal{V},\mathcal{E})$, and that our training sample is a dataset $\mathcal{D}$, defined as $\mathcal{D} = \big\{(x_{u_1v_1},\mathcal{G}_{u_1v_1}),\ldots,(x_{u_nv_n},\mathcal{G}_{u_nv_n})\big\}$. In other words, the training data are n observations of node pairs $\{u_i,v_i\}$ such that, for each one of them, we know both the value of $X_{u_iv_i}$ and the configuration of $\mathcal{G}_{u_iv_i}$ in $\mathcal{G}$. A simple estimate for $P(X_{uv})$ can then be obtained by computing the proportion of linked/unlinked node pairs $\{u_i,v_i\}$ in $\mathcal{D}$. Let $\mathcal{D}_{x_{uv}}$ denote the set $\big\{\{u_i,v_i\}\colon (x_{u_iv_i},\mathcal{G}_{u_iv_i}) \in \mathcal{D} \wedge x_{u_iv_i} = x_{uv}\big\}$. Then, $\widehat{P}(x_{uv}) = \frac{1}{n}\left|\mathcal{D}_{x_{uv}}\right|$. On the other hand, in order to estimate $p(\Delta\lambda_2(u,v,\mathcal{G}_{uv})|\,X_{uv})$, we need to make a choice concerning the form of the modeled density function. In the lack of prior knowledge concerning the form of the density, a reasonable choice is to adopt a nonparametric estimation technique. In particular, we use a kernel density estimator [Rosenblatt, 1956, Parzen, 1962], defined as follows:

$$\begin{aligned} &\hat{p}(\Delta\lambda_2(u,v,\mathcal{G}_{uv})|\,x_{uv}) = \\ &= \frac{1}{|\mathcal{D}_{x_{uv}}|} \sum_{\{u_i,v_i\}\in\mathcal{D}_{x_{uv}}} K_{\Delta\lambda_2}\big(\{u,v\},\{u_i,v_i\}\big) \end{aligned} \tag{3}$$

where

$$\begin{aligned} &K_{\Delta\lambda_2}\big(\{u,v\},\{u_i,v_i\}\big) = \\ &= \frac{1}{h}\,K\left(\frac{\Delta\lambda_2(u,v,\mathcal{G}_{uv}) - \Delta\lambda_2(u_i,v_i,\mathcal{G}_{u_iv_i})}{h}\right) \end{aligned} \tag{4}$$

and K is a kernel function with bandwidth h [Silverman, 1986]. In our implementation of FRGs, we use the Epanechnikov kernel [Epanechnikov, 1969], namely $K(t) = \frac{3}{4}\big(1-t^2\big)\,\mathbb{1}_1(|t|)$, where $\mathbb{1}_y(x) = 1$ if $x \le y$, and $\mathbb{1}_y(x) = 0$ otherwise. The Epanechnikov kernel is more appealing than other possible functions (such as the Gaussian kernel) because of its computational convenience. At the same time, it displays analogous properties in terms of statistical consistency [Silverman, 1986].

3.3 DEPENDENCE STRUCTURE

In order to illustrate the behavior of FRGs with respect to conditional independence, we first recall the definition of Markov dependence for random graph models [Frank and Strauss, 1986]. Let $\mathcal{N}(X_{uv})$ denote the set $\{X_{wz}\colon \{w,z\} \in \mathcal{E} \wedge |\{w,z\} \cap \{u,v\}| = 1\}$. A Markov random graph is then defined as follows:

Definition 2. *A random graph $\mathcal{G}$ is said to be a* Markov graph *(or to have a* Markov dependence structure*) if, for any pair of variables X_{uv} and X_{wz} in $\mathcal{G}$ such that $\{u,v\} \cap \{w,z\} = \emptyset$, we have that $P(X_{uv}|\,X_{wz},\mathcal{N}(X_{uv})) = P(X_{uv}|\,\mathcal{N}(X_{uv}))$.*

Based on Definition 2, we say that the dependence structure of a random graph $\mathcal{G}$ is *non-Markovian* if, for disjoint pairs of nodes $\{u,v\}$ and $\{w,z\}$, it does not imply that $P(X_{uv}|\,X_{wz},\mathcal{N}(X_{uv})) = P(X_{uv}|\,\mathcal{N}(X_{uv}))$, i.e. if it is consistent with the inequality $P(X_{uv}|\,X_{wz},\mathcal{N}(X_{uv})) \neq P(X_{uv}|\,\mathcal{N}(X_{uv}))$. We can then prove the following proposition:

Proposition 3. *There exist Fiedler random graphs with non-Markovian dependence structure.*

Proof. To prove the proposition, we make use of the following equalities [Fiedler, 1973]: if graphs $\mathcal{G}_1$ and $\mathcal{G}_2$ are, respectively, a path and a circuit of size n, then $\lambda_2(\mathcal{G}_1) = 2\,(1-\cos(\pi/n))$ and $\lambda_2(\mathcal{G}_2) = 2\,(1-\cos(2\pi/n))$. Consider a graph $\mathcal{G} = (\mathcal{V},\mathcal{E})$ such that $\mathcal{V} = \{u,v,w,z\}$ and $\mathcal{E} = \{\{u,v\},\{v,w\},\{w,z\},\{u,z\}\}$, and let $\mathcal{G}_{uv} = (\mathcal{V}_{uv},\mathcal{E}_{uv})$ be the subgraph of $\mathcal{G}$ incident to $\mathcal{E}_{uv} = \mathcal{E}\setminus\{\{w,z\}\}$. If $\mathcal{G}$ is a Markov graph, it must be the case that $P(X_{uv}|\,X_{wz},X_{vw},X_{uz}) = P(X_{uv}|\,X_{vw},X_{uz})$. Now, suppose that $\mathcal{G}$ is a FRG. In this case, we have that

$$\begin{aligned} P(X_{uv}|\,X_{wz},X_{vw},X_{uz}) &= P(X_{uv}|\,\mathcal{X}(\mathcal{G}) \setminus \{X_{uv}\}) \\ &= \frac{p(\Delta\lambda_2(u,v,\mathcal{G})|\,X_{uv})P(X_{uv})}{p(\Delta\lambda_2(u,v,\mathcal{G}))} \end{aligned} \tag{5}$$

and, similarly,

$$P(X_{uv}|\,X_{vw},X_{uz}) = \frac{p(\Delta\lambda_2(u,v,\mathcal{G}_{uv})|\,X_{uv})P(X_{uv})}{p(\Delta\lambda_2(u,v,\mathcal{G}_{uv}))} \tag{6}$$

Eqs. 5–6 imply that, if the dependence structure of $\mathcal{G}$ is Markovian, then the following equality must hold:

$$\frac{p(\Delta\lambda_2(u,v,\mathcal{G})|\,X_{uv})}{p(\Delta\lambda_2(u,v,\mathcal{G}))} = \frac{p(\Delta\lambda_2(u,v,\mathcal{G}_{uv})|\,X_{uv})}{p(\Delta\lambda_2(u,v,\mathcal{G}_{uv}))} \tag{7}$$

Since the configuration of $\mathcal{G}$ and $\mathcal{G}_{uv}$ is given by a circuit and a path respectively, where both have size 4, we know that $\lambda_2(\mathcal{G}) = 2\,(1-\cos(\pi/2))$ and $\lambda_2(\mathcal{G}_{uv}) = 2\,(1-\cos(\pi/4))$. Also, if $\mathcal{G}^- = (\mathcal{V}, \mathcal{E} \setminus \{\{u,v\}\})$ and $\mathcal{G}^-_{uv} = (\mathcal{V}_{uv}, \mathcal{E}_{uv} \setminus \{\{u,v\}\})$, notice that $\lambda_2(\mathcal{G}^-) = \lambda_2(\mathcal{G}_{uv})$, since $\mathcal{G}^-$ is also a path of size 4, and that $M(0,\mathcal{G}^-_{uv}) = M(0,\mathcal{G}_{uv}) + 1$, since $\mathcal{G}^-_{uv}$ has one more connected component than $\mathcal{G}_{uv}$. Therefore, we have that $\Delta\lambda_2(u,v,\mathcal{G}) = 2\cos(\pi/4)$ and $\Delta\lambda_2(u,v,\mathcal{G}_{uv}) = 2\,(1-\cos(\pi/4))$, i.e. $\Delta\lambda_2(u,v,\mathcal{G}) \neq \Delta\lambda_2(u,v,\mathcal{G}_{uv})$. Because of this inequality, there will exist parameterizations of p which do not satisfy Eq. 7, which means that the dependence structure of $\mathcal{G}$ is non-Markovian. □

Note that the proof of Proposition 3 can be straightforwardly generalized to the dependence between X_{uv} and X_{wz} in circuits/paths of arbitrary size n, since the expression used for the Fiedler eigenvalues of such graphs holds for any n. In fact, suppose that the 4-nodes circuit $\mathcal{G}$ used in the proof is replaced with a circuit $\mathcal{G}^* = (\mathcal{V}^*, \mathcal{E}^*)$ of size n, where $\mathcal{V}^* = \mathcal{V} \cup \{s_1,\ldots,s_1,\ldots,s_m,t_1,\ldots,t_m\}$ and $\mathcal{E}^*$ is obtained from $\mathcal{E}$ by replacing $\{u,z\}$ and $\{v,w\}$, respectively, with a path from u to z going through $s_1,\ldots,s_m$ and a path from v to w going through $t_1,\ldots,t_m$, so that $n = 2m+4$. In this case, if $\mathcal{G}^*_{uv}$ is the subgraph of $\mathcal{G}^*$ incident to $\mathcal{E}^*_{uv} = \mathcal{E}^* \setminus \{\{w,z\}\}$, we have again that $\Delta\lambda_2(u,v,\mathcal{G}^*) \neq \Delta\lambda_2(u,v,\mathcal{G}^*_{uv})$, which means that there exist FRGs such that $\frac{p(\Delta\lambda_2(u,v,\mathcal{G}^*)|\,X_{uv})}{p(\Delta\lambda_2(u,v,\mathcal{G}^*))} \neq \frac{p(\Delta\lambda_2(u,v,\mathcal{G}^*_{uv})|\,X_{uv})}{p(\Delta\lambda_2(u,v,\mathcal{G}^*_{uv}))}$.

4 OTHER CONDITIONAL RANDOM NETWORKS

In this section, we adapt three families of random graph models—namely the ERG, Watts-Strogatz (WS), and Barabási-Albert (BA) models respectively—to the task of conditional estimation of edge distributions, and we also review the entailed dependence structures. This will allow for a clear comparison of such models to FRGs in Sec. 5. Kronecker graphs are not considered here because it is not straightforward how they could be turned into conditional estimators.

4.1 EXPONENTIAL RANDOM GRAPH MODELS

Let $G(\mathcal{V})$ be the set of all possible (undirected) graphs $\mathcal{G}$ with fixed vertex set $\mathcal{V}$, where $|G(\mathcal{V})| = \sqrt{2^{|\mathcal{V}|^2-|\mathcal{V}|}}$. Suppose that Φ denotes a collection of potential functions φ_i over graphs, where each $\varphi_i(\mathcal{G})$ is a graph statistic such as the number of edges or the number of triangles in $\mathcal{G}$. Then, an ERG with parameter vector $\boldsymbol{\theta} = (\theta_1,\ldots,\theta_{|\Phi|})$ defines the following Boltzmann distribution [Robins et al., 2007]:

$$P(\mathcal{X}(\mathcal{G})|\,\boldsymbol{\theta}) = \frac{1}{Z(\boldsymbol{\theta})}\exp\left\{\sum_{i=1}^{|\Phi|}\theta_i\varphi_i(\mathcal{G})\right\} \tag{8}$$

where each θ_i is a real-valued parameter associated to the potential function φ_i, and $Z(\boldsymbol{\theta})$ denotes the partition function [Koller and Friedman, 2009], given by $Z(\boldsymbol{\theta}) = \sum_{\mathcal{G}_j\in G(\mathcal{V})}\exp\big\{\sum_{i=1}^{|\Phi|}\theta_i\varphi_i(\mathcal{G}_j)\big\}$. Computing the partition function exactly is clearly intractable for graphs with more than a few nodes, which makes it quite expensive to compute joint probabilities in large networks using ERGs.

ERGs entail a simple form for the conditional distribution of edges given the remainder of the graph:

$$P(X_{uv}|\,\mathcal{X}(\mathcal{G})\setminus\{X_{uv}\};\boldsymbol{\theta}) = \frac{\exp\left\{\sum_{i=1}^{|\Phi|}\theta_i\varphi_i(\mathcal{G})\right\}}{\sum_{x_{uv}}\exp\left\{\sum_{i=1}^{|\Phi|}\theta_i\varphi_i(\mathcal{G}_{x_{uv}})\right\}} \tag{9}$$

where $\mathcal{G}_{x_{uv}}$ denotes the configuration of $\mathcal{G}$ that we obtain by clamping the value of X_{uv} to x_{uv}. Therefore, if we want to estimate the parameters of an ERG so as to maximize the model log-likelihood with respect to a data sample $\mathcal{D} = \big\{(x_{u_1v_1},\mathcal{G}_{\mathcal{S}_1}),\ldots,(x_{u_nv_n},\mathcal{G}_{\mathcal{S}_n})\big\}$, we can optimize each parameter θ_i by taking the derivative $\frac{\partial}{\partial\theta_i}\sum_{j=1}^{n}\log P(x_{u_jv_j}|\,\mathcal{X}(\mathcal{G}_{\mathcal{S}_j})\setminus\{X_{uv}\};\boldsymbol{\theta})$ and applying any gradient-based optimization technique.

4.1.1 Markov Random Graphs

Given a graph $\mathcal{G} = (\mathcal{V},\mathcal{E})$, define a k-star (for $k \geq 2$) as a set $\mathcal{E}_{\mathcal{S}_k} \subseteq \mathcal{E}$ such that $|\mathcal{E}_{\mathcal{S}_k}| = k$ and, for any $\{u,v\}$ and $\{w,z\}$ in $\mathcal{E}_{\mathcal{S}_k}$, $\{u,v\}\cap\{w,z\} = 1$. Also, let a k-triangle (for $k \geq 1$) be a set $\mathcal{E}_{\mathcal{T}_k} \subseteq \mathcal{E}$ of size $2k+1$ such that the elements of $\mathcal{E}_{\mathcal{T}_k}$ are edges $\{u,v\},\{u,w_1\},\{v,w_1\},\ldots,\{u,w_k\},\{v,w_k\}$, where $w_i \neq w_j$ for any i and j such that $1 \leq i,j \leq k$. If we use $E(\mathcal{G})$, $S_k(\mathcal{G})$, and $T_k(\mathcal{G})$ to denote, respectively, the number of edges, the number of k-stars, and the number of k-triangles in $\mathcal{G}$, then an *exponential Markov random graph* (MRG) model with parameter vector $\boldsymbol{\theta}$ is defined by the following probability distribution [Frank and Strauss, 1986]:

$$P(\mathcal{G}|\,\boldsymbol{\theta}) = \frac{1}{Z}\exp\left\{\eta\,E(\mathcal{G}) + \sum_{k=2}^{K}\sigma_k S_k(\mathcal{G}) + \tau\,T(\mathcal{G})\right\} \tag{10}$$

where K is the maximum value that we want to consider for k in the k-star statistics, $\boldsymbol{\theta} = (\eta,\sigma_2,\ldots,\sigma_K,\tau)$, and $T(\mathcal{G}) = T_1(\mathcal{G})$ is simply the number of triangles in $\mathcal{G}$. That is to say, a MRG defines a Boltzmann distribution over graphs, with parameters corresponding to edge, k-star, and triangle

statistics. Interestingly, the ER model can be characterized as a special case of MRG, where all the parameters except for η are set to zero.

MRGs are known to satisfy Definition 2 [Robins et al., 2007]. Therefore, under the probability model defined by Eq. 10, we have that, for any pair of nodes $\{u, v\}$ and any subgraph sample $\mathcal{G}_{\mathcal{S}}$ from $\mathcal{G}$, $P(X_{uv} | \mathcal{X}(\mathcal{G}_{\mathcal{S}}) \setminus \{X_{uv}\}; \boldsymbol{\theta}) = P(X_{uv} | \mathcal{N}_{\mathcal{S}}(X_{uv}); \boldsymbol{\theta})$, where $\mathcal{N}_{\mathcal{S}}(X_{uv})$ is the set of all variables X_{wz} from $\mathcal{G}_{\mathcal{S}}$ such that $|\{w, z\} \cap \{u, v\}| = 1$. Note that while Definition 2 specifies a general class of random graph models, MRGs in the strict sense refer to the class of ERGs defined above.

4.1.2 Higher-Order Models

Higher-order ERG models (HRGs) are readily obtained from MRGs by adding k-triangle counts (for $k \geq 1$) to the Boltzmann distribution of Eq. 10 [Robins et al., 2007]. Moreover, in order to avoid fixing in advance the maximum value of the k parameter, a general formulation has been proposed for HRGs through the *alternating k-star* and the *alternating k-triangle* statistics [Snijders et al., 2006], obtaining the following probability model:

$$P(\mathcal{G} | \boldsymbol{\theta}) = \frac{1}{Z} \exp \{\eta\, E(\mathcal{G}) + \sigma\, S^*(\mathcal{G}) + \tau\, T^*(\mathcal{G})\} \quad (11)$$

where, if n is the number of nodes in $\mathcal{G}$ and S_k and T_k are the usual k-stars and k-triangle counts, $S^*(\mathcal{G})$ and $T^*(\mathcal{G})$ are defined as $S^*(\mathcal{G}) = \sum_{k=2}^{n-1} (-1)^k \frac{S_k}{\rho^{k-2}}$ and $T^*(\mathcal{G}) = \sum_{k=2}^{n-2} (-1)^k \frac{T_k}{\rho^{k-2}}$ (with $\rho \geq 1$ acting as a sort of regularization parameter).

It is known that, under the distribution given by Eq. 11, $P(X_{uv} | \mathcal{X}(\mathcal{G}_{\mathcal{S}}) \setminus \{X_{uv}\}; \boldsymbol{\theta}) = P(X_{uv} | \mathcal{N}^*_{\mathcal{S}}(X_{uv}); \boldsymbol{\theta})$ [Robins et al., 2007], where $\mathcal{N}^*_{\mathcal{S}}(X_{uv})$ is the set containing any X_{wz} from $\mathcal{G}$ such that $X_{wz} \neq X_{uv}$ and, for at least one edge $\{s, t\}$, we have that $|\{s, t\} \cap \{u, v\}| = 1$ and $\{s, t\} \cap \{w, z\} \neq \emptyset$. Clearly, $\mathcal{N}_{\mathcal{S}}(X_{uv}) \subseteq \mathcal{N}^*_{\mathcal{S}}(X_{uv})$, which is why HRGs are 'higher-order' than MRGs.

4.2 WATTS-STROGATZ MODEL

The WS network model [Watts and Strogatz, 1998] defines a random network as a regular ring lattice which is randomly 'rewired' so as to introduce a certain amount of disorder, which typically leads to small-world phenomena. Given nodes $u_1, \ldots, u_n$, a WS network is generated by constructing a regular ring lattice such that each node is connected to exactly $2\,\delta$ other nodes. Network edges are then scanned sequentially, and each one of them is rewired with probability β, where, if $i < j$, rewiring an edge $\{u_i, u_j\}$ means to replace it with another edge $\{u_i, u_k\}$ such that $k \neq i$ and u_k is chosen uniformly at random from the set of all nodes that are not already linked to u_i.

Interestingly, the degree distribution corresponding to a WS network $\mathcal{G}$ with parameters δ and β takes the following form [Barrat and Weigt, 2000], for any degree $k \geq \delta$:

$$P(k) = \sum_{i=0}^{I} \binom{\delta}{i} (1-\beta)^i\, \beta^{\delta - i}\, \frac{(\delta\,\beta)^{k-\delta-i}}{(k-\delta-i)!} \exp(-\beta\,\delta) \quad (12)$$

where $I = \min\{k - \delta, \delta\}$. Given Eq. 12, we model the conditional distribution of a variable X_{uv} given the remainder of $\mathcal{G}$ through the following quantity:

$$P(X_{uv} | \mathcal{X}(\mathcal{G}) \setminus \{X_{uv}\}) = \frac{P(d_u(\mathcal{G}))\, P(d_v(\mathcal{G}))}{\sum\limits_{x_{uv}} P(d_u(\mathcal{G}_{x_{uv}}))\, P(d_v(\mathcal{G}_{x_{uv}}))} \quad (13)$$

where $d_u(\mathcal{G})$ denotes the degree of node u in $\mathcal{G}$, and each P is implicitly conditional on the values of δ and β. We refer to the conditional random graph model specified in Eq. 13 as the *conditional Watts-Strogatz (CWS) model*.

For the CWS model, the following proposition follows straightforwardly from Eq. 13:

Proposition 4. *The dependence structure of CWS models is Markovian.*

A simple estimate of the δ parameter for a data sample $\mathcal{D} = \big\{(x_{u_1 v_1}, \mathcal{G}_{u_1 v_1}), \ldots, (x_{u_n v_n}, \mathcal{G}_{u_n v_n})\big\}$ is the following:

$$\hat{\delta} = \frac{1}{2\,n} \sum_{i=1}^{n} d_{u_i}(\mathcal{G}_{\mathcal{S}_i}) + d_{v_i}(\mathcal{G}_{u_i v_i}) \quad (14)$$

On the other hand, a simple strategy for estimating the rewiring probability by a maximum likelihood approach consists in parameterizing it as a sigmoid function $\beta = \frac{1}{1+\exp(-\theta_\beta)}$, where θ_β can be optimized by exploiting the derivative $\frac{\partial}{\partial \theta_\beta} \sum_{i=1}^{n} \log P(x_{u_i v_i} | \mathcal{X}(\mathcal{G}_{u_i v_i}) \setminus \{X_{uv}\}; \delta, \theta_\beta)$.

4.3 BARABÁSI-ALBERT MODEL

The BA model was originally proposed for explaining the scale-free degree distributions often observed in real-world networks [Barabási and Albert, 1999]. In the BA model, the probability $P(u)$ of linking to any particular node u in a network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ takes the form $P(u) = \frac{d_u(\mathcal{G})^\alpha}{\sum_{v \in \mathcal{V}} d_v(\mathcal{G})^\alpha}$ [Albert and Barabási, 2002], where α is a real-valued parameter affecting the shape of the degree distribution. Given $P(u)$, we can use the following expression to characterize the conditional probability of observing edge $\{u, v\}$ given the

remainder of $\mathcal{G}$ [Newman, 2001, Barabási et al., 2002]:

$$P(X_{uv} = 1 | \mathcal{X}(\mathcal{G}) \setminus \{X_{uv}\}; \alpha) = \frac{d_u(\mathcal{G})^\alpha \, d_v(\mathcal{G})^\alpha}{\left(\sum_{w \in \mathcal{V}} d_w(\mathcal{G})^\alpha\right)^2} \tag{15}$$

We refer to the random graph model of Eq. 15 as the *conditional Barabási-Albert (CBA) model*. The α parameter can be optimized straightforwardly by gradient-based methods, so as to maximize the objective $\sum_{i=1}^{n} \log P(x_{u_i v_i} | \mathcal{X}(\mathcal{G}_{u_i v_i}) \setminus \{X_{uv}\}; \alpha)$ over an observed sample of size n.

The following property holds for CBA networks:

Proposition 5. *The dependence structure of CBA models is non-Markovian.*

Proof. Consider a CBA network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\{u, v\}$ and $\{w, z\}$ are edges in $\mathcal{E}$ such that $\{u, v\} \cap \{w, z\} = \emptyset$. $\mathcal{G}$ is a Markov graph if and only if $P(X_{uv} | X_{wz}, \mathcal{N}(X_{uv})) = P(X_{uv} | \mathcal{N}(X_{uv}))$. Let $\mathcal{G}_1$ and $\mathcal{G}_2$ be the same as defined in the proof of Proposition 4. Although $d_u(\mathcal{G}_2) = d_u(\mathcal{G}_1)$ and $d_v(\mathcal{G}_2) = d_v(\mathcal{G}_1)$, we have that $\sum_{w \in \mathcal{V}} d_w(\mathcal{G}_2)^\alpha > \sum_{w \in \mathcal{V}} d_w(\mathcal{G}_1)^\alpha$. Therefore,

$$\begin{aligned} P(X_{uv} | X_{wz}, \mathcal{N}(X_{uv})) &= P(X_{uv} | \mathcal{X}(\mathcal{G}_2) \setminus \{X_{uv}\}) \\ &= \frac{d_u(\mathcal{G}_2)^\alpha \, d_v(\mathcal{G}_2)^\alpha}{\left(\sum_{w \in \mathcal{V}} d_w(\mathcal{G}_2)^\alpha\right)^2} \neq \frac{d_u(\mathcal{G}_1)^\alpha \, d_v(\mathcal{G}_1)^\alpha}{\left(\sum_{w \in \mathcal{V}} d_w(\mathcal{G}_1)^\alpha\right)^2} \\ &= P(X_{uv} | \mathcal{X}(\mathcal{G}_1) \setminus \{X_{uv}\}) = P(X_{uv} | \mathcal{N}(X_{uv})) \end{aligned} \tag{16}$$

□

5 EXPERIMENTAL EVALUATION

In order to assess experimentally the accuracy of FRGs as models of conditional edge distributions in large-scale networks, we test them in the following link prediction setting. First, we take a network $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, with a number of nodes ranging from a few thousands to a couple of millions, and a number of edges going up to several millions. We then sample n training pairs $\{u_i, v_i\}$ uniformly at random from $\mathcal{V}$, with $u_i \neq v_i$. For each sampled pair of nodes $\{u_i, v_i\}$, we recover the subgraph $\mathcal{G}_{u_i v_i}$ induced on $\mathcal{G}$ by the vertex set $\mathcal{V}_{u_i v_i} = \{u_i, v_i\} \cup \{w_i : \{u_i, w_i\} \in \mathcal{E} \vee \{v_i, w_i\} \in \mathcal{E}\}$, so as to get a training set $\mathcal{D} = \left\{(x_{u_1 v_1}, \mathcal{G}_{u_1 v_1}), \ldots, (x_{u_n v_n}, \mathcal{G}_{u_n v_n})\right\}$. We then estimate from $\mathcal{D}$ each one of the conditional random graph models described in the previous sections, using the respective learning techniques. Given the estimated models, we sample a test set $\mathcal{T} = \left\{(x_{u_1 v_1}, \mathcal{G}_{u_1 v_1}), \ldots, (x_{u_m v_m}, \mathcal{G}_{u_m v_m})\right\}$ from $\mathcal{G}$ such that $\mathcal{T} \cap \mathcal{D} = \emptyset$, where each element of $\mathcal{T}$ is sampled through the same technique used for $\mathcal{D}$. For each estimated model, we assess its accuracy by first using it to compute the conditional probability of observing a link for each pair of nodes $\{u_j, v_j\}$ in $\mathcal{T}$, and then calculating the area under the ROC curve (AUC) for the predictions delivered on $\mathcal{T}$. Since the problem of predicting the presence of edges in real-world networks is severely unbalanced, i.e. $|\mathcal{E}| \ll \frac{1}{2}\left(|\mathcal{V}|^2 - |\mathcal{V}|\right)$, the ROC curve is a particularly appropriate evaluation measure [Fawcett, 2006]. Also, in order to assess the sensitivity of each model to the size of the training sample, we ran some preliminary experiments with several different values of $|\mathcal{D}|$. The result of this preliminary investigation was that, provided that the training sample contains at least a few pairs of linked nodes (in the order of ten or twenty), then the behavior of the different models is not significantly affected by increasing sample sizes.

Table 1: General statistics for the network datasets used in the experiments. $CC_{\mathcal{G}}$ and $D_{\mathcal{G}}$ denote the average clustering coefficient and the network diameter respectively.

Network	$\lvert\mathcal{V}\rvert$	$\lvert\mathcal{E}\rvert$	$CC_{\mathcal{G}}$	$D_{\mathcal{G}}$
AstroPh	18,772	396,160	0.63	14
GrQc	5,242	28,980	0.52	17
HepPh	12,008	237,010	0.61	13
HepTh	9,877	51,971	0.47	17
Enron	36,692	367,662	0.49	12
RoadCA	1,965,206	5,533,214	0.04	850
RoadTX	1,379,917	3,843,320	0.04	1,049

We compare the performance of the MRG, HRG, CWS, CBA, and FRG models on seven different networks, drawn from the arXiv e-print repository, the Enron email corpus, and the US road network respectively [Leskovec et al., 2007, 2009]. The ER model is not considered in these experiments, since the involved independence assumption makes that model simply unusable for conditional estimation tasks. Some representative network statistics for the used datasets are summarized in Table 1. For the arXiv datasets (i.e. the AstroPh, GrQc, HepPh, and HepTh networks), we report results for a choice of $10,000$ node pairs both for the training and the test set, whereas for the Enron and US road (RoadCA and RoadTX) networks we have $|\mathcal{D}| = |\mathcal{T}| = 100,000$ and $|\mathcal{D}| = |\mathcal{T}| = 10,000,000$ respectively. However, notice that nearly identical results can be obtained in each case after reducing the number of training samples down to even 20%–40% of the indicated size (as discovered through preliminary analysis). ROC curves for the described datasets are plotted in Figs. 1–3, whereas the corresponding AUC values are given in Table 2. As a general remark, we point out that AUC values less

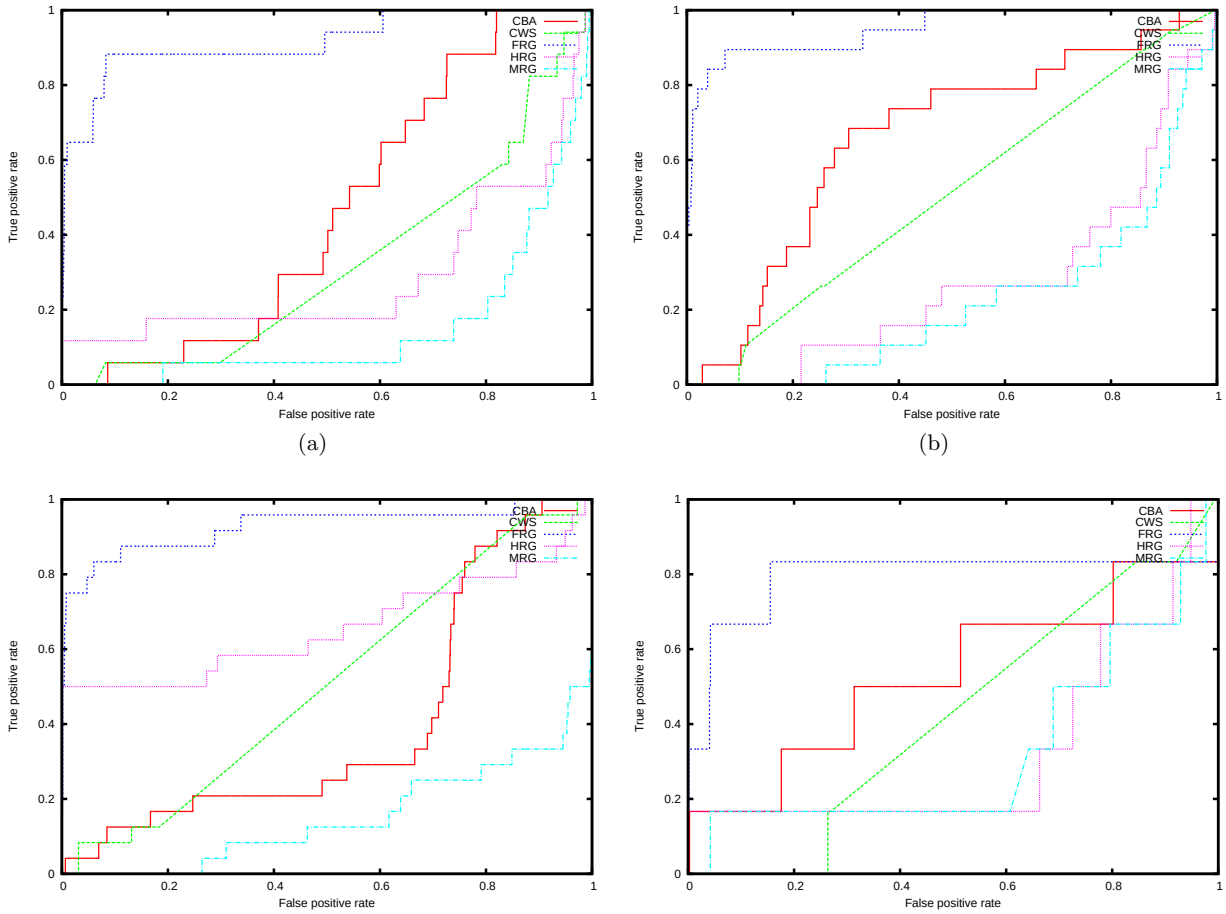

Figure 1: ROC curves for the AstroPh (a), GrQc (b), HepPh (c), and HepTh (d) networks.

than 0.5 (as recorded for some models) do not necessarily mean that prediction accuracy is being worse than random guessing. In fact, recent studies show that, depending on signal strength and stratification errors between training and test sets, random guessing can drop to AUC values even lower than 0.3 [Parker et al., 2007]. Therefore, AUC values less than 0.5 should be considered simply as *no better* than random guessing, rather than *worse* than random.

FRGs significantly outperform all other models both in the arXiv and in the Enron networks. Such networks are generally characterized by power law degree distributions, contrary to the road networks, which exhibit instead a regular topology, with degree distribution peaked around its mean. This explains the better behavior of the CBA model with respect to the remaining options in most of the scale-free networks. Interestingly, this trend is reverted for the HepPh data, where not only CWS outperforms CBA, but we also observe that HRG behaves much better than it does on the other scale-free networks. The fact that, in this particular case, FRGs remain the best available option provides evidence for their higher stability (i.e. robustness to variation in the underlying network properties) with

Table 2: AUC values for the ROC curves plotted in Figs. 1–3. $CC_{\mathcal{G}}$ and $D_{\mathcal{G}}$ denote the average clustering coefficient and the network diameter respectively.

	AUC (%)				
Network	**CBA**	**CWS**	**FRG**	**HRG**	**MRG**
AstroPh	46.04	32.39	**91.66**	28.69	14.78
GrQc	66.22	50.86	**94.90**	27.10	22.32
HepPh	40.04	50.84	**92.73**	65.62	15.02
HepTh	53.21	42.47	**79.34**	32.82	32.36
Enron	48.45	49.03	**85.92**	19.94	11.23
RoadCA	30.84	**91.21**	66.70	77.90	81.12
RoadTX	34.67	**93.01**	63.75	62.51	68.36

respect to the other models. On the other hand, for the US road networks we observe a completely different pattern of results. This time, the FRG model performs worse than the CWS model or the two variants of ERG. The reason is related to the lattice-shaped regularity exhibited by such graphs. This is not surprising, as the WS model subsumes regular lattices as special case scenarios. A natural explanation for the superiority of the CWS model on the road networks lies in the fact that their parametric assumption concerning the observed degree distribution happens to be satisfied for such data, while it is clearly violated by the scale-free networks, which is exactly the opposite of what happens for the CBA model. It is worth noting, however, that FRGs are again performing significantly better than the CBA model. Therefore, FRGs appear to be a more stable class of conditional random network models, since their predictions ensure a regularly accurate behavior across networks displaying significantly different statistical properties. Overall, the presented results encourage the hypothesis that a genuinely nonparametric approach to conditional random graph modeling can offer dramatic advantages over parametric approaches.

6 CONCLUSION

The work presented in this paper started from two motivations. On the one hand, we remarked that statistical modeling of networks cries for nonparametric estimation, because of the inaccuracy often resulting from fallacious parametric assumptions. In this respect, we showed that statistics derived from the Laplacian spectrum of graphs (such as the Fiedler delta function) offer practical ways of developing nonparametric estimators. On the other hand, we suggested that a conditional approach to random graph modeling can be very effective in the large-scale setting, since it allows e.g. to dispense with the intractable partition functions often involved in joint distributions. With respect to this point, we showed how FRGs allow us to tackle very large datasets, processing effectively even millions of queries over networks with millions of nodes and edges. Interesting options for future work consist in analyzing the effect of the subgraph sampling mechanism in determining the distribution of the Fiedler delta, as well as investigating alternative ways of exploiting the information enclosed in the graph spectrum.

Abstract

We consider the problem of Probably Approximate Correct (PAC) learning of a binary classifier from noisy labeled examples acquired from multiple annotators (each characterized by a respective classification noise rate). First, we consider the complete information scenario, where the learner knows the noise rates of all the annotators. For this scenario, we derive sample complexity bound for the Minimum Disagreement Algorithm (MDA) on the number of labeled examples to be obtained from each annotator. Next, we consider the incomplete information scenario, where each annotator is strategic and holds the respective noise rate as a private information. For this scenario, we design a cost optimal procurement auction mechanism along the lines of Myerson's optimal auction design framework in a non-trivial manner. This mechanism satisfies incentive compatibility property, thereby facilitating the learner to elicit true noise rates of all the annotators.

1 Background

In supervised learning, it is usually assumed that the training set is sampled i.i.d. from some fixed distribution, and the true labels are readily available. In contrast to this, there are many real-world applications in which obtaining true labels is a time consuming or costly process. However, for such applications, acquiring non-expert labels is easy, fast, and inexpensive. Web based *crowdsourcing* [Howe, 2008] platforms like *Rent-A-Coder* and *Galaxy Zoo* allow any web-user to perform various data annotation tasks. Amazon's Mechanical Turk allow any individual to publish a crowdsourcing task. In such cases, labels obtained from such sources are typically noisy, as the annotators can be careless or even deceitful. Further, the annotators can act strategically if it helps them fetch better rewards.

The problem of learning with noisy labeled examples has been studied mostly in two different contexts: (1) studying the learnability of the problem and developing learning algorithms under the PAC learning framework [Valiant, 1984], [Angluin and Laird, 1988], [Aslam and Decatur, 1996], [Blum et al., 1994], [Decatur and Gennaro, 1995], [Decatur, 1997], [Kearns, 1993], [Littlestone, 1991], and (2) estimating the noise rates of the annotators and building robust classifier models (independent or joint estimation and learning) [Dawid and Skene, 1979], [Raykar et al., 2009], [Yan et al., 2010], [Donmez et al., 2010]. In the former context, most of the work has been done in a single noisy annotator scenario with different kinds of noise models including *Malicious Noise* [Valiant, 1985], [Kearns and Li, 1993], [Goldman and Sloan, 1995] and *Nasty Noise* [Bshouty et al., 2002]. In the latter context, the focus has been mainly using different classifier models and presenting different noise rate estimation techniques. Our work differs from these works in the following way: (1) we extend PAC learning sample complexity bound

results to the multiple noisy annotators scenario as this problem is becoming more prevalent in recent times [Dekel and Shamir, 2009a], [Dekel and Shamir, 2009b], and (2) we design an optimal auction mechanism that facilitates eliciting (instead of estimating) true noise rates from the annotators followed by a cost-effective purchase of labeled examples satisfying the PAC learning constraint. We assume that annotators know their true noise rate. This is practical in many scenarios, e.g. many litigation service providing companies outsource document labeling tasks to paralegal agencies who in turn hire human editors. These agencies know the competence level of the editors through long standing relationship. The agencies bid for securing outsourcing contract while fully knowing the quality of its editors. The closest work in this direction is due to [Dekel et al., 2008] where they have focused on regression problem and took the elicitation approach via providing incentives to know the distribution information (privately held by the agents for evaluation). In contrast, our work is classification focused; furthermore, unlike the noisy annotators who charge labeling cost in our scenario, the strategic agents do not charge any price for annotation in their case. Instead, in their model, the agents have other vested interest in influencing the outcome of the learning; similar framework has also been used in [Meir et al., 2008], [Meir et al., 2009], [Dalvi et al., 2004], [L'Huillier et al., 2009], and [Kantarcioglu et al., 2008]. The main contributions of our work are:

- We consider the problem of PAC learning a binary classifier using noisy labeled examples obtained from multiple noisy annotators (in contrast to the conventional single noisy annotator scenario). We introduce the notion of annotation plan, and derive sample complexity bounds for PAC learning of finite concept class using the well-known minimum disagreement algorithm (MDA), in the known noise rates information scenario.
- We present an optimal auction mechanism to purchase labeled examples from strategic noisy annotators by eliciting true noise rate information in a more realistic scenario of unknown noise rates. Our approach is inspired by Myerson's Nobel prize winning work on optimal auction design [Myerson, 1981]. We derive allocation and payment rules for purchasing labeled examples at a near-optimal cost from strategic noisy annotators, satisfying the PAC constraint. To the best of our knowledge there has been no prior art with such results.

2 PAC Learning and Bounds

In this section, we provide basic definitions related to the PAC learning model [Valiant, 1984], [Angluin and Laird, 1988] with n noisy annotators, and derive sample complexity bounds for PAC learning with n noisy annotators. The PAC learning model comprises of an *instance space* $\mathscr{X}$ and a *concept class* $\mathscr{C}$. The instance space $\mathscr{X}$ is a fixed set which can be finite, countably infinite, $\{0,1\}^d$, or $\mathbb{R}^d$ for some $d \geq 1$. The concept class $\mathscr{C}$ is a set of *concepts*. A concept $\mathbf{c}$ is a subset of $\mathscr{X}$, which can equivalently be expressed as a boolean function from $\mathscr{X}$ to $\{0,1\}$, and it should be clear from the context whether $\mathbf{c}$ is referring to a subset or to a function. The task of the learner is to determine a close approximation to an unknown target (or true) concept $\mathbf{c}_t$, from the labeled examples. We assume that $\mathbf{c}_t \in \mathscr{C}$. The learner has access to n noisy annotators as the sources of its training data. Each call to an annotator returns a labeled example $\langle x, y \rangle$, where instance $x \in \mathscr{X}$ is drawn randomly and independently according to some unknown (to the learner) sampling distribution D. The learner gets $m_i \geq 0$ labeled examples from annotator i, where $i = 1, \ldots, n$, which together constitute the training dataset. Finally, the learner employs a learning algorithm to output a hypothesis $h \in \mathscr{C}$, based on the training data. The annotator $i, (i = 1, \ldots, n)$ reports the label y which is subject to an independent random mistake with a known probability η_i. So, the reported label is $y = \neg\, \mathbf{c}_t(x)$ with probability η_i and $y = \mathbf{c}_t(x)$ with probability $(1 - \eta_i)$. This noise model is known as *random classification noise* and was first studied by [Angluin and Laird, 1988] and [Laird, 1988] for the single noisy annotator case. The probability $\eta_i, i = 1, \ldots, n$ is known as *noise rate* of the annotator i. In this paper, we assume that $0 < \eta_i < 1/2, i = 1, \ldots, n$.

2.1 PAC learning with n noisy annotators

For any hypothesis $h \in \mathscr{C}$, the error rate (or generalization error) is defined to be the probability that $h(x) \neq \mathbf{c}_t(x)$ for an instance $x \in \mathscr{X}$ that is randomly drawn according to D. The error rate of a hypothesis h is given by $\mathbb{P}^D(\mathbf{c}_t \Delta h)$, where $\mathbf{c}_t \Delta h \subseteq \mathscr{X}$ is the symmetric difference between sets $\mathbf{c}_t$ and h, and $\mathbb{P}^D(\cdot)$ is the probability of this event (calculated with respect to D). A hypothesis h is said to be ϵ-bad if its error rate is more than ϵ, i.e. $\mathbb{P}^D(\mathbf{c}_t \Delta h) > \epsilon$. In the classical PAC model of [Valiant, 1984], the learner's goal is to come up with a learning algorithm which outputs an ϵ-bad hypothesis h with probability at most δ, where the probability is defined with respect to the distribution of training examples of a fixed size. Such a learning algorithm is known as PAC learning algorithm. In general, the error rate of the hypothesis chosen by a learning algorithm critically depends on the number of training examples supplied to the algorithm. Thus, a learning algorithm with single annotator is said to satisfy PAC bound with respect to the *sample size* $m(\epsilon, \delta)$ if the following condition holds true: $\mathbb{P}^{m(\epsilon,\delta)}(\mathbb{P}^D(\mathbf{c}_t \Delta h) > \epsilon) < \delta$, where h is the hypothesis output by the learning algorithm when trained on the $m(\epsilon, \delta)$ number of training examples. The sample size $m(\epsilon, \delta)$ is a non-negative integer valued function of the parameters ϵ and δ. The probability $\mathbb{P}^{m(\epsilon,\delta)}(\cdot)$ is taken over the distribution of $m(\epsilon, \delta)$ training examples (noisy or non-noisy). For a given algorithm, the smallest sample size $m^*(\epsilon, \delta)$ for which it still satisfies PAC bound is known as its *sample complexity*. Now, we extend the PAC learning framework to the case of n noisy annotators; starting with the following definitions:

- An **instance** of the PAC learning problem is a set of specifications of instance space $\mathscr{X}$, concept class $\mathscr{C}$, true concept $\mathbf{c}_t$, and sampling distribution D.

- An **annotation plan**, denoted by $\mathbf{m}(\epsilon, \delta) = (m_1(\epsilon, \delta), \ldots, m_n(\epsilon, \delta))$, is a vector of sample sizes (number of examples) annotated by the n annotators. This quantity is analogous to sample size $m(\epsilon, \delta)$ in the single annotator case. In rest of the paper, we use m_i and $m_i(\epsilon, \delta), i = 1, 2, \ldots, n$, interchangeably.

- A learning algorithm for n noisy annotators is said to satisfy **PAC bound** for annotation plan $\mathbf{m} = (m_1, \ldots, m_n)$ if following holds true:

$$\mathbb{P}^{(m_1,\ldots,m_n)}(\mathbb{P}^D(\mathbf{c}_t \Delta h) > \epsilon) < \delta \tag{1}$$

Note that the noise rates $\eta_1, \ldots, \eta_n$ of the annotators could be very different. Hence the PAC bound depends not just on $\sum_{i=1}^{n} m_i$, but on the individual numbers $m_1, \ldots, m_n$ also. This motivates us to define the notions of **feasible and infeasible annotation plans**, as:

- For a given learning algorithm, an annotation plan $\mathbf{m} = (m_1, \ldots, m_n)$ is said to be *feasible* if the learning algorithm satisfies PAC bound (1) for every instance of the problem when training data is supplied as per this plan.

- Given an algorithm, an annotation plan $\mathbf{m} = (m_1, \ldots, m_n)$ is said to be *infeasible* if the algorithm **fails** to satisfy PAC bound (1) for at least one instance of the problem when training data is supplied as per this plan.

2.2 Feasible annotation plans for MDA

In this section, we consider a simple learning algorithm, namely *Minimum Disagreement Algorithm (MDA)* and derive PAC learnability bound on annotation plan complexity for this algorithm in the presence of n noisy annotators. [Laird, 1988] analyzed this algorithm for single noisy annotator case. MDA outputs the hypothesis h, which minimizes the empirical loss, $L_e(h)$, on the training dataset. We describe MDA for multiple annotators, below.

Algorithm 1 (MDA) *Let* $\mathscr{D} = \{\langle x_j^i, y_j^i \rangle \;\; i = 1, \ldots, n; \; j = 1, \ldots, m_i\}$ *be the input training data, where* $\langle x_j^i, y_j^i \rangle$ *is supplied by annotator* i *in* j^{th} *call. The empirical loss* $L_e(h)$ *for hypothesis* h *is given as:*

$$L_e(h) = \sum_{i=1}^{n} \sum_{j=1}^{m_i} \mathbf{1}(h(x_j^i) \neq y_j^i) \tag{2}$$

where $\mathbf{1}(\cdot)$ *is an indicator variable. Output hypothesis* $h^* \in \mathscr{C}$*, such that* $L_e(h^*) \leq L_e(h), \forall h \in \mathscr{C}$ *(use any tie breaking rule).*

Next we derive a characterization of feasible annotation plans for MDA. For this, we define a few events and their corresponding probabilities, assuming a finite concept class $\mathscr{C}$ having $|\mathscr{C}| = N < \infty$. The events are defined for an annotation plan $(m_1, \ldots, m_n)$ and a hypothesis h. We assume that m_i samples of x^i are drawn randomly and independently, according to the distribution D by annotator i, and labels y^i are flipped independently with noise rates η_i. The events E_1, E_2, E_3, and E_4, of our interest are defined as:

- $E_1(h, m_1, \ldots, m_n)$: The empirical error of a given hypothesis $h \in \mathscr{C}$ is no more than the empirical error of the true hypothesis $\mathbf{c}_t$, i.e. $L_e(h) \leq L_e(\mathbf{c}_t)$.
- $E_2(h, m_1, \ldots, m_n)$: The empirical error of a given hypothesis $h \in \mathscr{C}$ is the minimum across all hypotheses in the class $\mathscr{C}$, i.e. $L_e(h) \leq L_e(h')\ \forall h' \in \mathscr{C}$.
- $E_3(h, m_1, \ldots, m_n)$: MDA outputs a given hypothesis h.
- $E_4(\epsilon, m_1, \ldots, m_n)$: MDA outputs an ϵ-bad hypothesis.

The probabilities of events $E_i, i = 1, 2, 3$ and E_4 are denoted by $\mathbb{P}^{(m_1,\ldots,m_n)}[E_i(h)]$ and $\mathbb{P}^{(m_1,\ldots,m_n)}[E_4(\epsilon)]$, respectively. Next, we show the following useful lemmas:

Lemma 1 *Given a concept class $\mathscr{C}$ such that $\mathbf{c}_t \in \mathscr{C}$ and $N = |\mathscr{C}|$, the following holds true for any given annotation plan $(m_1, \ldots, m_n)$:*

$$\mathbb{P}^{(m_1,\ldots,m_n)}[E_4(\epsilon)] \leq (N-1)\times \left[\max_{h \in \mathscr{C}, h \text{ is } \epsilon\text{-bad}} \mathbb{P}^{(m_1,\ldots,m_n)}[E_1(h)] \right]$$

Proof: By definition of the events, for any hypothesis $h \in \mathscr{C}$ that is ϵ-bad (for any $\epsilon > 0$), we have $E_3(h, m_1, \ldots, m_n) \subseteq E_2(h, m_1, \ldots, m_n) \subseteq E_1(h, m_1, \ldots, m_n)$. Also, $E_4(\epsilon, m_1, \ldots, m_n) = \bigcup_{h \in \mathscr{C}; h \text{ is } \epsilon\text{-bad}} E_3(h, m_1, \ldots, m_n)$. The lemma follows from taking probabilities of these events. *Q.E.D.*

Now, we state our main result regarding characterization of the feasible annotation plans for MDA.

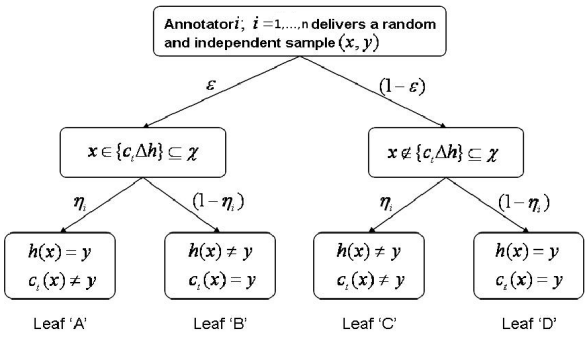

Figure 1: Probability Tree for $\mathbf{c}_t$ and h.

Theorem 1 *Consider the PAC learning model with n noisy annotators and the MDA (Algorithm 1). Let $N = |\mathscr{C}| < \infty$. Then, for any given $0 < \epsilon, \delta < 1$ and $0 < \eta_i < 1/3, i = 1, \ldots, n$, if $m_i, i = 1, \ldots, n$, satisfy the following inequality then the MDA will satisfy PAC bound.*

$$\log(N/\delta) \leq \sum_{i=1}^{n} m_i \psi(\eta_i) \tag{3}$$

where $\psi(\eta_i) = \log\left[1 - \epsilon\left(1 - \exp\left(-(1-3\eta_i)/8\right)\right)\right]^{-1}$ for $i = 1, \ldots, n$

Remark: The inequality (3) characterizes a subset of the feasible annotation plans. This characterization is independent of the problem instance and the tie breaking rule of the MDA.

Proof: MDA satisfies PAC bound iff there exists an annotation plan $(m_1, \ldots, m_n)$ such that $\mathbb{P}^{(m_1,\ldots,m_n)}[E_4(\epsilon)] < \delta$. From Lemma 1, it can be seen that for any $0 < \epsilon, \delta < 1$, if an annotation plan $(m_1, \ldots, m_n)$ satisfies the following condition, then MDA will satisfy PAC bound.

$$\left[\max_{h \text{ is } \epsilon\text{-bad}} \mathbb{P}^{(m_1,\ldots,m_n)}[E_1(h)] \right] \leq \delta/N \tag{4}$$

Notice a change in the LHS expression as compared to Lemma 1. The LHS in the above expression is an upper bound for the RHS of the expression in Lemma 1 (excluding $N-1$), because here h may not belong to $\mathscr{C}$. This makes the bound independent of the problem instance, although MDA will only output $h \in \mathscr{C}$. Now, we upper bound the LHS of (4). To do this, we derive an upper bound for $\mathbb{P}^{(m_1,\ldots,m_n)}[E_1(h)]$ when hypothesis h has an error rate of ϵ (for any $\epsilon \in (0, 1)$).

To derive this bound, we note that for any random and independent sample (x, y) that is delivered by

an annotator i, the probability of its agreeing (or disagreeing) with hypotheses $\mathbf{c}_t$ and h (having error rate ϵ) is given by a probability tree shown in Figure 1. From the tree, it can be seen that $\mathbb{P}^{(m_1,\ldots,m_n)}[E_1(h)]$ is same as the probability that the number of samples that fall under leaf B in the probability tree is at most the number of samples that fall under leaf A.

To compute the above quantity, first we compute the conditional probability, $\mathbb{P}^{k_1,\ldots,k_n}(L_e(h) \leq L_e(\mathbf{c}_t))$, defined as: if k_i examples, $(0 \leq k_i \leq m_i)$, from annotator i $(i = 1,\ldots,n)$ come from the set $(\mathbf{c}_t \Delta h)$, then the probability that empirical error of h (given by $L_e(h)$) is less than or equal to empirical error of $\mathbf{c}_t$ (given by $L_e(\mathbf{c}_t)$).

Consider the random variable $Z_i^j, i = 1,\ldots,n$ $j = 1,\ldots,k_i$, which is the indicator of whether j^{th} sample from i^{th} annotator is from leaf node B, given that all the data points are from $\mathbf{c}_t \Delta h$ region. Thus, $\mathbb{P}(Z_i^j = 1) = (1-\eta_i)$ and $\mathbb{P}(Z_i^j = 0) = \eta_i$. Let $Z = \sum_{i=1}^{n}\sum_{j=1}^{k_i} Z_i^j$. Then the event $L_e(h) \leq L_e(\mathbf{c}_t)$ is same as the event $Z \leq \sum_{i=1}^{n} k_i/2$. Hence, we are interested in finding an upper bound on $\mathbb{P}(Z \leq \sum_{i=1}^{n} k_i/2)$. We can use the multiplicative form of Chernoff bound (see e.g. Theorem 4.2 in [Motwani and Raghavan, 1995]), which says $\mathbb{P}[Z \leq (1-\nu)\mu] \leq \exp(-\mu\nu^2/2)$, where $\mu = E[Z] = \sum_{i=1}^{n}(1-\eta_i)k_i$. Hence, by letting $\nu = \frac{\sum_{i=1}^{n} k_i(1-2\eta_i)}{2\sum_{i=1}^{n} k_i(1-\eta_i)}$, we get the following bound:

$$\mathbb{P}^{(k_1,\ldots,k_n)}(L_e(h) \leq L_e(\mathbf{c}_t)) \leq e^{\frac{-(\sum_{i=1}^{n} k_i(1-2\eta_i))^2}{8\sum_{i=1}^{n} k_i(1-\eta_i)}}$$

Simplifying this bound, for $0 \leq \eta_i \leq 1/3$ we get:

$$\mathbb{P}^{(k_1,\ldots,k_n)}(L_e(h) \leq L_e(\mathbf{c}_t)) \leq e^{\frac{-\sum_{i=1}^{n} k_i(1-3\eta_i)}{8}} \quad (5)$$

Summing up the above conditional probability bound over all possible values of k_i, the total probability $\mathbb{P}^{(m_1,\ldots,m_n)}[E_1(h)]$ becomes:

$$\sum_{k_1=0}^{m_1}\cdots\sum_{k_n=0}^{m_n}\left(\prod_{i=1}^{n}\left(\binom{m_i}{k_i}\epsilon^{k_i}(1-\epsilon)^{m_i-k_i}\right)\right. \quad (6)$$
$$\left.\mathbb{P}^{(k_1,\ldots,k_n)}(L_e(h) \leq L_e(\mathbf{c}_t))\right)$$

Using the bound in (5), we get the following upper bound on $\mathbb{P}^{(m_1,\ldots,m_n)}[E_1(h)]$:

$$\prod_{i=1}^{n}\left(\sum_{k_i=0}^{m_i}\binom{m_i}{k_i}\epsilon^{k_i}(1-\epsilon)^{m_i-k_i}\exp\left(-k_i(1-3\eta_i)/8\right)\right)$$

Using the moment generating function of the Binomial distribution, the bound becomes

$$\prod_{i=1}^{n}\left[1-\epsilon(1-\exp(-(1-3\eta_i)/8))\right]^{m_i}$$

In above bound, h has an error rate exactly equal to ϵ. However, this bound is valid for an ϵ-bad hypothesis also because the expression decrease as ϵ increases. Substituting this upper bound on the LHS of (4), we get the desired claim. *Q.E.D.*

Note that the Theorem 1 is valid only for the range of $0 < \eta_i < 1/3$. However, we can extend the definition of $\psi(\cdot)$ to the boundary points in a manner that the same relation (3) holds true. For this, observe that minimum number of examples required from a single **non-noisy** annotator would be $m_0 = \log(N/\delta)/\log\left[1-\epsilon\right]^{-1}$. This is because in such a case, we have $\mathbb{P}(L_e(h) \leq L_e(\mathbf{c}_t) \mid x \in \mathbf{c}_t\Delta h) = 0$ and $\mathbb{P}(x \notin \mathbf{c}_t\Delta h) = (1-\epsilon)$. Hence, we can let $\psi(0) = \log\left[1-\epsilon\right]^{-1}$. Also, we let $\psi(1/3) = \log\left[1-\epsilon\left(1-\exp(-(1/18))\right)\right]^{-1}$ and $m_{1/3} = \log(N/\delta)/\psi(1/3)$ from [Laird, 1988].

3 Cost Optimal Mechanism Design for PAC Learning

We consider the problem of procuring a feasible annotation plan when the learner needs to pay annotators for their efforts, under known and unknown noise rate scenarios. In the unknown noise rate scenario, we propose an auction model and present an optimal auction mechanism.

We assume that each annotator i (with noise rate η_i) incurs an internal cost $c(\eta_i)$ of annotation for labeling one data point; note that the cost is dependent on the noise rate, and the cost function is same for all the annotators. The cost function is assumed to be a bounded, continuously differentiable, strictly decreasing function in $0 \leq \eta_i < 1/2\ \forall\ i = 1,\ldots,n$. If an annotator is more competent (i.e. less noisy) then he can make more money by selling his services and time to somewhere else in the market, which translates to saying that his internal cost of annotation is high.

Consider a simplistic scenario of complete information where the learner knows noise rates of all the annotators. In such a case, the goal of the learner is purchase an annotation plan $m =$

$(m_1, m_2, \ldots, m_n)$ in such a way that the procurement cost (that is, cost of annotation), given by $\sum_{i=1}^{n} m_i c(\eta_i)$, is minimized subject to the PAC learning constraint (3). This is an integer linear programming problem. An approximate solution can be obtained by relaxing the integer constraint and rounding off the optimal solution to the nearest integer value.

Now, let us consider a more realistic scenario of incomplete information where the learner does not know noise rates $\eta = (\eta_1, \ldots, \eta_n)$. There are two possible approaches: (1) estimation, and (2) elicitation. In the estimation approach, the learner estimates η_i using previously acquired examples (say, for example, comparing labels from different annotators). In the elicitation approach, the learner gets η_i directly from the annotators. The former approach has the disadvantage that poor estimates result in either paying more (when overestimated) or not satisfying the PAC bound (when underestimated). Due to this reason, we are interested in elicitation. In this approach, the learner pays an incentive (*a.k.a.* price of information) to get η_i from the annotators. Note that the learner needs to pay this price of information to elicit true noise rates. (Otherwise, the annotators can falsely report the noise rate.) For this purpose, we propose to design a procurement auction mechanism to procure a feasible annotation plan with minimum cost; now, the procurement cost also includes the price of information. This problem is challenging because from annotator's perspective, he would like to maximize his utility (i.e., the payment received minus the internal cost for annotation). The choice of mechanism depends crucially on various design parameters such as $N, \epsilon, \delta, \eta_i, c(\cdot)$, and the choice of the learning algorithm. We assume that $N, \epsilon, \delta, c(\cdot)$, and the choice of the learning algorithm are public knowledge, and only η_i is the private information of i^{th} annotator.

3.1 Procurement Auction Model

The learner solicits simultaneous and confidential bids for the noise rates from annotators. Let $\hat{\eta}_i$ be the bid of i^{th} annotator that can possibly be a false noise rate. Assume that annotator i draws his true noise rate η_i in an independent random manner using a density function ϕ_i in the interval $I_i = [0, 1/3]$ with the corresponding cumulative distribution function (Φ_i), and let $\phi_i(\eta_i) > 0$ for all $\eta_i \in I_i$ and $i = 1, 2, \ldots, n$. Let $I = I_1 \times I_2 \times \ldots \times I_n$ and $\phi = \phi_1 \times \phi_2 \ldots \times \phi_n$ denote respective joint spaces. We use the subscript $-i$ to exclude i^{th} annotator in any variable (e.g. I_{-i}, η_{-i}) and, we also use the notation $\hat{\eta} = (\hat{\eta}_i, \hat{\eta}_{-i})$.

After receiving the bids (i.e. $\hat{\eta} = (\hat{\eta}_1, \ldots, \hat{\eta}_n)$), the learner allocates a contract of supplying certain number of labeled examples to each annotator and an associated payment. Thus, a procurement auction mechanism is a pair of mappings $\mathcal{M} = (a, p)$, where $a : I \mapsto \mathbb{N}_0^n$ [1] is the **allocation rule** and $p : I \mapsto \mathbb{R}^n$ is the **payment rule**.

Given an auction mechanism $\mathcal{M} = (a, p)$, an annotator i, having noise rate η_i, gets the following utility when all the annotators report their bids $\hat{\eta}$:

$$u_i(\hat{\eta}; \eta_i) = p_i(\hat{\eta}) - a_i(\hat{\eta}) c(\eta_i) \tag{7}$$

Note that the first and the second term denote the payment received from the learner and the internal cost in supplying the labeled examples, respectively. Since each annotator i does not know η_{-i} and moreover, others' bids $\hat{\eta}_{-i}$ affect his utility, it is useful to define **expected allocation rule** α and the **expected payment rule** π for any mechanism $\mathcal{M} = (a, p)$ in the following manner (from i^{th} annotator's perspective).

$$\alpha_i(\hat{\eta}_i) = \int_{I_{-i}} a_i(\hat{\eta}_i, \hat{\eta}_{-i}) \phi_{-i}(\hat{\eta}_{-i}) d\hat{\eta}_{-i} \tag{8}$$

$$\pi_i(\hat{\eta}_i) = \int_{I_{-i}} p_i(\hat{\eta}_i, \hat{\eta}_{-i}) \phi_{-i}(\hat{\eta}_{-i}) d\hat{\eta}_{-i} \tag{9}$$

The **expected utility** of annotator i, when he bids $\hat{\eta}_i$ while having true value η_i, can now be given by

$$U_i(\hat{\eta}_i; \eta_i) = \pi_i(\hat{\eta}_i) - \alpha_i(\hat{\eta}_i) c(\eta_i) \tag{10}$$

When both arguments in (10) are same, we use $U_i(\eta_i)$ to mean $U_i(\eta_i; \eta_i)$ (for notational simplicity). Given this background, we first present several definitions that are essential to prove our results. A Mechanism $\mathcal{M} = (a, p)$ is said to be:

[1] The symbol $\mathbb{N}_0$ denotes the set of natural numbers inclusive of zero. The allocation and the payment rules are functions of $N, \epsilon, \delta, c(\cdot)$, and the algorithm. For notational simplicity, we drop these parameters.

- **Dominant Strategy Incentive Compatible** (DSIC) if for every annotator i and for every possible true noise rate $\eta_i \in I_i$, the utility $u(\cdot)$ is maximized when $\hat{\eta}_i = \eta_i$ irrespective of what others are bidding, i.e., $u_i(\eta_i, \hat{\eta}_{-i}; \eta_i) \geq u_i(\hat{\eta}_i, \hat{\eta}_{-i}; \eta_i)\ \forall\ \hat{\eta}_i \in I_i, \hat{\eta}_{-i} \in I_{-i}$.
- **Bayesian Incentive Compatible** (BIC) if for every annotator i and for every possible true noise rate $\eta_i \in I_i$, the expected utility $U_i(\cdot)$ is maximized when $\hat{\eta}_i = \eta_i$, i.e., $U_i(\eta_i) \geq U_i(\hat{\eta}_i; \eta_i)\ \ \forall \hat{\eta}_i \in I_i$. Note, any mechanism satisfying DSIC will also satisfy BIC but the other way is not necessarily true.
- **PAC compatible** if the annotation plan procured by this mechanism satisfies the PAC bound condition (3) whenever all the annotators report their true noise rates, i.e., $\log(N/\delta) \leq \sum_{i=1}^{n} a_i(\eta)\psi(\eta_i)$.
- **Individually Rational** (IR) if no annotator loses (in expected sense) anything by reporting true noise rates, i.e., $\pi_i(\eta_i) - \alpha_i(\eta_i)c(\eta_i) \geq 0\ \forall\ \eta_i \in I_i$.

Our goal is to design a procurement auction mechanism that satisfies BIC, PAC Compatibility, and IR properties; and minimizes the expected cost of procurement for the learner. We call such an auction mechanism as *Optimal Auction for Data Labeling*. Our design is inspired from the Nobel Prize winning work of Roger Myerson on optimal auction design [Myerson, 1981]. For a comprehensive treatment of this topic, readers are referred to [Krishna, 2002] and [Mishra, 2008].

3.2 Characterization of Incentive Compatibility

To design an optimal auction mechanism for data labeling problem, we need to first characterize the space of auction rules that satisfy BIC property. For this, we begin with the following definitions. An allocation rule a is said to be:

- **weakly monotone (WM)** if for every annotator i and for every $\hat{\eta}_{-i} \in I_{-i}$, we have $a_i(\eta_i, \hat{\eta}_{-i}) \geq a_i(\hat{\eta}_i, \hat{\eta}_{-i})$ for all $\eta_i, \hat{\eta}_i \in I_i$, with $\eta_i > \hat{\eta}_i$.
- **weakly monotone in expectation (WME)** if for every annotator i and for every $\eta_i, \hat{\eta}_i \in I_i$ with $\eta_i > \hat{\eta}_i$, we have $\alpha_i(\eta_i) \geq \alpha_i(\hat{\eta}_i)$.

[Myerson, 1981] showed that BIC is characterized by the WME allocation rules in the setting of single object auction. Interestingly, a similar characterization holds in our problem setting also. We state this result as an important theorem.

Theorem 2 *A Mechanism $\mathcal{M} = (a, p)$ is a BIC mechanism iff (i) the allocation rule $a(\cdot)$ is WME, and (ii) the expected payment rule $\pi(\cdot)$ satisfies:*

$$\pi_i(\eta_i) = \gamma_i + \alpha_i(\eta_i)c(\eta_i) - z_i(\eta_i) \tag{11}$$

where $\gamma_i = \pi_i(0) - \alpha_i(0)c(0)$ and $z_i(\eta_i) = \int_0^{\eta_i} \alpha_i(t_i)c'(t_i)dt_i$.

Proof: Suppose $\mathcal{M} = (a, p)$ is a BIC mechanism. Then, we show that the allocation rule is WME and (11) holds. Consider an annotator i and $\eta_i, \hat{\eta}_i \in I_i$ with $\eta_i > \hat{\eta}_i$. Then, it follows from (10) and BIC that $\pi_i(\eta_i) - \alpha_i(\eta_i)c(\eta_i) \geq \pi_i(\hat{\eta}_i) - \alpha_i(\hat{\eta}_i)c(\eta_i)$ and $\pi_i(\hat{\eta}_i) - \alpha_i(\hat{\eta}_i)c(\hat{\eta}_i) \geq \pi_i(\eta_i) - \alpha_i(\eta_i)c(\hat{\eta}_i)$. Adding these two inequalities, we get $[\alpha_i(\eta_i) - \alpha_i(\hat{\eta}_i)]\,[c(\hat{\eta}_i) - c(\eta_i)] \geq 0$. Since $\eta_i > \hat{\eta}_i$ and $c(\cdot)$ is a strictly decreasing function, this implies that $\alpha_i(\eta_i) \geq \alpha_i(\hat{\eta}_i)$ (i.e. α_i is non-decreasing). Now, since $\mathcal{M}$ is BIC, for every $\eta_i, \hat{\eta}_i \in I_i$, we have $U_i(\eta_i) \geq U_i(\hat{\eta}_i) - \alpha_i(\hat{\eta}_i)\,[c_i(\eta_i) - c_i(\hat{\eta}_i)]$. This is obtained from adding and subtracting $\alpha_i c(\hat{\eta}_i)$ to $U_i(\hat{\eta}_i; \eta_i)$ (Equation (10)) and rearranging the terms. Similarly, switching the roles of η_i and $\hat{\eta}_i$, we get $U_i(\hat{\eta}_i) \geq U_i(\eta_i) - \alpha_i(\eta_i)\,[c_i(\hat{\eta}_i) - c_i(\eta_i)]$. On combining these two inequalities, we get $-\alpha_i(\eta_i)\,[c_i(\hat{\eta}_i) - c_i(\eta_i)] \leq U_i(\hat{\eta}_i) - U_i(\eta_i) \leq -\alpha_i(\hat{\eta}_i)\,[c_i(\hat{\eta}_i) - c_i(\eta_i)]$. Now, by dividing with $(\hat{\eta}_i - \eta_i)$ and letting $\hat{\eta}_i \to \eta_i$, the two-sided inequality implies that $-\alpha_i(\cdot)c'(\cdot)$ is the derivative of $U_i(\cdot)$. Since $c'(\cdot)$ is continuous and $\alpha_i(\cdot)$ is non-decreasing, the function $\alpha_i(\cdot)c'(\cdot)$ has finitely many points of discontinuity and hence is Riemann integrable in the interval $[0, 1/3]$. Thus, we have $\int_0^{\eta_i} -\alpha_i(t_i)c'(t_i)dt_i = U_i(\eta_i) - U_i(0)$. On substituting $U_i(\eta_i) = \pi_i(\eta_i) - \alpha_i(\eta_i)c(\eta_i)$ and $U_i(0) = \pi_i(0) - \alpha_i(0)c(0)$, we get (11).

Now, suppose that a is WME and (11) holds. We will show that $\mathcal{M} = (a, p)$ is a BIC mechanism. For any annotator i and any $\eta_i, \hat{\eta}_i \in I_i$, we have $\pi_i(\eta_i) - \pi_i(\hat{\eta}_i) = \alpha_i(\eta_i)c(\eta_i) - \alpha_i(\hat{\eta}_i)c(\eta_i) +$

$\alpha_i(\hat{\eta_i})\left[c(\eta_i) - c(\hat{\eta_i})\right] - z_i(\eta_i) + z_i(\hat{\eta_i})$. Using the facts $\alpha_i(\cdot)$ is non-decreasing and $c'(\cdot) \leq 0$, it can be shown that $\alpha_i(\hat{\eta_i})\left[c(\eta_i) - c(\hat{\eta_i})\right] - z_i(\eta_i) + z_i(\hat{\eta_i}) \geq 0$. Therefore,$\pi_i(\eta_i) - \pi_i(\hat{\eta_i}) \geq \alpha_i(\eta_i)c(\eta_i) - \alpha_i(\hat{\eta_i})c(\eta_i)$ which is the condition for BIC. *Q.E.D*

A similar characterization result can be derived for the DSIC case also. Due to lack of space, we skip the results. Note that Theorem (2) suggests that the learner can only increase the contract size with higher noise rate. This is a bit counter intuitive as the learner is buying more examples from a more noisy annotator (in a relative sense). However, this is essentially the key to enforce truthful elicitation of the noise rates. Even if an annotator misreports higher noise rate to get a bigger size contract, the payment rule would make sure that the additional payment is not enough to cover the cost of labeling the required additional examples. A similar argument holds for the other direction as well.

3.3 Optimal Auction Mechanism

We pose the optimization problem of designing the auction mechanism as follows:

$$\min_{a(\cdot),p(\cdot)} \Pi(a,p) = \sum\nolimits_{i=1}^{n} \int_0^{1/3} \pi_i(t_i)\phi_i(t_i)dt_i \quad s.t. \quad (12)$$

$$\alpha_i(\cdot) \text{ is non-decreasing} \quad (13)$$

$$\pi_i(\eta_i) = \gamma_i + \alpha_i(\eta_i)c(\eta_i) - z_i(\eta_i)\ \forall \eta_i \in I_i, \forall i \quad (14)$$

$$\pi_i(\eta_i) \geq \alpha_i(\eta_i)c(\eta_i)\ \forall \eta_i \in I_i, \forall i \quad (15)$$

$$\log(N/\delta) \leq \sum\nolimits_i a_i(\eta_i, \eta_{-i})\psi(\eta_i)\ \forall (\eta_i, \eta_{-i}) \in I \quad (16)$$

Note that the objective function (12) constitutes the total expected payment made to all the annotators. The constraints (13) and (14) are BIC constraints, (15) is the IR constraint, and (16) is the PAC compatibility constraint. Recall, $c(\cdot)$ is a strictly decreasing function. If (14) is satisfied then (15) will be satisfied iff $\gamma_i \geq 0$ (i.e. $\pi_i(0) \geq \alpha_i(0)c(0))\ \forall i$. Because our goal is to minimize (12), we must set $\gamma_i = 0$. Then, by setting $\gamma_i = 0$ and using the definition of $\alpha_i(\cdot)$, we can rewrite the objective function after some algebraic manipulations as:

$$\Pi(a,p) = \int_I \left(\sum\nolimits_{i=1}^{n} v_i(x_i)a_i(x)\right)\phi(x)dx \quad (17)$$

where $v_i(\eta_i) = c(\eta_i) - \frac{1-\Phi_i(\eta_i)}{\phi_i(\eta_i)}c'(\eta_i)$ is called as **virtual cost function**. Note that since $c'(\eta_i)$ is negative, $\phi_i(\cdot) > 0$ for all i and for all $\eta_i \in I_i$, the virtual cost function is always non-negative, well defined and is higher than $c(\eta_i)$. Note that (17) is essentially a function of the allocation rule $a(\cdot)$ since $p(\cdot)$ is dictated by $a(\cdot)$ via (14). We need to minimize (17) subject to the constraints (13) and (16). It seems difficult to solve this problem, particularly with the constraint (13) without imposing additional regularity condition. To arrive at this condition, we consider solving (17) by ignoring the constraint (13) momentarily. So, we consider minimizing (17) subject to the constraint (16) alone for the moment. Note, for minimizing (17), it suffices to minimize $\sum_{i=1}^{n} v_i(\eta_i)a_i(\eta)$ for every possible profile η subject to the constraint (16). For a fixed η, this is an integer linear programming (ILP) problem whose approximate solution can be obtained by relaxing the integer constraint and rounding off the optimal solution to the nearest integer value. This approximate solution is a near-optimal way of purchasing examples from noisy annotators for PAC learning (ignoring (13)). By looking at the dual of such a relaxed LP, one can verify that in this near-optimal scheme, the learner should purchase $\lceil \log(N/\delta)/\psi(\eta_{i^*}) \rceil$ number of examples from only that annotator, say i^*, for whom the ratio $v_i(\eta_i)/\psi(\eta_i)$ is the minimum. Let us call this rule as the **minimum allocation rule** whose approximation guarantee is given below.

Theorem 3 *Let ALG be the total cost of purchase incurred by the min allocation rule. Let OPT be the optimal value of the ILP and m_0 be non-noisy sample complexity. Then, we must have*

$$ALG \leq OPT + v_{i^*}(\eta_{i^*}) \leq OPT(1 + 1/m_0) \quad (18)$$

Proof: The optimal solution of the linear relaxation is always a lower bound on the optimal solution of the ILP. Therefore, we must have $\log(N/\delta)v_{i^*}(\eta_{i^*})/\psi(\eta_{i^*}) \leq OPT$. This implies

$$\begin{aligned} ALG &= v_{i^*}(\eta_{i^*})\lceil \log(N/\delta)/\psi(\eta_{i^*}) \rceil \\ &\leq \log(N/\delta)v_{i^*}(\eta_{i^*})/\psi(\eta_{i^*}) + v_i(\eta_{i^*}) \\ &\leq OPT + v_i(\eta_{i^*}) \end{aligned} \quad (19)$$

To get the other bound, note that the number of examples suggested by the minimum allocation rule is at least as much as m_0. Therefore, we must have $\log(N/\delta)/\psi(\eta_{i^*}) \geq m_0$. Thereby, we get:

$$OPT \geq \log(N/\delta)v_{i^*}(\eta_{i^*})/\psi(\eta_{i^*}) \geq m_0\ v_i(\eta_{i^*}) \quad (20)$$

Substituting the bound on $v_i(\eta_{i^*})$ from (20) into (19) will give us the second term. *Q.E.D*

Regularity Condition: So far, we considered the approximate optimal auction mechanism design without the constraint (13). Therefore, the minimum allocation rule need not satisfy the WME property. However, it is WME under the regularity condition that $v_i(\cdot)/\psi(\cdot)$ *is a non-increasing function.* Under this condition, as η_i increases, the annotator i remains the winner if he/she is already the winner (with an increased contract size) or becomes the winner as per the minimum allocation rule. Therefore, the allocation rule satisfies the WM property (hence, WME). This implies that the allocation rule would give an approximate optimal mechanism satisfying BIC + IR+ PAC compatibility properties. For every (η_i, η_{-i}) and every i, the associated payment rule can be given by

$$p_i(\eta_i, \eta_{-i}) = a_i(\eta_i, \eta_{-i})c(\eta_i) - w_i(\eta_i) \qquad (21)$$

where $w_i(\eta_i) = \int_0^{\eta_i} a_i(t_i, \eta_{-i})c'(t_i)dt_i$. One can verify that the corresponding expected payment rule $\pi_i(\cdot)$ satisfies BIC and IR constraints. In fact, it turns out that the minimum allocation rule and the payment rule (21) together satisfy the DSIC property. We skip this proof as it follows the same line of arguments given in the proof of Theorem 2.

Simplified Payment Rule: We define for every annotator i, the smallest bid value sufficient to win the contract as per the minimum allocation rule as:

$$q_i(\eta_{-i}) = \inf\left\{\hat{\eta_i} \mid \frac{v_i(\eta_i)}{\psi(\eta_i)} \leq \frac{v_j(\eta_j)}{\psi(\eta_j)}\ \forall j \neq i\right\} \qquad (22)$$

Then, the minimum allocation rule and simplified payment rule can be written as:

$$a_i(\eta) = \begin{cases} \lceil \log(N/\delta)/\psi(\eta_i) \rceil & : \text{ if } \eta_i \geq q_i(\eta_{-i}) \\ 0 & : \text{ otherwise} \end{cases} \qquad (23)$$

$$p_i(\eta) = \begin{cases} \left\lceil \frac{\log(N/\delta)}{\psi(\eta_i)} \right\rceil c(q_i(\eta_{-i})) & : \text{ for winner} \\ 0 & : \text{ otherwise} \end{cases} \qquad (24)$$

Thus, we now have the following mechanism.

Algorithm 2 (Approx_Mechanism) *The learner should choose an annotator i^* for whom the score $v_i(\eta_i)/\psi(\eta_i)$ is minimum (breaking ties arbitrarily), and award a contract of supplying $\lceil \log(N/\delta)/\psi(\eta_{i^*}) \rceil$ labeled examples. The learner must pay an amount equal to $c(q_{i^*}(\eta_{-i^*}))$ per example to this annotator, where $q_{i^*}(\eta_{-i^*})$ denotes the smallest noise rate bidding which the winning annotator i^* still stays as the winner. The other annotators are not paid any amount.*

For the winning annotator i^*, we have $q_{i^*}(\eta_{-i^*}) \leq \eta_{i^*}$ (under the regularity condition). This implies that $c(q_{i^*}(\eta_{-i^*})) \geq c(\eta_{i^*})$. Note that the right hand side of this inequality is the cost involved when η is known. Therefore, the learner needs to pay some extra cost to annotators for eliciting the true noise rates. The following theorem is now apparent from the analysis done so far.

Theorem 4 *Suppose the regularity condition holds. Then,* **Approx_Mechanism** *is an approximate optimal mechanism satisfying DSIC, IR, and PAC compatibility properties. The approximation guarantee of this mechanism is given by $ALG \leq OPT + v_{i^*}(\eta_{i^*}) \leq OPT(1 + 1/m_0)$.*

Note, DSIC is a preferred condition than BIC and DSIC implies BIC. The above result says that under the regularity condition, a DSIC mechanism comes very close to the optimal BIC mechanism.

4 Conclusion

To the best of our knowledge, this is the first paper to model and analyze the problem of acquiring labeled examples from multiple noisy **strategic** annotators for PAC learning. For such a setting, we have proposed an approximate cost optimal auction mechanism for the unknown noise rates scenario, by extending Myerson's optimal auction design framework in a non-trivial manner. As future enhancements, (1) the assumption of finite concept class can be relaxed by making use of VC-dimension, (2) PAC bound can be derived for an improved Weighted MDA (WMDA) algorithm, where we give more importance to the samples from less noisy annotator while computing the loss $L_e(\cdot)$, and (3) one can design better approximate algorithms to solve the underlying ILP problems.

Abstract

Computing a Nash equilibrium (NE) is a central task in computer science. An NE is a particularly appropriate solution concept for two–agent settings because coalitional deviations are not an issue. However, even in this case, finding an NE is PPAD–complete. In this paper, we combine path following algorithms with local search techniques to design new algorithms for finding exact and approximate NEs. We show that our algorithms largely outperform the state of the art and that almost all the known benchmark game classes are easily solvable or approximable (except for the GAMUT CovariantGame–Rand class).

1 Introduction

Finding a Nash equilibrium (NE) of a normal–form (aka strategic–form aka bimatrix) game is PPAD–complete [8] even with just two players [6]. Although PPAD $\subseteq$ NP (but PPAD $\not\subseteq$ NP–complete unless NP = co–NP) it is generally believed that PPAD $\neq$ P. Thus the worst–case complexity of finding an NE is exponential in the size of the game. This pushed researchers to study approximate solution concepts, providing some polynomial–time algorithms that compute solutions with a guaranteed approximation bound [2, 11, 22]. However, bimatrix games do not have a fully polynomial–time approximation scheme unless PPAD $\subseteq$ P [6].

Worst–case complexity, being too pessimistic, is often a bad indicator of the actual performance of an algorithm, and *average–case* complexity is difficult to determine. A new metric of complexity, called *smoothed* complexity, has been gaining interest in recent years [21]. It studies how the introduction of small perturbations affects the worst–case complexity. Unfortunately, finding an NE in two–player games is not smoothed polynomial unless PPAD $\subseteq$ RP [5].

In this paper, we focus on two–player general–sum strategic–form games. An NE is a particularly appropriate solution concept in two–agent settings because coalitional deviations are not an issue. The main known algorithms are LH [14] based on linear complementarity mathematical programming (LCP), PNS [18] based on support enumeration, and MIP Nash [19] based on mixed–integer linear programming (MILP). None of these beats the others on all games, and all of them have worst–case complexity exponential in the size of the game. In particular, there are game instances, called hard–to–solve games (HtSG), that always require exponential time when solved with LH and PNS [20].

The integration of local search techniques with support enumeration algorithms, called LS–PNS, can be effective on games that are hard for all three algorithms above [3, 4]. (Other local search algorithms, based on simulated annealing or homotopy, that are slower but have convergence guarantees, have also been designed [12, 13].) In this paper, we combine local search techniques with path following algorithms (e.g., LH) instead. This opens new promising opportunities, allowing a dramatic reduction of the solution space: path following algorithms work on a solution space that is $O(2.6^m)$ where m is the number of actions per agent, while the number of supports is $O(4^m)$. Our contributions include the following.

(i) We design new algorithms: (a) an LH version with random restarts (rrLH)[1], (b) a version of the adaptation of the Lemke algorithm (L) proposed in [24] with random restarts (rrL), (c) a local search algorithm moving on the best response vertices (LS–v), and (d) an anytime LH version based on iteratively decreasing perturbation of the payoff matrices (ip–LH).

[1] A similar algorithm is presented in [7]. We extend such algorithm with an iterative deepening cutoff, we theoretically analyze its properties, and we provide a more thorough experimental analysis, developing a floating–point implementation that is about two times faster and developing a new arbitrary–precision implementation.

(*ii*) We prove that rrLH is asymptotically optimal in the space of algorithms that randomize over LH paths (the result can be extended to rrL).

(*iii*) We experimentally show that LH requires arbitrary precision with some classes of GAMUT games [17] and HtSG. L requires arbitrary precision for almost all the game instances.

(*iv*) rrLH outperforms all our and state–of–the–art algorithms, requiring an average number of steps that is linear in the size of the game except for CovariantGame–Rand and HtSG. rrL works asymptotically as rrLH, but its compute time is usually larger.

(*v*) LS–v outperforms the other algorithms in approximating hard instances, except HtSG.

(*vi*) HtSG can be easily approximated by ip–LH even with a perturbation of 10^{-10}. Thus there must exist a different worst case for LH unless PPAD $\subseteq$ RP. (In contrast, CovariantGame–Rand stays hard even when perturbed, thus it is a possible candidate.)

2 Game model and solution concepts

A bimatrix game is a tuple (N, A, U), where $N = \{1, 2\}$ is the set of agents (we denote by $i \in N$ a generic agent); $A = (A_1, A_2)$ where A_i is the set of $m_i = |A_i|$ actions available to agent i (we denote by $a \in A_1 \cup A_2$ a generic action); $U = (U_1, U_2)$ where U_i is the utility matrix of agent i [9]. Without loss of generality, we assume that $\max_{j,k}\{U_i(j,k)\} = 1$ and $\min_{j,k}\{U_i(j,k)\} = 0$ for every $i \in N$.

We denote by $\mathbf{x}_i$ the strategy (vector of probabilities) of agent i and by $x_{i,a}$ the probability with which agent i plays action $a \in A_i$. We denote by Δ_i the space of strategies over action space A_i, i.e., vectors where the probabilities sum to 1. Given strategy $\mathbf{x}_i$, the *support* S_i is the set of actions $a \in A_i$ played with a non–zero probability in $\mathbf{x}_i$.

The central solution concept is NE. A profile of strategies $(\mathbf{x}_1, \mathbf{x}_2)$ is an NE if and only if, for each $i \in N$, $\mathbf{x}_i^T U_i \mathbf{x}_{-i} \geq \mathbf{x}_i'^T U_i \mathbf{x}_{-i}$ for every $\mathbf{x}_i' \in \Delta_i$. The problem of finding an NE can be expressed as an LCP:

$$\mathbf{x}_i \geq 0 \qquad \forall i \in \{1,2\} \qquad (1)$$

$$\mathbf{1}v_i - U_i\mathbf{x}_{-i} \geq 0 \qquad \forall i \in \{1,2\} \qquad (2)$$

$$\mathbf{x}_i^T(\mathbf{1}v_i - U_i\mathbf{x}_{-i}) = 0 \qquad \forall i \in \{1,2\} \qquad (3)$$

$$\mathbf{1}^T\mathbf{x}_i = 1 \qquad \forall i \in \{1,2\} \qquad (4)$$

Here v_i is the expected utility of agent i. Constraints (1) and (4) state that every $\mathbf{x}_i \in \Delta_i$. Constraints (2) state that no pure strategy of agent i gives expected utility greater than v_i. Constraints (3) state that each agent plays only optimal actions.

The most common approximate solution concept is ϵ–Nash equilibrium (ϵ–NE): $(\mathbf{x}_1, \mathbf{x}_2)$ is an ϵ–NE if, for each $i \in N$, $\mathbf{x}_i^T U_i \mathbf{x}_{-i} \geq \mathbf{x}_i'^T U_i \mathbf{x}_{-i} - \epsilon$ for every $\mathbf{x}_i' \in \Delta_i$. Informally, $(\mathbf{x}_1, \mathbf{x}_2)$ is an ϵ–NE if at most each player loses a utility of ϵ w.r.t. playing her best response. Other approximate solution concepts that we use in this paper are ϵ–Well Supported–Nash equilibrium (ϵ_{WS}–NE) and regret–Nash equilibrium (r–NE). $(\mathbf{x}_1, \mathbf{x}_2)$ is an ϵ_{WS}–NE if, for each $i \in N$, $\mathbf{e}_k^T U_i \mathbf{x}_{-i} \geq \mathbf{e}_j^T U_i \mathbf{x}_{-i} - \epsilon$ for every $k \in S_i, j \in A_i$ ($\mathbf{e}_k$ is a vector of 0 but 1 in position k). Thus playing singularly each action of the support, the agent loses a utility of at most ϵ w.r.t. playing the her best response. Finally, $(\mathbf{x}_1, \mathbf{x}_2)$ is an r–NE if, for each $i \in N$, $r = \sum_{i=\{1,2\}} \sum_{l \in S_i} r_{i,l}$ and $\mathbf{e}_k^T U_i \mathbf{x}_{-i} \geq \mathbf{e}_j^T U_i \mathbf{x}_{-i} - r_{i,k}$ for every $k \in S_i, j \in A_i$.

3 Randomizing over paths

In this section we develop NE algorithms that randomize over *almost complementary* paths.

3.1 Randomizing over Lemke–Howson (LH) paths

For every agent i, define the best response polyhedron $P_i = \{\tilde{\mathbf{x}}_i \in \mathbb{R}^{m_i} | U_{-i}\tilde{\mathbf{x}}_i \leq \mathbf{1}, \tilde{\mathbf{x}}_i \geq \mathbf{0}\}$. Let V_i be the vertices of P_i. The space Θ of solutions traversed by LH is a subset of pairs of vertices of $V = V_1 \times V_2$. Let $\mathbf{s}_{-i}$ be the slack variables of $U_{-i}\tilde{\mathbf{x}}_i + \mathbf{s}_{-i} = \mathbf{1}$. Variables $s_{i,a}$ and $x_{i,a}$ are called *complementary*. A basic solution of the tableaux associated with P_1 and P_2 is *complementary* if the basis contains exactly one complementary variable for all i and a, while it is *almost complementary* if both variables of a single pair of complementary variables are in the basis. A completely complementary solution is an NE.

The initial solution of the LH algorithm [14] is generated by starting from the artificial solution $(\mathbf{0}, \mathbf{0})$ (corresponding to the case in which all the slack variables $\mathbf{s}_i$, for every i, are in the basis), and putting in the basis of one of the two tableaux a variable $x_{i,a}$ associated with some action $a \in A_1 \cup A_2$. Thus, there are $m_1 + m_2$ different possible initial solutions. LH follows a path of almost complementary solutions by repeatedly applying complementary pivoting steps. At each step, the current basis is changed by putting in the basis the variable that is complementary to the variable that has left the basis in the previous step, until a completely complementary solution has been found. The leaving variable is determined by the minimum ratio test [15] and it is unique except for degenerate games; however, degeneracy can be removed by introducing lexicographic perturbation [24].

For each initial solution, there is a different path leading to a (potentially different) NE: LH partitions the solution space in $m_1 + m_2$ different paths. If the path that the algorithm is following is an exponentially long one, it may be convenient to have restart.

We observe that any random restart policy over the solutions traversed by the LH algorithm can be formulated as a two–stage randomization policy: (1) ran-

domization over the $m_1 + m_2$ possible paths and (2) randomization, given a path, over its solutions. We initially present an algorithm, called rrLH, that adopts only a blind randomization of type (1) and, subsequently, we investigate randomization of type (2).

rrLH is described in Algorithm 1. It randomly chooses one of the paths (Step 2) and follows it (Step 4) until an NE is found; if the length (in terms of number of pivoting steps) of the path is larger than a given *cutoff* and there is a path that has not been visited till *cutoff* (Steps 5, 6, and 8), the algorithm restarts with a new path, otherwise (Step 7) *cutoff* is updated in an iterative deepening fashion and a restart is done.

Algorithm 1 Lemke–Howson with random restart (rrLH)

```
1: cutoff = cutoff_0
2: randomly choose one path non–visited till cutoff
3: repeat
4:     apply complementary pivoting
5:     if the path is longer than cutoff then
6:         if all the paths are visited till cutoff then
7:             cutoff = cutoff + cutoff_0
8:         go to Step 2
9: until a completely complementary solution is found
10: return current solution
```

(To improve the efficiency of the algorithm, we save the variables of the current basis before making a restart and, when a path is re–visited, we derive the last visited basis by matrix inversion and we restart from it.) The advantages of rrLH are simplicity and completeness. The potential drawbacks are that the number of possible paths is limited and that the algorithm is forced to move along fixed paths. Call l^* the shortest LH path. The compute time of rrLH is linear in l^*. When l^* is known or it is possible to estimate a tight upper bound, $cutoff_0$ can be conveniently fixed. Assigning, e.g., $cutoff_0 = l^*$, we have that the worst case compute time is $l^*(m_1 + m_2)$, while the average is $l^*(m_1 + m_2 + 1)/2$. Thus, if l^* grows in length exponentially in $m_1 + m_2$, also rrLH compute time grows in length exponentially. Adopting a non–blind randomization of type (1) would keep the compute time, even in the best case, linear in l^* and hence is useless.

We focus on randomization of type (2). This type of randomization cannot be efficiently achieved with LH. Indeed, differently from what happens with support–enumeration algorithms [3, 4] where it is possible to start from any support profile, no every possible almost complementary basis corresponds to a feasible starting solution for LH: some sets of almost complementary variables are not feasible basic solutions, while the feasible ones can belong to LH paths or not, and in this latter case they may belong to cyclic paths that do not lead to any equilibrium (the membership of a solution to a path can be discovered only during the traversing of the path itself and therefore, if the algorithm starts from an arbitrary solution, it cannot know the path over which it is moving and cannot distinguish paths from cycles). Thus, an initial solution must be searched by using pivoting and the number of pivoting steps may be exponential in $m_1 + m_2$. However, we show that any algorithm with randomization of type (2) has a compute time that is asymptotically the same of our rrLH and therefore rrLH is (asymptotically) optimal in the space of the algorithms making random restarts over the LH paths. This holds even dropping completeness and considering algorithms that find an NE with a probability p. Initially, we state the following lemma.

Lemma 1. *The best* cutoff *of a generic randomized algorithm that finds the terminal vertex of an l–step–long path with probability p and is able to position blindly in every vertex of the path is $l \cdot p$.*

Proof. The best configuration of the algorithm can be obtained by minimizing the number of steps of the algorithm (i.e., $cutoff \cdot res$, where res is the number of restarts), under the constraint that the probability to find the terminal is p, i.e., $p = 1 - (1 - cutoff/l)^{res}$, $res \geq 1$, and $cutoff \geq 1$. From $p = 1-(1-cutoff/l)^{res}$ it follows that $res = \log(1-p)/\log(1-cutoff/l) \geq 1$, thus $\log(1-p) \geq \log(1 - cutoff/l)$, that means $p \leq cutoff/l$. $res \cdot cutoff$ can be rewritten as $\log(1-p)/\log(1 - cutoff/l) \cdot cutoff$. After having removed the negative constant $\log(1-p)$ the objective is to maximize the monotonic decreasing function $cutoff/\log(1-cutoff/l)$ under the constraint $p \leq cutoff/l$. The optimum is $cutoff = l \cdot p$ and $res = 1$. □

From Lemma 1 it follows that, even when it is possible to perform a blind randomization over the solutions composing a single path, like stage (2) prescribes, the optimal configuration of the algorithm is such that this path is traversed only once without making restarts (i.e. $res = 1$). Thus, this path can be safely removed from the set of the available paths at stage (1). From Lemma 1, we can easily derive the following lemma.

Lemma 2. *The worst case compute time of a randomized algorithm finding the terminal vertex of an l–step–long path and able to position blindly in every vertex of the path is l, while the average time is $l/2$.*

Finally, we show that including randomization of type (2) the compute time keeps to be linear in l^* as stated by Lemma 3. From Lemma 2 we can state the following.

Lemma 3. *LH with blind randomization policy of type (2) has a compute time $O(l^*)$.*

We can evaluate for specific interesting cases the ratio between the average compute time of an algorithm Π adopting randomization of type (2) and the one of an algorithm Π' that does not. Assign $cutoff = l^*$ and assume, for simplicity, that the length of all the non–shortest paths is $l > l^*$ and $m_1 = m_2 = m$.

The average compute time of Π is $(2m+1)/2 \cdot l^*$. The average case compute time of Π' is given by $1/2m \cdot l^*/2 \cdot \sum_{k=0}^{2m}(1-l^*/2)^k + (l^*)^2/2l \cdot 1/2n \cdot \sum_{k=0}^{2m-1}(1-l^*/l)^k(2m-1-k)$. The two opposite possible situations are: $l^*/l \to 1$ and $l^*/l \to 0$. In the best situation $l^*/l \to 1$ the average compute time is $l^*/2$ and therefore randomization of type (2) reduces the compute time by $2m+1$ times. In the worst situation $l^*/l \to 0$, the ratio is 1 and therefore no reduction is obtained. In both cases, the compute time keeps to be linear in l^*. We observe that, randomization of type (2) exploits the existence of paths that are not excessively longer than the shortest path.

Now, we focus on non–blind randomization of type (2), providing a negative result.

Lemma 4. *Any algorithm that finds the terminal vertex of an l–step–long path with probability p and able to position non–blindly in every vertex of the path, requires either an exponential number (*res*) of restarts or an exponential* cutoff *as l grows in length exponentially.*

Proof. Suppose to have an oracle that, given a *cutoff* and an almost complementary solution, is able to say whether or not such a solution is farther than *cutoff* from the terminal vertex. If the solution is farther, then it is discarded, otherwise the algorithm follows the path from the given solution and the terminal vertex. The probability to find a randomly generated solution that is not farther than *cutoff* from the equilibrium by *res* random restarts is: $1-(1-\mathit{cutoff}/l)^{res}$. By posing: $1-(1-\mathit{cutoff}/l)^{res} = p$, we obtain $res = \log(1-p)/\log(1-\mathit{cutoff}/l)$. When $\lim_{l\to+\infty} \mathit{cutoff}/l = 0$, we can write $res = -l\log(1-p)/\mathit{cutoff}$. Therefore, if l grows in length exponentially then either *res* or *cutoff* grow in length exponentially. When $\lim_{l\to+\infty} \mathit{cutoff}/l > 0$, *cutoff* grows in length exponentially as l does. □

From the above lemma, it can be easily observed that when all the LH paths grow in length exponentially non–blind randomization is useless: even dropping the completeness and accepting that the NE can be found with a probability p, in the worst case the compute time is $O(l^*)$. Thus, rrLH is asymptotically optimal among algorithms randomizing over LH paths.

3.2 Randomizing over Lemke (L) paths

As discussed in the previous section, randomization over paths exhibits a compute time that depends on the length of shortest path. The main drawback of LH is that the number of available paths is small. In this section, we resort to the Lemke algorithm adaptation as prescribed by [24], which we will call L. This algorithm allows for an arbitrary initial solution, each corresponding to a different path, and therefore it allows for an infinite number of paths. Define the polyhedron P as follows.

$$P = \left\{ [z_0 \;\; \mathbf{z}_1 \;\; \mathbf{z}_2] \;\middle|\; \begin{array}{cc} M_{1,1}\mathbf{z}_1 + M_{1,2}\mathbf{z}_2 + \mathbf{d}_1 z_0 & = \mathbf{q}_1 \\ M_{2,1}\mathbf{z}_1 + M_{2,2}\mathbf{z}_2 + \mathbf{d}_2 z_0 + \mathbf{q}_2 & \geq 0 \\ z_0, \mathbf{z}_2 & \geq 0 \end{array} \right\}$$

with $\mathbf{d}_1 = \mathbf{1}, \mathbf{d}_2 = [-(U_1\overline{\mathbf{x}}_2)^T, -(U_2\overline{\mathbf{x}}_1)^T]^T$ where $\overline{\mathbf{x}}_1$ and $\overline{\mathbf{x}}_2$ are parameters (therefore P is parametric), $\mathbf{q}_1 = -\mathbf{1}$, $\mathbf{q}_2 = \mathbf{0}$ and

$$\mathbf{z}_1 = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \quad M_{1,1} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \quad M_{1,2} = \begin{bmatrix} \mathbf{1}^T & \mathbf{0}^T \\ \mathbf{0}^T & \mathbf{1}^T \end{bmatrix}$$

$$\mathbf{z}_2 = \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix} \quad M_{2,1} = \begin{bmatrix} \mathbf{1} & \mathbf{0} \\ \mathbf{0} & \mathbf{1} \end{bmatrix} \quad M_{2,2} = \begin{bmatrix} 0 & -U_1 \\ -U_2 & 0 \end{bmatrix}$$

Let V be the set of vertices of P. The space Θ of solutions traversed by the Lemke algorithm is a subset of V. Call $\mathbf{w}$ the slack variables of $M_{2,1}\mathbf{z}_1 + M_{2,2}\mathbf{z}_2 + \mathbf{d}_2 z_0 + \mathbf{q}_2 - \mathbf{w} = 0$ and consider the associated tableau. Call z_j, with $j \neq 0$, the j–th element of $\mathbf{z} = [\mathbf{z}_1^T, \mathbf{z}_2^T]$. Variables z_j and w_j are called complementary. A solution is completely complementary if the basis contains one complementary variable between z_j and w_j for every j (therefore z_0 is out the basis), while a solution is almost complementary if both variables z_j and w_j for a single j are not in the basis but z_0 is.

The algorithm moves along almost complementary solutions, each corresponding to a pair of strategies $(\mathbf{x}_1 + z_0\overline{\mathbf{x}}_1, \mathbf{x}_2 + z_0\overline{\mathbf{x}}_2)$. The initial solution is such that: (a) z_0 is in the basis and it is equal to 1, (b) all the variables $x_{i,a}$ such that a is a best response to $\overline{\mathbf{x}}_{-i}$ are in the basis except one, and (c) for all the non–best–response actions a the complementary variable w_j of $x_{i,a}$ is in the basis. Given the initial solution, the algorithm follows a path of almost complementary solutions by repeatedly applying complementary pivoting (the entering variable is the complementary variable of the leaving variable at the previous step, while the leaving variable is determined by the lexico minimum ratio test). At the first step of L, the entering variable is $x_{i,a}$ such that a is the only best response not yet in the basis. (L terminates when z_0 is the leaving variable, finding as NE.)

LH has a finite number of possible paths $(m_1 + m_2)$, while L has an infinite number of them, thus we try to design a non–blind randomization policy among paths and we fixed a limit to the restarts, otherwise in the worst case the compute time would be infinite. We design the version of L with random restarts (rrL) like rrLH except that: (a) the initial solution is determined by randomly generating $\overline{\mathbf{x}}_1$ and $\overline{\mathbf{x}}_2$; since there are infinitely many possible initial solutions and many of them could lead to potentially long paths, (b) we use quality metrics to accept or discard an initial solution θ (we accept θ if $g(\theta) > th$, where g can be defined in different ways, e.g., ϵ, ϵ_{WS}, and r, and th is a threshold), (c) we use a cutoff as a function of how the different metrics ϵ, ϵ_{WS}, r, and z_0 decrease

along the path; and (d) we disable the cutoff after a given number of restarts to guarantee completeness, the potential restarts would be infinite otherwise.

The advantage of rrL is that the initial solution can be any and thus much more paths than rrLH can be followed. The potential drawbacks are that the algorithm is forced to move along fixed paths and that the pivoting step requires about twice as much compute time as LH due to the tableau size.

4 Local search on best response vertices

We cast NE finding as a local search based optimization problem (Θ, f, N) where Θ is the solution space, f is a function $f : \Theta \to \mathbb{R}$ to minimize, and N is the *neighborhood function* that specifies, for each solution $\theta \in \Theta$, a set $N(\theta) \subseteq \Theta$ of solutions that can be directly reached from θ [16].

The solution space Θ is the set of vertices V_i of the polyhedron $P_i = \{\tilde{\mathbf{x}}_i \in \mathbb{R}^{m_i} | U_{-i}\tilde{\mathbf{x}}_i \leq \mathbf{1}, \tilde{\mathbf{x}}_i \geq \mathbf{0}\}$ that constitutes the best response polyhedron of agent i, where agent i is the agent with the minimum number of actions. This choice allows one to reduce the solution space as shown below (however, our algorithm can be applied with any i). Every vertex $\tilde{\mathbf{x}}_i$ of V_i, except for $\tilde{\mathbf{x}}_i = \mathbf{0}$, is equivalent to a strategy $\mathbf{x}_i = \frac{1}{\mathbf{1}^T\tilde{\mathbf{x}}_i}\tilde{\mathbf{x}}_i$.

The function f to minimize associates each strategy $\mathbf{x}_i = \overline{\mathbf{x}}_i$ with the ϵ value of the best ϵ–Nash equilibrium when agent i plays $\overline{\mathbf{x}}_i$. This value can be computed as:

$$\min_{\epsilon, \mathbf{x}_{-i}} \quad \epsilon \tag{5}$$

$$\text{s.t.} \quad \overline{\mathbf{x}}_i^T U_i \mathbf{x}_{-i} + \epsilon - \mathbf{e}_k^T U_i \mathbf{x}_{-i} \geq 0 \qquad \forall k \in A_i \tag{6}$$

$$\overline{\mathbf{x}}_i^T U_{-i} \mathbf{x}_{-i} + \epsilon - \overline{\mathbf{x}}_i^T U_{-i} \mathbf{e}_k \geq 0 \qquad \forall k \in A_{-i} \tag{7}$$

$$\mathbf{1}^T \mathbf{x}_{-i} = 1 \tag{8}$$

$$\mathbf{x}_{-i} \geq \mathbf{0} \tag{9}$$

$$\epsilon \geq 0 \tag{10}$$

The constraints ensure that $\mathbf{x}_{-i} \in \Delta_{-i}$ and ϵ is non–negative. Note that the solution ϵ^* of the above linear program is 0 if and only if there is some $\mathbf{x}_{-i} = \overline{\mathbf{x}}_{-i}$ such that $(\overline{\mathbf{x}}_i, \overline{\mathbf{x}}_{-i})$ is an NE. Therefore, we recognize whether or not a local minimum is a global minimum.

Given a vertex $\tilde{\mathbf{x}}_i$ of V_i, the neighbors are all the adjacent vertices of $\tilde{\mathbf{x}}_i$. These vertices can be found by exploiting pivoting. More precisely, consider the tableau $U_{-i}\tilde{\mathbf{x}}_i + \mathbf{s} = \mathbf{1}$ where $\mathbf{s}$ are slack variables. A basic solution of the tableau is composed by m_{-i} variables belonging to $\tilde{\mathbf{x}}_i$ and $\mathbf{s}$ (when only variables $\mathbf{s}$ are in the basis we have the artificial solution $\tilde{\mathbf{x}}_i = 0$). A vertex $\tilde{\mathbf{x}}_i$ of V_i corresponds to a basic solution of the tableau. We can change the basis by making a non–basic variable enter the basis (the leaving variable is uniquely determined by the minimum ratio test). The number of entering variables is m_i; thus each vertex has exactly m_i neighbors. In contrast, in the local search over supports, each solution has $m_1 \cdot m_2$ neighbors.

The local search algorithm for solving (Θ, f, N), called LS–v, is provided in Algorithm 2. The initial solution (Step 1) is generated starting from the artificial solution $\tilde{\mathbf{x}}_i = \mathbf{0}$ and applying a random number of random pivoting steps (as described above). In principle, any possible vertex of P_i may be an initial solution. We use a tabu list to keep track of previously generated initial solutions in order to avoid repetitions. Given solution s, the algorithm searches in the neighborhood $N(s)$ for a solution s' such that $f(s') < f(s)$ (Step 3). This search is driven by a heuristic. We use three main heuristics: *best improvement* (BI) where all neighbors are generated and the best neighbor better than the current is chosen, *first improvement* (FI) where the neighbors are searched in a given order and the first neighbor better than the current is chosen, *first improvement with random generation* (FIR) where the neighbors are searched randomly and the first neighbor better than the current solution is chosen. (With FIR we disable the tabu list for the initial solution because randomization makes the algorithm follow different paths at every execution, and we generate at most *max–n* neighbors.) If there is no neighbor better than the current solution or if the path length is longer than *cutoff* and there exists an unvisited initial solution, then a restart is conducted (Steps 4 and 5).

Algorithm 2 Local search on best response vertices (LS–v)

1: randomly choose an unvisited initial solution s from $\tilde{\mathbf{x}}_i = \mathbf{0}$ by pivoting
2: **repeat**
3: choose neighbor $\theta' \in N(\theta)$ with $f(\theta') < f(\theta)$ and assign $\theta = \theta'$
4: **if** there is no θ' or the path is longer than *cutoff* **then**
5: go to Step 1
6: **until** $f(\theta) > 0$
7: return current solution

The advantages of rrL are that it can traverse solutions that are not in LH/L paths and that the number of neighbors is low (w.r.t. local search on supports). The drawback is that the algorithm is incomplete.

5 Anytime iterative perturbation over paths

Given a two–player game with utilities (U_1, U_2) and a game with (U_1', U_2') where every U_i' is obtained by perturbing each payoff of U_i with an arbitrary probability distribution over $[-\delta, \delta]$, it has been shown that an NE for (U_1', U_2') is an ϵ–NE for (U_1, U_2) with $\epsilon \leq 4\delta$ [5]. We argue that the bound is tighter:

Theorem 1. *Given a two–player game with (U_1, U_2) and a game with (U_1', U_2') where every U_i' is obtained by perturbing each payoff of U_i with an arbitrary probability distribution over $[-\delta, \delta]$, an NE $(\hat{x}_1, \hat{x}_2)$ for*

(U_1', U_2') *is an* ϵ*–NE for* (U_1, U_2) *with* $\epsilon \leq 2\delta$.

Proof Call x_1^* the best response of agent 1 to $\hat{x}_2$ of agent 2 for the game (U_1, U_2). By definition, $||U_i - U_i'||_\infty \leq \delta$. We can compute the upper bound over the expected utility loss of agent 1: $\epsilon = x_1^* U_1 \hat{x}_2 - \hat{x}_1 U_1 \hat{x}_2 \leq x_1^* U_1 \hat{x}_2 - x_1^* U_1' \hat{x}_2 + \hat{x}_1 U_1' \hat{x}_2 - \hat{x}_1 U_1 \hat{x}_2 \leq |x_1^* U_1 \hat{x}_2 - x_1^* U_1' \hat{x}_2| + |\hat{x}_1 U_1' \hat{x}_2 - \hat{x}_1 U_1 \hat{x}_2| \leq x_1^* ||U_1 - U_1'||_\infty \hat{x}_2 + \hat{x}_1 ||U_1' - U_1||_\infty \hat{x}_2 \leq ||U_1 - U_1'||_\infty + ||U_1' - U_1||_\infty \leq 2\delta$. The same reasoning can be applied to agent 2, obtaining the same upper bound. Hence, the theorem is proved. □

We exploit this result to produce a simple anytime algorithm (Algorithm 3) based on the idea that an hard game could become easy after perturbed. The algorithm iteratively applies LH starting from a perturbed game obtained with a large perturbation (i.e., $\delta = 0.125$) and then exponentially reducing the perturbation at each step where LH has found an NE.

Algorithm 3 Anytime iterative perturbation over paths (ip-LH)

```
1: set k = 3
2: while deadline has not been reached do
3:     set δ = 1/2^k
4:     apply δ–uniform perturbation on (U_1, U_2)
5:     apply LH to perturbed (U_1, U_2)
6:     set k = k + 1
7: return current solution
```

6 Experimental evaluation

6.1 Experimental setting

We implemented LH, L, rrLH, rrL and ip–LH in C in two different versions: one with floating–point and one with arbitrary–precision integer arithmetic by means of the GMP library[2]. We implemented LS–v, PNS and LS–PNS in C calling CPLEX via AMPL to solve LPs, while MIP Nash directly in AMPL[3] with CPLEX[4]. All the algorithms that use pivoting techniques are optimized with the revised technique [15] and those using GMP with integer pivoting [23] to save compute time. (Revised technique allows us to store and perform pivoting on a reduced tableau, obtaining a relevant improvement in the performance of the algorithms.) We conducted the experiments on a UNIX computer with 2.33GHz CPU, 16GB RAM and kernel 2.6.24.

Using GAMUT [17], we generated 500 instances of CovariantGame–Rand, GraphicalGame–RG and PolymatrixGame–RG games (being the hardest classes w.r.t. PNS, LH and MIP Nash) and 10 instances of all the other classes with $m_1 = m_2 = m \in \{5, \ldots, 150\}$ and a step of 5. We also generated an instance of SGC games with $m \in \{3, \ldots, 99\}$ and a step of 4 as prescribed in [19]. In SGC games, all equilibria have a medium number of pure strategies in their supports. Finally, we generated one instance of HtSG (its generation not being random) with $m \in \{2, \ldots, 18\}$ and a step of 2 as prescribed in [20]. In HtSG, all the LH paths are exponentially long.[5]

6.2 Numerical instability with floating point precision

We evaluated numerical instability of LH and L with floating–point precision for different game classes, comparing their results to those obtained with arbitrary precision. With GAMUT game classes, L presents numerical instability (the algorithm goes in ray termination) even with small games ($m = 30$) for all the game classes, while LH presents instability with a limited number of game classes (not recognizing equilibria or finding non–NE solutions). With long double precision, LH performs a wrong path on 96.1% of 100x100 TravelersDilemma instances and on 22.75% of 100x100 WarOfAttrition instances. More available tricks could be used to diminish the numerical instability than the ones used in our implementation, but the result would be the same: LH and L are intrinsically unstable. Using other tricks we can increase the size of the games at which instability appears. However, the relative comparison of the game classes in terms of arbitrary precision stands. On HtSG, arbitrary precision arithmetic is required even during the game instance generation. We generated game instances using both the trigonometric and the non–trigonometric moment curves as described in the appendix of [20]. We counted, using the *lrs* algorithm [1], the number of vertices of the polyhedron associated with the game generated with floating point precision and compared it to that obtained with arbitrary precision. When at least one vertex is lost, the polyhedron loses its hardness characteristics and at least a short path appears. Tab. 1 shows that arbitrary precision is required for instances with ≥ 14 actions per agent.

Table 1: Percentage of lost vertices in HtSG due to floating–point precision with different moment curves.

Actions per agent					
6	8	10	12	14	16
non–trigonometric					
0%	0%	0%	0%	1%	29%
trigonometric					
0%	64%	72%	95%	92%	82%

6.3 Path distribution

We ran LH along every possible path with all the 100x100 (99x99 with SGC) instances of our experimental setting (except HtSG), measuring the length of

[2] http://gmplib.org/.

[3] http://www.ampl.com.

[4] http://www-01.ibm.com/software/integration/optimization/cplex-optimizer/.

[5] Although HtSG square instances can be easily solved by support enumeration algorithms, the equilibrium being unique and fully mixed, non–square games can be built such that support enumeration algorithms require exponential time.

the paths and deriving their distribution for each game class. Almost all the distributions are *fat–tailed* [10]. These distributions present a lot of data points in the tail, showing that the performance of an algorithm may vary dramatically from run to run. Formally, a distribution is fat–tailed if its *kurtosis* (μ_4/μ_2^2, where μ_j is the j–th moment) is larger than 3 (i.e., the kurtosis of a standard normal). All the game classes have a kurtosis larger then 3, except for DispersionGame, MinimunEffortGame (the kurtosis is not defined since $\mu_2 = 0$ and $\mu_4 = 0$, all the paths having the same length), SGC (1.0), TravelersDilemma (1.8), and WarOfAttrition (2.39). As suggested in [10], with fat–tailed distributions, random restarts may drastically improve performance. Our experiments, discussed below, confirm this.

Although almost all the classes present fat–tailed distributions, the performance of LH varies greatly across them. We ran LH with instances of different sizes and bucketed the game classes into five groups:

1. (DispersionGame, MinimumEffortGame) The length of all the paths is constant (= 2) with game size.
2. (BidirectionalLEG–CG/RG/SG, CovariantGame–Pos, LocationGame, UniformLEG–CG/RG/SG, WarOfAttrition) The average and maximum path length tends to a constant value (< 10) as game size increases.
3. (SGC, TravelersDilemma) The average path length increases linearly in game size.
4. (BertrandOligopoly, CovariantGame–Rand/Zero, GraphicalGame–RG/Road/SG/SW, PolymatrixGame–CG/RG/Road/SW, RandomGame) These games have an exponential growth of the average number of steps with the game size, but there can be some paths with polynomial length. Fig. 1 reports, for two classes, the average number of steps and the pertinent *box–plot* diagram: *median*, 1–st and 3–rd *quartiles* (dashed), *max* and *min* (dotted).
5. (HtSG). All the paths are exponentially long.

We produced the same analysis for L by randomly generating m initial solutions. All the classes present the same behavior they have with LH — except DispersionGame, which, when solved with L, belongs to Group 2. HtSG preserves, with L, the same characteristic exhibited with LH: the length of the shortest paths grows exponentially.

6.4 Finding an NE by rrLH

Groups 1–3 are easy even without resorting to random restarts (these games are easy also with other algorithms, e.g. PNS). Thus, we just briefly summarize the main results omitting details. Instances of

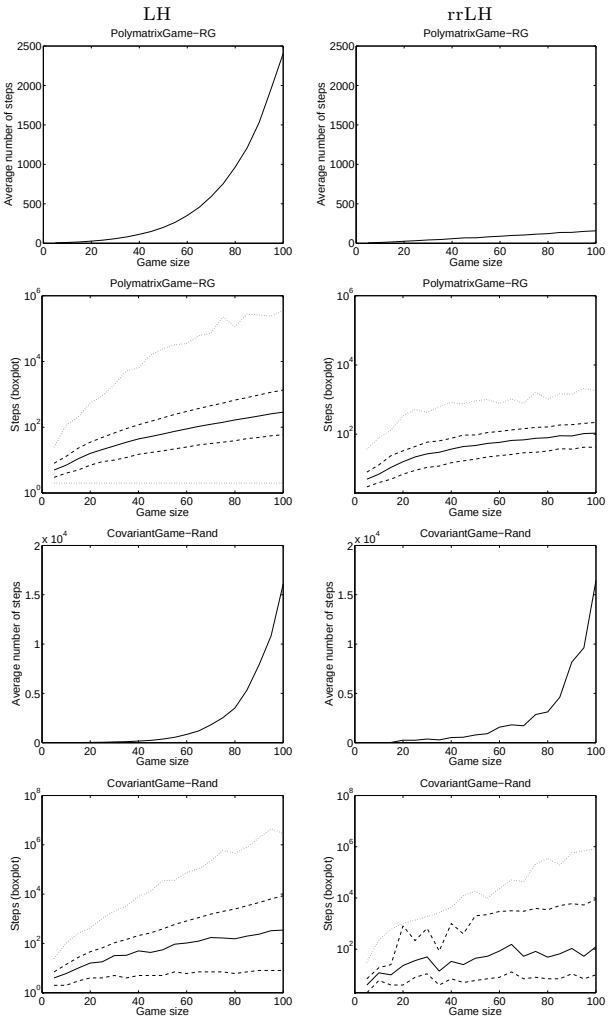

Figure 1: Comparison between LH (left) and rrLH (right) in terms of average number of steps and box–plot (median, 1–st/3–rd quartiles with dotted lines, min/max with dashed lines) of PolymatrixGame–RG and CovariantGame–Rand.

Groups 1 and 2 are solved by LH with a very small number of steps even in the worst cases (the compute times are less than one second). With Group 3, LH requires a linear compute time. With SCG it has already been experimentally demonstrated that LH outperforms MIP Nash and PNS [19]. With TravelersDilemma, LH (with arbitrary precision) is essentially the unique applicable algorithm — the commercial LP solvers do not support arbitrary precision, while a preliminary evaluation of GLPK with arbitrary precision led to compute times two orders of magnitude longer.

Random restarts play a crucial role with Group 4. These games are hard (in average) when solved with LH (and the other known algorithms: PNS, MIP Nash, LS–PNS). The application of rrLH with *cutoff* = 20 makes all the classes except for CovariantGame–Rand easy: all the executions of rrLH find an NE by the deadline and the average compute time is lin-

Table 2: Termination percentage and compute times.

rr–LH		MIP Nash		PNS

ear the game size (the same for max and median), as shown in Fig. 1 for PolymatrixGame–RG. With CovariantGame–Rand, we observed that there is at least an instance whose shortest path grows in length exponentially (therefore, as shown in Section 3, no *cutoff*, even with iterative deepening, can lead to non–exponential compute times). As a result, the average number of steps is not smaller than that of LH.

We compared rrLH with floating–point precision (arbitrary precision is averagely 56 times slower) to MIP Nash and PNS with 150x150 instances of Group 4 (LS–PNS is not useful for non–hard instances [3]). Tab. 2 shows the percentage of instances solved within 600 s and the compute time in seconds. rrLH dramatically outperforms the other two algorithms. More precisely, PNS terminates very quickly if there is an NE with very small support and takes exponential time otherwise. Call $\underline{s}$ the smallest support size of all the NEs of a game. PNS scans $O(n^{2\underline{s}})$ supports before finding an NE, instead we observed that rrLH makes $O(2n\underline{s})$ pivoting steps. Thus, as n increases, PNS is inefficient even with small $\underline{s}$, instead rrLH scales well. MIP Nash performs radically worse than the others.

With HtSG, obviously, rrLH is not effective.

6.5 Finding an NE by rrL

The performance of rrL with blind random restarts are similar to rrLH, requiring for some classes (e.g. CovariantGame–Rand) a smaller number of steps but requiring more time per step. Given that all the other classes can be easily solved by applying rrLH except for CovariantGame–Rand and HtSG, we focused only on these two hard classes exploiting the main peculiarity of rrL: adopting a non–blind approach, trying to characterize good initial solutions and discarding those that are not promising.

We initially studied correlation between the values of ϵ, ϵ_{WS}, and r of the initial solutions and the length of the paths with L, and we observed that no statistical correlation is present. Thus, such parameters cannot be used to identify short paths and discard those potentially long. Instead, we found statistical correlation for CovariantGame–Rand (and PolymatrixGame–RG) between the length of the L paths and the distance (d_∞) in $||\cdot||_\infty$ between the initial solution and the equilibrium (the steps reduce as d_∞ increases), as shown in Fig. 2. Because the equilibrium is unknown, we can only use the vertices of the simplices as initial solutions (these are by definition the farthest points). However, with these initial solutions, L behaves like LH. This justifies why, although L allows potentially infinite paths, LH performs like L.

Given the difficulty of characterizing good initial solutions, we tried to characterize good paths by analyzing how some metrics (ϵ, ϵ_{WS}, r, z_0) vary during the paths. We designed a measure defined as $decr(z_0, h) = \frac{1}{z_{0_1}} \sum_{k=1}^{h} |z_{0_k} - z_{0_{k+1}}|$ that is equal to 1 when z_0 decreases monotonically and greater than 1 otherwise. Fig. 2 shows that with CovariantGame–Rand, $decr(z_0, h)$ is high on long paths. However, experimentally, this strategy resulted ineffective even fixing a small *cutoff*. Furthermore, there is no statistical correlation when ϵ or ϵ_{WS} or r are used in place of z_0.

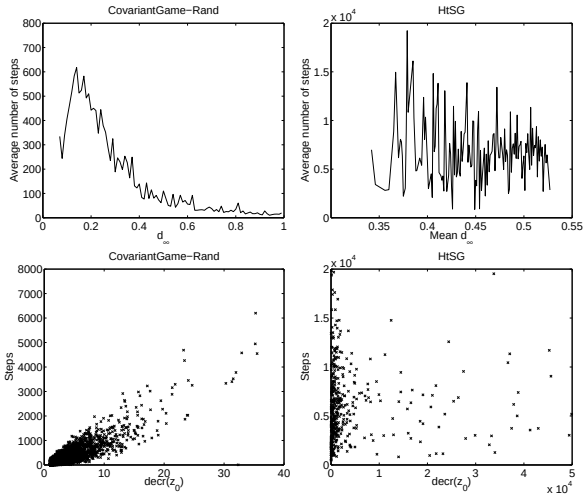

Figure 2: Relation between the measures d_∞, $decr(z_0, m)$ and number of steps with 50x50 CovariantGame–Rand and 16x16 HtSG.

6.6 Finding an NE by LS–v

We mainly focused the evaluation of LS–v on CovariantGame–Rand, the other classes being easy and LS–v being not applicable to HtSG due to lack of arbitrary precision. We tuned the parameters

cutoff and *max–n* of FIR in LS–v as follows. We isolated 15 100x100 hard CovariantGame–Rand instances that cannot be solved by 600 s by PNS, MIP Nash or rrLH. We randomly chose 5 instances and tuned LS–v with $cutoff \in \{m, 2m, m^2, 2m^2\}$ and $max\text{–}n \in \{m/2, m, 2m, m^2/2\}$. The best configuration was $cutoff = m^2/2$ and $max\text{–}n = 2m^2$. With such configuration, the number of random restarts is very small. In practice, every solution has a better neighbor with high probability. Then we compared the performance of the three heuristics BI, FI and FIR (with its best configuration) with the other 10 hard instances (non–used for the tuning). The best heuristic was FIR with $\epsilon = 3.64 \cdot 10^{-4}$ by 600 s, while $\epsilon > 3 \cdot 10^{-3}$ with the other two. However, LS–v never found an NE with these 10 hard instances. In addition, we evaluated LS–v with generic (not necessarily hard) instances. Tab. 3 reports success probability and ϵ of the best solution found by 600 s. LS–v is outperformed by rrLH and rrL (that found an NE with GraphicalGame–RG and PolymatrixGame–RG with a probability of 100% and of 30% with 100x100 CovariantGame–Rand).

Table 3: Percentage of solved instances and average best ϵ–NE found within 600 s with LS–v.

Actions per agent		
60	80	100
CovariantGame–Rand		
(56%)$9.34 \cdot 10^{-5}$	(63%)$1.82 \cdot 10^{-4}$	(13%)$1.80 \cdot 10^{-4}$
GraphicalGame–RG		
(56%)$1.32 \cdot 10^{-4}$	(38%)$1.72 \cdot 10^{-4}$	(36%)$7.83 \cdot 10^{-4}$
PolymatrixGame–RG		
(60%)$3.91 \cdot 10^{-5}$	(40%)$3.95 \cdot 10^{-4}$	(30%)$2.57 \cdot 10^{-4}$

6.7 Approximating an NE

We compared LS–v to the anytime versions of the other algorithms, obtained by keeping track of the best ϵ–NE during the pivoting, and ip–LH. Tab. 4 shows that LS–v is the best anytime algorithm (including PNS–anyT) for the 15 hard CovariantGame–Rand instances by an order of magnitude. It can be observed that ip–LH does not perform well with CovariantGame–Rand. This result shows that CovariantGame–Rand instances are stable, keeping to be hard even when perturbed.

We compared the anytime performance of LS–v and LH–anyT, these algorithms working on a similar solution space. Fig. 3 shows that LS–v found very good approximate solutions within a small number of steps and it outperforms LH–anyT for all setting of run time (the other heuristics provide similar results: LS–v finds very quickly a good approximate equilibrium).

We studied the ϵ–NEs with 16x16 HtSG. These games were easy for ip–LH (with arbitrary precision), requiring less than 10 steps even with a perturbation of 10^{-10}, returning $\epsilon \approx 10^{-12}$ (we cannot apply a perturbation smaller than 10^{-10} due to limits of GMP library). This shows that HtSG instances are highly unstable when perturbed. Therefore, there must exist another game class that is hard for LH and that is stable unless PPAD $\subseteq$ RP. Finally, LH–anyT provided best performance, returning $\epsilon \approx 10^{-34}$ within 600 s.

Table 4: Average best ϵ–NE found within 600 s on 100x100 hard CovariantGame–Rand.

LH–anyT	L–anyT	PNS–anyT	MILP–anyT
$6 \cdot 10^{-3}$	$2 \cdot 10^{-2}$	$8 \cdot 10^{-2}$	$3 \cdot 10^{-3}$

ip–LH	LS–v	LS–PNS
$1 \cdot 10^{-2}$	$\mathbf{3 \cdot 10^{-4}}$	$2 \cdot 10^{-3}$

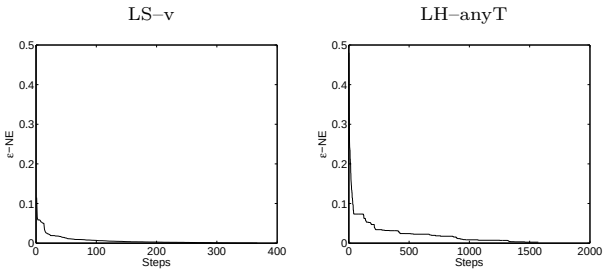

Figure 3: How the best ϵ–NE found so far changes during two sample executions of LS–v and LH–anyT.

7 Conclusions and future research

The computation of an NE is a challenging task even with two agents. In this paper we present by and large the fastest algorithms for the problem to date. We also present other results about the problem. For many situations, arbitrary–precision arithmetic is necessary even with LH. Complementary pivoting with blind random restarts over paths is the best heuristic, linearizing the average compute time in game size and outperforming all our and state–of–the–art algorithms for all the benchmark game classes except CovariantGame–Rand and HtSG. We provide theoretical results that allow us to say that rrLH is asymptotically optimal among algorithms that randomize over LH paths. We did not find any metric to characterize good L paths and therefore to have non–blind random restarts. Local search guided by the minimization of ϵ exhibits worse performance in finding exact equilibria, but it is the best in approximating hard instances, except for HtSG. HtSG games are unstable in the sense that they can be easily approximated by introducing a very small perturbation; therefore there must exist an alternative hard instance for LH that is stable (CovariantGame–Rand is a possible candidate, it being stable). In the future, we will extend our algorithms to games with more than two agents and isolate hard stable instances for each algorithm.

Abstract

This paper provides some new guidance in the construction of region graphs for Generalized Belief Propagation (GBP). We connect the problem of choosing the outer regions of a Loop-Structured Region Graph (SRG) to that of finding a fundamental cycle basis of the corresponding Markov network. We also define a new class of *tree-robust* Loop-SRG for which GBP on any induced (spanning) tree of the Markov network, obtained by setting to zero the off-tree interactions, is exact. This class of SRG is then mapped to an equivalent class of *tree-robust* cycle bases on the Markov network. We show that a tree-robust cycle basis can be identified by proving that for every subset of cycles, the graph obtained from the edges that participate in a single cycle only, is multiply connected. Using this we identify two classes of tree-robust cycle bases: planar cycle bases and "star" cycle bases. In experiments we show that tree-robustness can be successfully exploited as a design principle to improve the accuracy and convergence of GBP.

1 Introduction

Loopy belief propagation (BP) on Markov networks (MNs) [16, 29, 5, 22, 1, 17] has remained an active area of research for more than a decade. Much progress has been made in characterizing its fixed points [26, 33, 9], improving and understanding its convergence properties [26, 4, 11, 12], designing convergent alternatives [32, 35, 9, 7, 8, 19], developing new message passing algorithms based on alternative convex objectives [27, 28, 10, 25], and extending BP to GBP based on larger clusters (also known as the Kikuchi approximation or Cluster Variation Method) [14, 20, 34].

Despite all this progress, very little attention has been paid to the question of how to actually choose the outer regions (clusters, cliques) for any of the GBP algorithms. This is surprising given that GBP has the potential to improve the accuracy of BP by orders of magnitude without necessarily adding all that much computational burden. Moreover, GBP is very sensitive to the choice of outer regions; a bad choice can lead to poor convergence behavior and little improvement in accuracy, while a good choice can result in fast convergence and an accurate approximation.

Some guidance on choosing regions has appeared in the literature. In [30] a (greedy) region pursuit algorithm was proposed that ranks candidate clusters by sending a limited set of messages through the network. This approach is computationally expensive because all candidate clusters need to be evaluated. Moreover, the algorithm has no way of deciding when to stop adding regions. A similarly expensive "wrapper" approach based on the edge deletion method was published in [2]. A scheme that utilizes mini-bucket elimination to choose regions in a two layer region graph (called a join graph) is presented in [3]. In this region graph, inner regions represent the separators and connections between outer and inner regions are chosen so that the running intersection property holds.

Two desirable properties of region graphs on partially ordered sets (posets) - k-connectedness and k-balancedness - were proposed in [18, 23]. Those authors also show that the Cluster Variation Method (CVM) [14, 20, 34] yields a region graph that is totally connected and balanced and that the join-graph construction is only 1-connected and 1-balanced. Structured Region Graphs (SRGs) introduced in [31] also inherit the total connectedness and balancedness properties. Another desirable property of region graph constructions discussed in [34] is that the sum of all counting numbers should equal 1. This property ensures exact results for infinitely strong interactions. A condition called maxent-normality, which ensures that the free energy is maximal in the limit of zero interactions, was also introduced in [34]. Maxent-uniqueness was strengthened in [31] to guarantee that uniform beliefs are the unique fixed points of GBP.

In [31] it was shown that Loop-SRGs - a specific class of

SRG with loop outer regions - satisfy all the desirable conditions when the loop regions form a linearly independent set of size #edges - #nodes + 1 - i.e. a cycle basis. Our contribution can be seen as a refinement of the criteria proposed in [31]. In particular, we show that to satisfy the desirable conditions (e.g. non-singularity and sum of counting numbers equal 1), the set of loop regions must form a fundamental cycle basis. We also propose a condition called "tree-robustness" that further restricts the choice of loop regions. The idea of tree-robustness is to require GBP on a SRG to be *exact on every possible tree embedded in the Markov Network*, where an embedded tree is obtained by zeroing out the interactions on the off-tree edges. For loop SRGs, we show that this idea can be translated to an equivalent problem in graph theory, namely that of finding tree-robust cycle bases. We then characterize the class of tree robust cycle bases and identify two families of tree robust cycle bases. Finally, we demonstrate the performance of GBP on Loop-SRGs constructed to satisfy tree-robustness.

2 Generalized Belief Propagation and Structured Region Graphs

Belief Propagation (BP) [24] is an algorithm for computing marginal probabilities in distributions taking the following form:

$$p(\mathbf{x}) = \frac{1}{Z}\prod_a f_a(\mathbf{x}_a) \tag{1}$$

where a indexes the factors in the model and $f(\mathbf{x}_a)$ is a function on $\mathbf{x}_a$, which is a subset of $\{x_1, ..., x_n\}$, the n discrete-valued random variables in the distribution. In this paper we assume $p(\mathbf{x})$ to be comprised of only pairwise factors but the extension to factor graphs is straightforward.

BP is a message passing algorithm that computes marginals by iteratively sending messages from one node to its neighboring nodes. It is most easily described in terms of messages passed along the edges of a *factor graph* [15] (factors are pairwise interactions in this paper), which is a bipartite graph comprised of *factor* nodes and *variable* nodes. The edges in a factor graph connect each factor node a to the variable nodes i for which $x_i \in \mathbf{x}_a$. The belief $b_i(x_i)$ at variable node i is an approximation to the exact marginal $p(x_i)$ and is defined as:

$$b_i(x_i) \propto \prod_{a \in N(i)} m_{a \to i}(x_i) \tag{2}$$

where $m_{a\to i}(x_i)$ is a message from factor node a to variable node i and $N(i)$ is the set of factor nodes neighboring variable node i. The belief $b_a(\mathbf{x}_a)$ over the variables $\mathbf{x}_a$ is defined in an analogous fashion, as a product of messages from variable nodes to factor node a. These beliefs will be exact if the factor graph contains no cycles.

An important limitation of BP is that messages are defined on a single variable. This means that interactions between variables may be lost during message passing. Generalized Belief Propagation (GBP) [34] is a class of algorithms that address this limitation. In GBP, messages over one or more variable are passed among sets of nodes or *regions*. A *region* graph is a structure, analogous to the factor graph, that helps organize the computation of GBP messages.

DEFINITION **1.** *A Region R is a set of variable nodes and factor nodes such that if factor node a is in region R, all variable nodes i where $x_i \in \mathbf{x}_a$ are also in R.*

Let $\mathcal{R}$ denote the set of all regions. Let $\mathbf{x}_R$ denote the set of variables in region R and $f_R(\mathbf{x}_R) = \prod_{a\in R} f_a(\mathbf{x}_a)$ be the factors in region R. Every variable and factor must belong to some region.

DEFINITION **2.** *A Region Graph (RG) is a directed graph $G(V, E)$, where each vertex $v \in V$ is associated with a region $R \in \mathcal{R}$ and the directed edges $e \in E$ are from some vertex v_p to vertex v_c if $\mathbf{x}_{R_c} \subset \mathbf{x}_{R_p}$, where $\mathbf{x}_{R_i}$ is the set of variables in region R_i. In such cases, vertex (region) p is the parent of vertex c.*

Let $pa(R)$ denote the parents, $an(R)$ denote the ancestors and $de(R)$ denote the descendants of region R. Regions with no parents will be referred to as *outer* regions; all other regions are *inner* regions. The Bethe RG is a RG with outer regions for each factor and inner regions for each variable.

Each region R is associated with a counting number κ_r used to define the region-based free energy of a RG. Let $R(i) = \{R \in \mathcal{R} | x_i \in \mathbf{x}_R\}$ denote the set of regions containing variable i. A RG is considered *1-balanced* if:

$$\sum_{R\in R(i)} \kappa_R = 1 \; \forall \, i \tag{3}$$

1-balancedness is satisfied if κ_R is defined recursively as:

$$\kappa_R = 1 - \sum_{A\in an(R)} \kappa_A \tag{4}$$

A RG is *1-Connected* if the subgraph consisting of the regions $R(i)$ is connected for all i. These conditions can be strengthened by considering the set of regions containing a larger set of variables - i.e. $R(s) = \{R \in \mathcal{R} | \mathbf{x}_s \in \mathbf{x}_R\}$ for $\mathbf{x}_s \subseteq \{x_1, ..., x_n\}$. A RG is called *totally* connected and balanced if it is connected and balanced for all sets of variables that are subsets of an outer region - i.e. for any $\mathbf{x}_s \subseteq \mathbf{x}_R$ for outer region R [23]. Junction graphs [18] and Join Graphs [3] are two-layer RG constructions satisfying 1-balancedness and 1-connectednesss, while CVM [14, 21] ensures total connectivity and balancedness.

Many different GBP algorithms can be defined on RGs. The parent-to-child (or canonical) GBP algorithm is one such algorithm. It is defined in terms of messages sent from a parent region to a child region. As in BP, the belief at a particular region R is computed as a product of messages

into R. However, the messages do not come from the regions neighboring R, but rather from regions external to R. The belief $b_R(\mathbf{x}_R)$ at region R is given by:

$$b_R(\mathbf{x}_R) \propto f_R(\mathbf{x}_R) \prod_{P \in pa(R)} m_{P \to R}(\mathbf{x}_R) \cdot \quad (5)$$

$$\prod_{D \in de(R)} \prod_{P' \in P'(R)} m_{P' \to D}(\mathbf{x}_D) \quad (6)$$

where $P'(R) = \{pa(D) \setminus \{R \cup de(R)\}\}$. Figure 1 illustrates how beliefs are computed on a 3-by-3 grid.

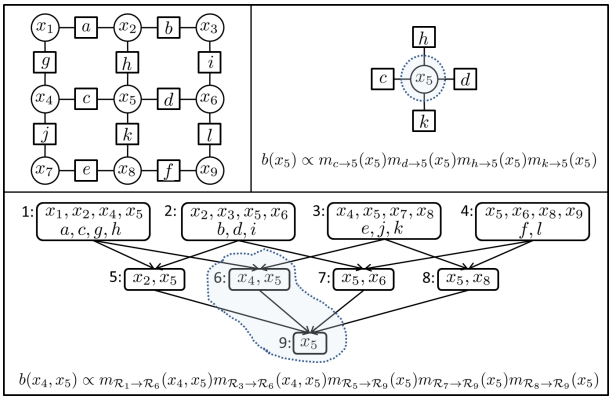

Figure 1: Illustration of message passing on a factor graph (top right) and region graph (bottom) for the 3-by-3 grid in the top-left. In BP, the belief $b_5(x_5)$ is a product of messages into variable node 5. The belief at region 6, $b_{R_6}(x_4, x_5)$, is a product of messages into region 6 and its descendants (i.e. region 9).

The RG framework was extended in [31] to structured message passing algorithms.

DEFINITION **3.** *A Structured Region Graph (SRG) is a region graph in which each region R is associated with a set of cliques $\mathcal{C}(R)$. Every variable in $\mathbf{x}_R$ must appear in some clique or factor. The set of factors and cliques associated with a region define a structure $\mathcal{G}(R)$, which is an undirected graph with vertices for each variable in $\mathbf{x}_R$ and edges connecting any pair of variables appearing in the same factor or clique.*

In the rest of the paper, we restrict our attention to Loop-SRGs, which are a particular type of SRG.

DEFINITION **4.** *A Loop-SRG is a 3-level SRG consisting of loop outer regions and edge and node inner regions, where a loop outer region has a structure $\mathcal{G}(R)$ that forms an (elementary) cycle. Loop outer regions are connected to the set of edge inner regions comprising the loop and edge inner regions are connected to the two node regions comprising the edge.*

A Loop-SRG on the grid in Figure 1 can be formed by taking the faces of the grid as the loop regions, the edges of the grid as edge regions and all vertices as node regions. Importantly, Loop-SRGs are not limited to planar graphs. In fact, a Loop-SRG can be constructed on any graph structure containing cycles.

3 Properties of SRGs

The balancedness and connectedness conditions can be satisfied by many different SRGs for some distribution $p(\mathbf{x})$. However, some SRGs will give better quality approximations than others. Two properties of SRGs that are useful in identifying "good" SRGs were identified in [34]. The first property is that $\sum_R \kappa_R = 1$. This property ensures that the region-based entropy is correct if the variables in $p(\mathbf{x})$ are perfectly correlated. This property will be referred to as *counting number unity*. The second property is *maxent-normality*, which requires the region-based entropy of a connected SRG to achieve its maximum when the region beliefs $b_R(\mathbf{x}_R)$ are uniform. The maxent-normality property was strengthened in [31] to require that message passing with uniform factors have a *unique* fixed point at which $b_R(\mathbf{x}_R)$ are uniform. This stronger property is referred to as *non-singularity*. An SRG that does not satisfy this condition is *singular*.

In [31] it was shown that an acyclic SRG is non-singular. Proving this required a set of reduction operators that modify an SRG's structure while preserving the fixed points of the region-based free energy. The reduction operators will be used in this paper, but are not presented for space reasons (see [31, 30]).

The following qualities of Loop-SRGs come from [31]:

THEOREM **1.** *A Loop-SRG has $\sum_R \kappa_R = |L| - |E| + |V|$, where $|L|$ is the number of loop regions, $|E|$ the number of edge regions and $|V|$ the number of node regions.*

THEOREM **2.** *A Loop-SRG is singular if $\sum_R \kappa_R > 1$.*

THEOREM **3.** *A Loop-SRG is singular iff there is a subset of loop regions and constituent edge regions such that all of the edge regions have 2 or more parents.*

These theorems are illustrated on the grid in Figure 2. In this Loop-SRG, every edge region has exactly 2 loop regions as parents and is thus singular by Theorem 3. There are also $|L| = 3$ loop regions, $|E| = 7$ edge regions and $|V| = 6$ node regions, so that $\sum_R \kappa_R = 2$. Thus, the Loop-SRG is also singular by Theorem 2.

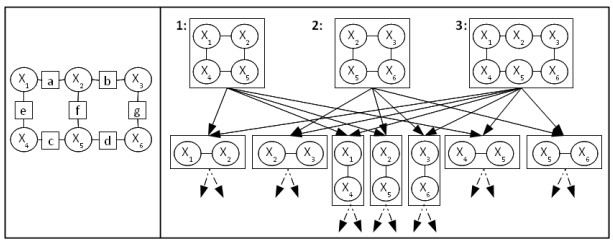

Figure 2: A Loop-SRG (right) for the 2-by-3 grid (left). There are 3 loop outer regions and 7 edge inner regions. The node regions have been dropped for clarity.

Theorems 2 and 3 describe conditions that are undesirable in Loop-SRGs, but offer no guidance on how to identify

"good" Loop-SRGs. The following section establishes a connection between the set of loop regions in a Loop-SRG and cycle bases of a graph that will prove useful in constructing well-behaved Loop-SRGs.

4 Loop Regions and Cycle Bases

In [31] it was noted that counting number unity in a Loop-SRG requires $|L| = |E| - |V| + 1$ loops. This number of loops is exactly the dimension of the cycle space of the undirected graph G describing the MN $p(\mathbf{x})$. The connection between loop regions and cycle bases is formalized in this section. We begin with some background on cycle bases taken from [13].

Let $G = (V, E)$ be a 2-connected graph. A simple cycle C in G is a connected Eulerian subgraph in which every vertex has degree 2. The cycle space $\mathfrak{C}(G)$ of a graph G consists of all simple and non-simple cycles of G including the empty cycle $\emptyset$. The dimension of a cycle space for a graph with 1 connected component is $\mu \equiv \mu(G) = |E| - |V| + 1$.

DEFINITION **5.** *A Cycle Basis of $\mathfrak{C}(G)$ is a set of simple cycles $\mathcal{B} = \{C_1, ..., C_\mu\}$ such that for every cycle C of G, there exists a unique subset $\mathcal{B}_C \subseteq \mathcal{B}$ such that the set of edges appearing an odd number of times in $\mathcal{B}_C$ comprise the cycle C.*

DEFINITION **6.** *A cycle basis $\mathcal{B}$ is a Fundamental Cycle Basis (FCB) if there exists a permutation π of the cycles in $\mathcal{B}$ such that $C_{\pi(i)} \setminus \{C_{\pi(1)} \cup \cdots \cup C_{\pi(i-1)}\} \neq \emptyset$ for $i = 2...\mu$. In other words, the cycles can be ordered so that cycle $C_{\pi(i)}$ has some edge that does not appear in any cycle preceding it in the ordering.*

Consider mapping each loop outer region R to a cycle C in the basis $\mathcal{B}$ of the undirected graph of $p(\mathbf{x})$.[1] Using this mapping, we can claim the following.

THEOREM **4.** *A Loop-SRG is Non-Singular and satisfies Counting Number Unity if its loop outer regions are a Fundamental Cycle Basis (FCB) of G.*

The proof[2] uses reduction operators to show that a loop outer region with a unique edge (i.e. an edge not shared with any other loop region) can be *reduced* to the set of edges comprising that loop. Since the set of loops form a FCB, we are guaranteed to find a loop region with a unique edge if we reduce loops along π - i.e. beginning with the loop corresponding to $C_{\pi(\mu)}$ and ending at loop $C_{\pi(1)}$.

This result implies that the loop regions in an SRG should form a FCB. This greatly reduces the set of loops considered when constructing a Loop-SRG. However, a graph may have many fundamental bases, so one may ask if Loop-SRGs formed from certain FCBs are better than others. The next section defines a class of Loop-SRG with loop regions corresponding to a specific type of FCB.

[1] More specifically, the structure $\mathcal{G}(R)$ of each outer region R is chosen to be a unique cycle $C \in \mathcal{B}$

[2] Formal proofs of all theorems in this paper are provided as supplementary material.

5 Tree Robust Cycle Bases

Non-singularity and counting number unity ensure that GBP behaves sensibly in two opposite and extreme situations. Non-singularity requires GBP to be exact in the presence of uniform factors, while counting number unity ensures that GBP is exact in the presence of perfectly correlated variables.

Tree-Robustness is a condition which ensures that GBP behaves sensibly in an orthogonal way. The idea of *Tree-Robustness* is as follows. Imagine removing some set of factors from $p(\mathbf{x})$ to produce a modified MN $p'(\mathbf{x})$ that is acyclic. It would be nice if GBP run on the original Loop-SRG of $p(\mathbf{x})$ but retaining only the factors of $p'(\mathbf{x})$, were equivalent to BP run directly on the Bethe RG for $p'(\mathbf{x})$ (since BP will be exact in that case). A Tree Robust SRG is a Loop-SRG that is exact w.r.t. all acyclic MNs produced by retaining some of the factors in $p(\mathbf{x})$.

More formally, let T be some spanning tree of the undirected graph G describing $p(\mathbf{x})$ and let $\bar{T}$ denote the off-tree edges. A SRG is Tree Exact w.r.t. to T if by removing only factors on edges $\bar{T}$, the SRG can be *reduced* so that inference on T is exact. In other words, a sequence of reduction operations can be applied to the SRG so that it can be reduced to a Bethe RG with edge regions for each edge in T and node regions for each variable. Since T is acyclic, running GBP on this resulting RG will be exact. Finally, we say that a SRG is Tree Robust (TR) if it is Tree Exact w.r.t. all spanning trees of G.

The previous section established that a Loop-SRG is non-singular if its loops form a FCB. In this section, we first define a TR cycle basis and then show that a Loop-SRG is TR if its loops form a TR cycle basis.

DEFINITION **7.** *Let T be some spanning tree of G. A cycle basis $\mathcal{B}$ is Tree Exact w.r.t. T if there exists an ordering π of the cycles in $\mathcal{B}$ such that $\{C_{\pi(i)} \setminus \{C_{\pi(1)} \cup \cdots \cup C_{\pi(i-1)}\}\} \setminus T \neq \emptyset$ for $i = 2...\mu$. In other words, the cycles can be ordered so that cycle $C_{\pi(i)}$ has some edge that: 1) does not appear in any cycle preceding it in the ordering; and 2) does not appear in the spanning tree T.*

DEFINITION **8.** *A cycle basis $\mathcal{B}$ is Tree Robust (TR) if it is Tree Exact w.r.t. all spanning trees of G.*

By mapping each loop outer region to a cycle in basis $\mathcal{B}$ it can be shown that[3]:

[3] See supplementary material for formal proof.

THEOREM **5.** *A Loop-SRG is Tree Robust if its loop outer regions are a Tree Robust cycle basis of G.*

In the remainder of this section, we introduce two theorems that characterize TR cycle bases. These results prove useful in showing that, for example, the faces of a planar graph constitute a TR cycle basis. The ensuing theorems require the following definition.

DEFINITION **9.** *The Unique Edge Graph of a set of cycles $\mathcal{C} = \{C_1, ..., C_k\}$ is a graph comprised of the set of edges that are in exactly one cycle in $\mathcal{C}$. We will use $I(\mathcal{C})$ to denote the unique edge graph for cycle set $\mathcal{C}$. $I(\mathcal{C})$ is* cyclic *if it contains at least one cycle.*

Using this definition we can now state the following equivalent characterization of TR cycle bases.

THEOREM **6.** *Let $\mathfrak{B}^{|k|}$ denote all size k subsets of cycles in $\mathcal{B}$. A FCB $\mathcal{B}$ is Tree Robust iff $I(\mathcal{B}_k)$ is cyclic and not empty for all $\mathcal{B}_k \in \mathfrak{B}^{|k|}$ for $1 \leq k \leq \mu$. In other words, the unique edge graph must be cyclic for all pairs of cycles, and all triples of cycles,..., and all of the μ cycles.*

COROLLARY **1.** *An FCB is TR iff $\mathcal{B}_k$ is TR for all $\mathcal{B}_k \in \mathfrak{B}^{|k|}$ for $1 \leq k \leq \mu$.*

We sketch the main idea of the proof here. Sufficiency follows because whatever ordering π we choose to remove the cycles in, there is never a tree T that can block all of the edges of the unique edge graph under consideration (since it is always cyclic). Necessity follows because if there were a subset of cycles for which the exposed edge graph is acyclic then there exists no ordering π that can avoid that subset (or a larger subset with an acyclic unique edge graph). Hence, by choosing the tree T to block all edges of the acyclic unique edge graph under consideration we prove that the bases is not tree robust.

6 Planar and Complete Graphs

Using the theorems from the previous section, we now identify TR cycle bases of planar and complete graphs. In the case of planar graphs, a TR basis can be constructed from the cycles forming the faces of the planar graph. This supports the observation of previous authors that GBP run on the faces of planar graphs gives accurate results.

THEOREM **7.** *Consider a planar graph G. The cycle basis $\mathcal{B}$ comprised of the faces of G is TR.*

Proof. We use theorem 6. Consider the graph formed by any subset of k faces of the planar graph. Consider any of its connected components. The path that traces the circumference of that component is a loop and also consists of unique edges. □

In the case of complete graphs, a TR basis can be constructed by choosing some vertex as a root, creating a spanning tree with edges emanating from that root and constructing loops of length 3 using each edge not in the spanning tree. This is exactly the 'star' construction of [31], which was shown empirically to be superior to other Loop-SRGs on complete graphs.

THEOREM **8.** *Consider a complete graph G on n vertices (i.e. K_n). Construct a cycle basis $\mathcal{B}$ as follows. Choose some vertex v as the root. Create a 'star' spanning tree rooted at v (i.e. with all edges v-u). Now construct cycles of the form v-i-j from each off-tree edge i-j. The basis $\mathcal{B}$ constructed in this way is TR.*

Proof. We use again theorem 6. Consider the graph constructed from any subset of k triangles. The edges not on the spanning tree (i.e. not connecting to the root) are all unique and will either form a loop (in which case we are done) or a tree. In case of a tree, consider a path connecting two leaf nodes, which are both also connected to the root, thus forming a loop. Because the two edges connecting to the root are also unique (since they correspond to leaf nodes) we have proven the existence of a cycle in the unique edge graph. □

This result can be extended to partially complete graphs where there exists some vertex v that is connected to all the other vertices in G.

7 TR SRGs in General Graphs

The previous section identified TR cycle bases for two specific classes of graphs. The prescription for how to construct TR SRGs for MNs on these types of graphs is clear: simply find a TR basis $\mathcal{B}$ of the underlying graph and make the cycles in $\mathcal{B}$ the loop regions. This prescription can be generalized in some cases to graphs containing many TR components. More formally,

THEOREM **9.** *Consider a graph G comprised of components (subgraphs) $H_1, ..., H_k$. Let the components $H_1, ..., H_k$ be mutually singly connected if for any two components H_i and H_j there exist vertices $v_i \in H_i$ and $v_j \in H_j$ that are singly connected (i.e. connected through a single path). Let $\mathcal{B}_{H_1}, ..., \mathcal{B}_{H_k}$ denote the TR cycle bases for each component. Then a TR cycle basis of G is $\mathcal{B}_G = \{\mathcal{B}_{H_1} \cup \cdots \cup \mathcal{B}_{H_k}\}$.*

Proof. First note that by singly connecting the components $H_1, ..., H_k$ we do not create any new cycles. Thus $\mathcal{B}_G$ is a cycle basis of G. Every subset of cycles of $\mathcal{B}_G$ is the union of some subset of cycles from the component cycle bases $\{\mathcal{B}_{H_i}\}$. Moreover, for any of these subsets the unique edge graph must be cyclic (by theorem 6). Since the component cycle bases do not overlap it thus follows that the unique edge graph for every subset of cycles of $\mathcal{B}_G$ must also be cyclic. □

For MNs defined over more general graphs, the picture of how to construct a TR SRG is less clear. Since verifying

that a basis is TR requires inspecting all subsets of cycles in that basis, searching for a TR basis in a general graph seems difficult. Moreover, not every graph will admit a TR basis. In this section we describe a method for constructing Loop-SRGs that are partially TR. In other words, we sacrifice finding a TR basis of G to find a basis that is Tree Exact for many (just not all) spanning trees of G.

The method for finding a partially TR basis works as follows. We first find the largest complete or planar subgraph H of G and construct a TR basis $\mathcal{B}(\mathcal{H})$ for H as described in the previous section. Since the TR core H is a subgraph of G, the $\mu(H)$ cycles in $\mathcal{B}(\mathcal{H})$ will not form a complete basis of G. We choose the remaining $\mu(G) - \mu(H)$ cycles so that the basis of G is fundamental. We do so by finding a sequence of *ears* (simple paths or cycles) in G, such that each new *ear* has some edge not occurring in some previous ear. This process is described in Algorithm *Construct Basis* and is illustrated on a 2×3 grid in Figure 3.

Algorithm: Construct Basis

Input: MN $p(\mathbf{x})$ described by undirected graph G
Output: Cycle Basis $\mathcal{B}$

Find TR subgraph H of G with TR basis $\mathcal{B}(\mathcal{H})$
if G contains no TR subgraph (i.e. $H = \emptyset$) **then**
  Let H be some simple cycle in G
end if
Add cycles $\mathcal{B}(\mathcal{H})$ to $\mathcal{B}$
Mark all edges in H as *used*
Mark all vertices in H as *visited*
while $\exists$ *unused* edge $e = (s, t)$ from a *visited* vertex s **do**
  If t is *visited*, then set $p_1 = e$
  Else, find an ear p_1 from s through edge $e = (s, t)$ to some *visited* vertex u.
  Find shortest path p_2 from s to u on *used* edges
  Add cycle C consisting of $p_1 \cup p_2$ to the bases $\mathcal{B}$
  Mark all edges (vertices) on C as *used* (*visited*)
end while

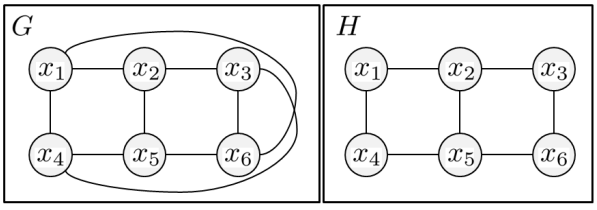

Figure 3: A graph G (left) and its TR core H (right). Add the faces $(1, 2, 5, 4)$ and $(2, 3, 6, 5)$ of H to $\mathcal{B}$. Mark all edges (vertices) in H as used (visited). Edge $(1, 6)$ is an ear (unused edge). The path $6, 3, 2, 1$ connects the start and end vertices of this ear along used edges, so cycle $(1, 6, 3, 2)$ is added to $\mathcal{B}$. Similarly, cycle $(3, 4, 5, 6)$ might be added for ear $(3, 4)$, giving us the partially TR basis $\mathcal{B} = \{(1, 2, 5, 4), (2, 3, 6, 5), (1, 6, 3, 2), (3, 4, 5, 6)\}$.

8 Experiments

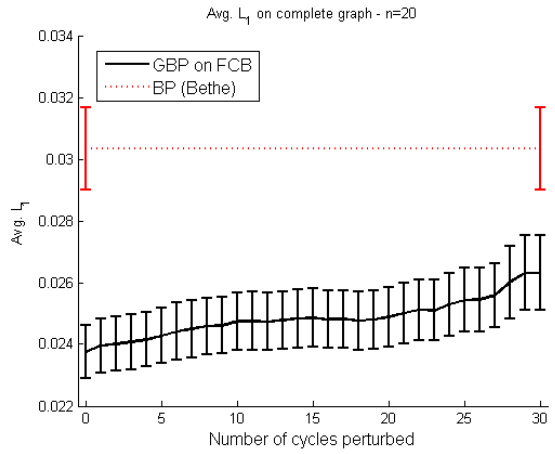
We conducted a series of experiments to validate the recommendations for constructing Loop-SRGs made in this paper. In each of the experiments that follow, we generated a set of M random MNs with binary variables. Each MN instance has unary potentials of the form $f_i(x_i) = [\exp(h_i); \exp(-h_i)]$ and pairwise potentials of the form $f_{ij}(x_i, x_j) = [\exp(w_{ij}) \exp(-w_{ij}); \exp(-w_{ij}) \exp(w_{ij})]$. The values of h_i and w_{ij} were drawn from Normal distributions $\mathcal{N}(0, \sigma^2_{h_i})$ and $\mathcal{N}(0, \sigma^2_{w_{ij}})$, respectively. Two different error measures are reported. $Error_Z = |\log Z - \log \tilde{Z}|$ is the absolute error in the exact (Z) and approximate ($\tilde{Z}$) values of the log partition function. $Error_{L_1}$ measures the error in the marginal probabilities and is computed as $Error_{L_1} = \frac{1}{n} \sum_{i=1}^{n} |b(x_i) - p(x_i)|$ where n is number of variables in a MN instance. Averages of $Error_Z$ and $Error_{L_1}$ were computed across the M MN instances. Error bars indicate standard error. To aid convergence, GBP was run with a damping factor of 0.5 for at most 1000 iterations.

8.1 TR Bases vs non-TR Bases

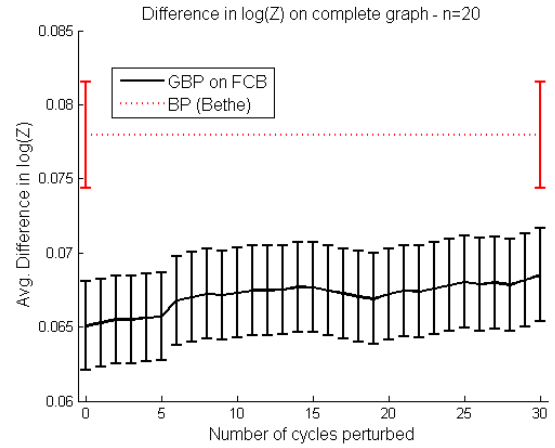
We first ran a set of experiments to show that tree robustness is a desirable property. To test this hypothesis, we generated 31 different Loop-SRGs for a MN defined on a complete graph with 20 binary variables (i.e. on K_{20}). We first constructed a TR basis $\mathcal{B}$ comprised of all cycles of length 3 passing through vertex 1 (e.g. using the *star* construction from Section 6 with vertex 1 as root). From this TR basis, a sequence of 30 fundamental bases were created as follows: for $i = 1...30$, we choose a cycle C_i of the form $C_i = (1, u, v)$ from $\mathcal{B}$ and modify it by swapping vertex 1 with some vertex w ($w \neq u \neq v \neq 1$) so that $C_i = (w, u, v)$. At every iteration we choose cycles that have not been modified and reject modifications that make the basis non-fundamental. In this way, as i increases the basis is made less TR but always remains fundamental.

Figure 4 shows $Error_{L_1}$ and $Error_Z$ as the Loop-SRG is made less TR. In this figure, we generated $M = 500$ random MN instances with $\sigma_{h_i} = 1$ and $\sigma_{w_{ij}} = 1/\sqrt{20 - 1}$. Note that by keeping the cycle length at 3 and ensuring that each basis is fundamental, the increase in error can only be explained by the change in the TR core of the basis. Since error increases as the basis is made less TR, these results support the hypothesis that tree robustness is a desirable property. It was also observed that GBP took an increasing number of iterations to converge as the basis was made less TR.

We also ran a set of experiments to characterize the convergence properties of TR SRGs on Ising grid models. Though not reported, these experiments confirm the finding in [34] that running GBP on an RG where the outer regions are



(a) $Error_{L_1}$ on increasingly non-TR Loop SRGs.



(b) $Error_Z$ on increasingly non-TR Loop SRGs.

Figure 4: Performance of GBP run on a sequence of increasingly non-TR Loop-SRGs.

taken as the faces of the grid model is more accurate than ordinary BP. We also found the TR SRG construction to be more accurate than GBP run on Loop-SRGs constructed from fundamental, but non-TR cycle bases on Ising grids.

8.2 Partially TR SRGs

The previous experiment considered a class of MNs for which a TR basis is known. This section considers more general MNs.

The algorithm in Section 7 seeks an initial TR subgraph H of the graph G. The previous experiments showed that GBP yields accurate approximations when $H = G$. When a graph contains no TR core (i.e. $H = \emptyset$) the algorithm *Construct Basis* method simply finds a fundamental basis of G. We wish to study the performance of GBP between these two extremes - i.e. on partially TR SRGs. We conducted experiments on two types of MNs, where the size of H (relative to G) can be controlled.

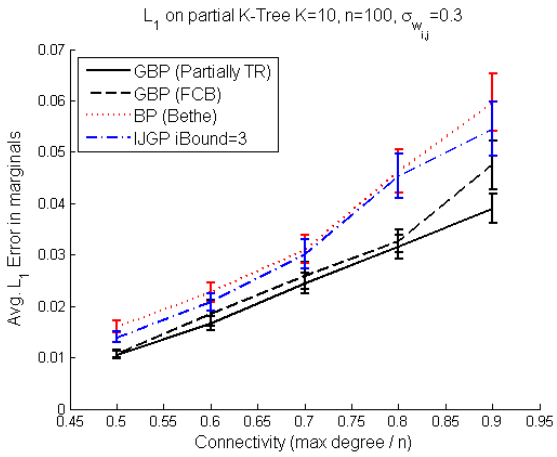
The following experiments include a comparison to the Iterative Join Graph Propagation (IJGP) method [3]. This method forms a join graph (i.e. a 1-connected and 1-balanced RG) using a heuristic, "mini-bucket" clustering strategy. In IJGP, the number of variables appearing in an outer region is restricted to be less than or equal to an *iBound* parameter. The *iBound* controls the computational complexity of message computations in IJGP because in the join graph construction each outer region forms a clique over all variables in that region. Importantly, since Loop-SRGs assume a loop structure in the outer regions, message computations on Loop-SRGs are equivalent to IJGP with $iBound = 3$.

8.2.1 Partial K-Trees

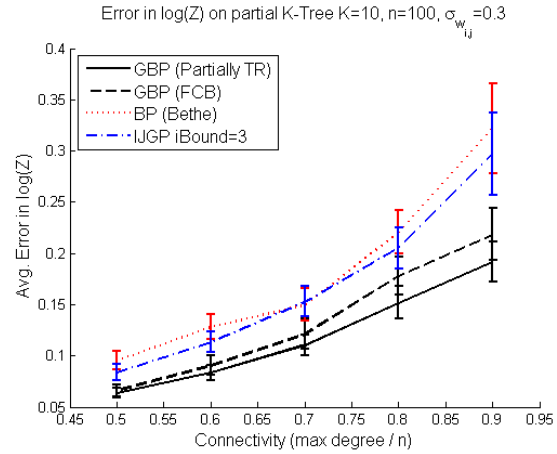
In these experiments we construct a set of partial K-tree instances via the following procedure[4]. We first build a random K-tree on n vertices using the process described in [6]. The number of neighbors (degree) of the vertices in K-trees constructed by this procedure follow a power law. This means there will exist a few vertices that are adjacent to most of the vertices in G. As a result, the TR core will comprise a large portion of G. To reduce the size of the TR core, we iteratively remove edges from the K-tree as follows: choose a vertex v with probability proportional to the current degree of that vertex. Modify G by removing an edge from v to one of its neighbors, so long as removing that edge does not disconnect G. This process is repeated until the ratio of the maximum degree in G to n falls below some threshold. We refer to this ratio as the connectivity of the graph. A random MN is formed over each partial K-tree structure by assigning random unary and pairwise potentials to the vertices and edges.

Figure 5 shows the performance of GBP as a function of connectivity. In these figures, we generated $M = 100$ random MN instances at each level of connectivity (with $K = 10$, $n = 100$, $\sigma_{h_i} = 1$ and $\sigma_{w_{ij}} = 0.3$). The partially TR SRGs are found by choosing the TR core to be the subgraph H found using the max degree vertex as the root of the *star* construction described in Section 6. Cycles are added to this TR core as described in algorithm *Construct Basis*. The partially TR SRGs are compared to Loop-SRGs formed by finding a fundamental cycle basis (FCB) of each partial K-tree (constructed using algorithm "*Construct Basis*" with $H = \emptyset$). Importantly, these FCBs do not build upon the TR core. Figure 5 shows that the benefit of the partially TR SRG diminishes as connectivity is decreased. This behavior confirms our belief that the benefit of finding a TR core decreases as the TR core comprises a smaller proportion of cycles in the fundamental basis. Even so, it is important to note that choosing a Loop-SRG with outer regions forming a FCB yields more accurate approximations than both IJGP and BP.

[4] K-trees are chordal graphs w/ size K maximal cliques. Partial K-trees are non-chordal graphs w/ size K maximal cliques

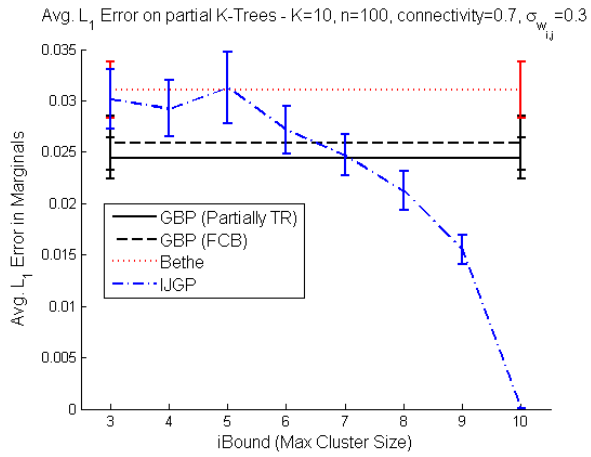


(a) $Error_{L_1}$ as a function of *connectivity*.

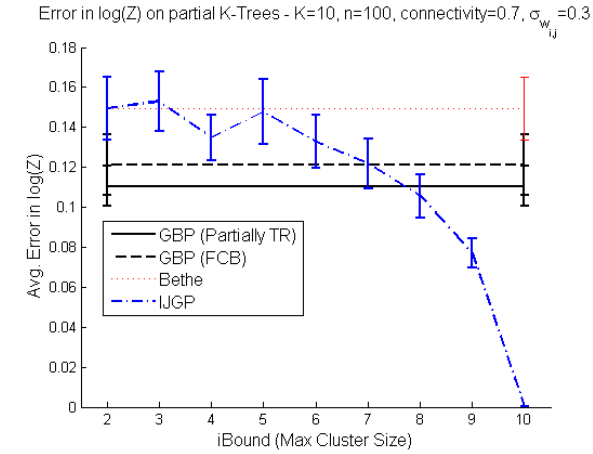


(b) $Error_Z$ as a function of *connectivity*.

Figure 5: Performance of GBP run on the partial TR construction, the FCB construction and IJGP with $iBound = 3$ as a function of *connectivity* (see text for discussion).



(a) $Error_{L_1}$ as a function of $iBound$.



(b) $Error_Z$ as a function of $iBound$.

Figure 6: Performance of the SRG constructions as a function of $iBound$ with fixed *connectivity* of 0.7.

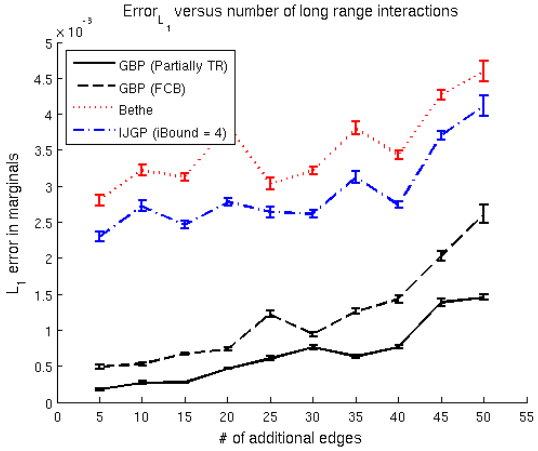
Figure 6 shows the performance of GBP as a function of $iBound$ for a fixed connectivity level. $iBound$ is increased from 2 (which is equivalent to BP) to 10 (which is exact). These plots show that GBP run on the partial TR SRG is roughly equivalent to IJGP with $iBound = 7$, while GBP run on the FCB is equivalent to IJGP with $iBound = 6$. The fact that GBP run on both SRGs performs better than IJGP with $iBound = 6$ is quite remarkable considering that message passing on Loop-SRGs is computationally equivalent to IJGP with $iBound = 3$.

8.2.2 Grids with long range interactions

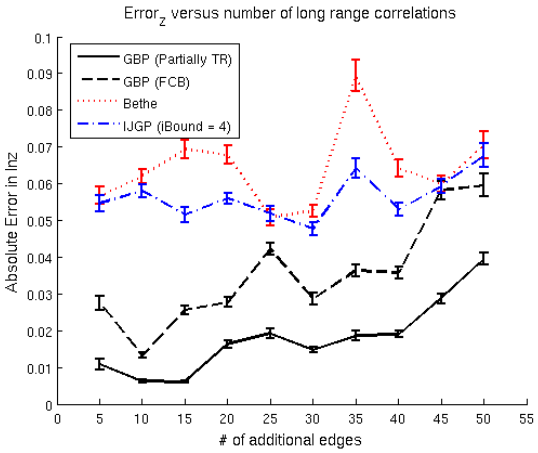
In addition to the partial K-tree instances, we also considered grid instances with an increasing number of long range interactions. The additional interactions were added via the following procedure. We begin with a 10×10 grid. Let G_0 denote this initial graph. Two vertices u and v are randomly chosen from the grid. If edge (u, v) exists in graph G_{i-1}, new vertices u and v are chosen randomly; if edge (u, v) is not in G_{i-1}, then graph G_i is created by adding edge (u, v) to G_{i-1}. This process is repeated until a specified number of edges have been added to G_0.

Figure 7 compares the $Error_{L_1}$ and $Error_Z$ of GBP run on different loop SRG constructions. $M = 25$ instances were generated with 5,10,.., and 50 additional edges. In all 250 of these MN instances the unary and pairwise terms were drawn with $\sigma_{h_i} = 1$ and $\sigma_{w_{ij}} = 0.5$. For the partially TR SRG construction, we take the TR core H to be G_0 and fill out the cycle basis using algorithm *Construct Basis* (as illustrated in Figure 3). As in the partial K-tree experiments, for the FCB construction we choose a fundamental basis that does not build upon the TR core by using algorithm "*Construct Basis*" with $H = \emptyset$. In Figure 7, we see that both the partially TR and FCB construction outperform IJGP with an equivalent $iBound$. Interestingly, when adding 50 additional edges we do not see the $Error_{L_1}$ of the partially TR and the FCB constructions coalesce. This may be explained by the fact that even with 50 additional edges more than 60% of the loops in the SRG are TR (131

cycles in the basis, 81 of which come from the TR core).



(a) $Error_{L_1}$ on grids with long range interactions



(b) $Error_Z$ on grids with long range interactions

Figure 7: Performance of the different SRG constructions as an increasing number of long range interactions are added to a 10×10 grid.

9 Conclusion

This paper provides some new guidance in the construction of region graphs. In particular, we connected the problem of choosing the loop outer regions of a Loop-SRG to that of finding a fundamental cycle basis of the undirected graph describing a MN. We proposed tree robustness as a refinement to the criterion that the loop regions form a fundamental basis and offered a characterization of the class of TR cycle bases. We identified TR cycle bases for planar and complete graphs. This characterization helps explain the success of GBP on the "star" construction of [31] for complete graphs and the "all faces" construction on planar graphs. We also proposed a practical Loop-SRG construction that first identifies a TR core and then expands to a full cycle basis using an ear construction which makes sure the final basis is still fundamental (and partially TR).

The experiments in this paper confirm that GBP can yield very accurate approximations when the loop regions of a Loop-SRG form a fundamental basis and that these approximations can be further improved by choosing a fundamental basis that is at least partially tree robust. The criteria proposed in this paper also lead to approximations that are comparable to IJGP run with a much higher $iBound$ (and therefore much higher space and computational complexity).

These findings open the door for much future work. Rather than simply finding a TR subgraph, as the method in Section 7 does, it would be preferable to have an algorithm that searches for TR bases in a graph or at the very least identifies when a graph does not admit a TR basis. The recommendations in this paper are also purely structural in nature. A natural extension would be to incorporate interaction strengths in the search for suitable loop regions.

The current paper considered pairwise interactions only. A natural extension is to consider factor graphs or more generally region graphs. We argue that we should be looking for a maximal collection of subsets $\{C_i\}$ of outer regions (or factors) that have the property that there exists an ordering π for which $C_{\pi(i)} \setminus \{C_{\pi(1)} \cup \cdots \cup C_{\pi(i-1)}\} \neq \emptyset$. In other words, the subsets can be ordered so that subset $C_{\pi(i)}$ has some element that does not appear in any subset preceding it in the ordering. This definition is identical to the one for a fundamental cycle basis (see definition 6) and will guarantee through the reduction rules of [31] that the region graph (factor graph) can be decomposed into independent variable nodes, establishing non-singularity. A next step would then be to define tree-robustness as a collection of region-subsets that can still be decomposed along some ordering if we do not allow certain elements that correspond to the regions of any embedded junction tree to become unique. Again this is very similar to definitions 7 and 8 for TR cycle bases. Whether these generalizations can be captured with mathematical structures as elegant as the theory of cycle spaces (or more generally matroids) remains to be seen and will be left for future research.

Abstract

The recent proliferation of richly structured probabilistic models raises the question of how to automatically determine an appropriate model for a dataset. We investigate this question for a space of matrix decomposition models which can express a variety of widely used models from unsupervised learning. To enable model selection, we organize these models into a context-free grammar which generates a wide variety of structures through the compositional application of a few simple rules. We use our grammar to generically and efficiently infer latent components and estimate predictive likelihood for nearly 2500 structures using a small toolbox of reusable algorithms. Using a greedy search over our grammar, we automatically choose the decomposition structure from raw data by evaluating only a small fraction of all models. The proposed method typically finds the correct structure for synthetic data and backs off gracefully to simpler models under heavy noise. It learns sensible structures for datasets as diverse as image patches, motion capture, 20 Questions, and U.S. Senate votes, all using exactly the same code.

1 Introduction

There has been much interest recently in learning hierarchical models, which extend simpler models by introducing additional dependencies between the parameters. While there have been many advances in modeling particular kinds of structure, as the desired structure becomes higher level and more abstract, the correct model becomes less obvious a priori. We aim to determine an appropriate model structure automatically from the data, in order to make hierarchical modeling usable by non-experts and to explore a wider variety of structures than would be possible by manual engineering.

There has been much work on structure learning in particular model classes, such as undirected (Lee et al., 2006) and directed (Teyssier and Koller, 2005) graphical models. Most such work focuses on determining the particular factorization and/or conditional independence structure within a fixed model class. Our concern, however, is with identifying the overall form of the model. For instance, suppose we are interested in modeling the voting patterns of U.S. Senators. We can imagine several plausible modeling assumptions for this domain: e.g., that political views can be summarized by a small number of dimensions, that Senators cluster into voting blocks, or that votes can be described in terms of binary attributes. Choosing the correct assumptions is crucial for uncovering meaningful structure. Right now, the choice of modeling assumptions is heavily dependent on the intuition of the human researcher; we are interested in determining appropriate modeling assumptions automatically.

Many common modeling assumptions, or combinations thereof, can be expressed by a class of probabilistic models called matrix decompositions. In a matrix decomposition model, component matrices are first sampled independently from a small set of priors, and then combined using simple algebraic operations. This expressive model class can represent a variety of widely used models, including clustering, co-clustering (Kemp et al., 2006), binary latent factors (Griffiths and Ghahramani, 2005), and sparse coding (Olshausen and Field, 1996). Nevertheless, the space of models is *compositional*: each model is described recursively in terms of simpler matrix decomposition models and the operations used to combine them. We propose to exploit this compositional structure to efficiently and generically evaluate and perform inference in matrix decomposition models, and to automatically search through the space of structures to find one appropriate for a dataset.

A common heuristic researchers use for designing hierarchical models is to fit an existing model, look for additional dependencies in the learned representation, and extend the model to capture those dependencies. We formalize this process in terms of a context-free grammar. In particular,

we present a notation for describing matrix decomposition models as algebraic expressions, and organize the space of models into a context-free grammar which generates such expressions. The starting symbol corresponds to a structureless model where the entries of the input matrix are modeled as *i.i.d.* Gaussians. Each production rule corresponds to a simple unsupervised learning model, such as clustering or dimensionality reduction. These production rules lie at the heart of our approach: we fit and evaluate a wide variety of models using a small toolbox of algorithms corresponding to the production rules, and the production rules guide our search through the space of structures.

The main contributions of this paper are threefold. First, we present a unifying framework for matrix decompositions based on a context-free grammar which generates a wide variety of structures through the compositional application of a few simple production rules. Second, we exploit our grammar to infer the latent components and estimate predictive likelihood in all of these structures generically and efficiently using a small toolbox of reusable algorithms corresponding to different component matrix priors and production rules. Finally, by performing greedy search over our grammar using predictive likelihood as the criterion, we can (in practice) typically choose the correct structure from the data while evaluating only a small fraction of all possible structures.

Section 3 defines our matrix decomposition formalism, and Sections 4 and 5 present our generic algorithms for inferring component matrices and evaluating individual structures, respectively. Section 6 describes how we search our space of structures. Finally, in Section 7, we evaluate the structure learning procedure on synthetic data and on real-world datasets as diverse as image patches, motion capture, 20 Questions, and Senate voting records, all using *exactly the same code*. Our procedure learns correct and/or plausible model structures for a wide variety of synthetic and real datasets, and gracefully falls back to simpler structures in high-noise conditions.

2 Related work

There is a long history of attempts to infer model structures automatically. The field of algorithmic information theory (Li and Vitanyi, 1997) studies how to represent data in terms of a short program/input pair which could have generated it. One prominent example, Solomonoff induction, can learn any computable generative model, but is itself uncomputable. Minimum message length (Wallace, 2005), minimum description length (Barron et al., 1998), and Bayesian model comparison (MacKay, 1992) are frameworks which can, in principle, be used to compare very different generative models. In practice, they have primarily been used for controlling complexity within a given model class. By contrast, our aim is to choose from a very large space of model classes by exploiting shared structure between the models.

Other work has focused on searching within more restricted spaces of models, such as undirected (Lee et al., 2006) and directed (Teyssier and Koller, 2005) graphical models, and graph embeddings (Kemp and Tenenbaum, 2008). Kemp and Tenenbaum (2008) model human "domain structure" learning as selecting between a fixed set of graph structures. Similarly to this paper, their structures are generated from a few simple rules; however, whereas their set of structures is small enough to exhaustively evaluate each one, we search over a much larger set of structures in a way that explicitly exploits the recursive nature of the space. Furthermore, our space of matrix decomposition structures is especially broad, including many bread-and-butter models from unsupervised learning, as well as the building blocks of many hierarchical Bayesian models.

We note that several other researchers have proposed unifying frameworks for unsupervised learning which overlap substantially with our own. Roweis and Ghahramani (1999)'s "generative model for generative models" presents a lattice showing relationships between different models. Srebro (2004) and Singh and Gordon (2008) each interpreted a variety of unsupervised learning algorithms as factorizing an input matrix into a product of two factors. Exponential family PCA (Collins et al., 2002; Mohamed et al., 2008) generalizes low-rank factorizations to other observation models in the exponential family. Our work differs from these in that our matrix decomposition formalism is specifically designed to support efficient generic inference and structure learning. We defer discussion of particular matrix decomposition models to Section 3.1, after we have introduced our formalism.

Our work has several parallels in the field of equation discovery. Langley et al. (1984) built a knowledge discovery system called BACON which reproduced classical scientific discoveries. BACON followed a greedy search procedure similar to our own: it repeatedly fit statistical models and looked for additional structure in the learned parameters. Our work is similar in spirit, but uses matrices rather than scalars as the building blocks, allowing us to capture rich structure in high-dimensional spaces. Todorovski and Dzeroski (1997) used a context-free grammar to define spaces of candidate equations. Our approach differs in that we explicitly use the grammar to structure posterior inference and search over model structures.

3 A grammar for matrix decompositions

We first present a notation for describing matrix decomposition models as algebraic expressions, such as $MG + G$. Each letter corresponds to a particular distribution over matrices. When the dimensions of all the component matrices are specified, the algebraic expression defines a generative

model: first sample all of the component matrices independently from their corresponding priors, and then evaluate the expression. The component priors are as follows:

1. **Gaussian (G).** Entries are independent Gaussians:

$$u_{ij} \sim \text{Gaussian}(0, \lambda_i^{-1}\lambda_j^{-1}).$$

   This is our most generic component prior, and gives a way of deferring or ignoring structure.[1]

2. **Multinomial (M).** Rows are independent multinomials, with one 1 and the rest 0's:

$$\pi \sim \text{Dirichlet}(\alpha) \qquad u_i \sim \text{Multinomial}(\pi).$$

   This is useful for clustering models, where u_i determines the cluster assignment for the i^{th} row.

3. **Bernoulli (B).** Entries are independent Bernoullis:

$$\pi_j \sim \text{Beta}(a, b) \qquad u_{ij} \sim \text{Bernoulli}(\pi_j).$$

   This is useful for binary latent feature models.

4. **Integration matrix (C).** Entries below the diagonal are deterministically 1:

$$u_{ij} = \mathbf{1}_{i \geq j}.$$

   This is useful for modeling temporal structure, as multiplying by this matrix has the effect of cumulatively summing the rows. (Mnemonic: C for "cumulative.")

We allow expressions consisting of addition, matrix multiplication, matrix transpose, elementwise multiplication ($\circ$), and elementwise exponentiation ($\exp$). Some of the dimensions of the component matrices are determined by the size of the input matrix; the rest (the latent dimensions) are determined automatically using the techniques of Section 4.

We observe that this notation for matrix decompositions is recursive: each sub-expression (such as $GM^T + G$ in the above example) is itself a matrix decomposition model. Furthermore, the semantics is compositional: the value of each expression depends only on the values of its sub-expressions and the operations used to combine them. These observations motivate our decision to define a space of models using a context-free grammar, a formalism which is widely used for representing recursive and compositional structures such as languages.

[1]The precision parameters λ_i and λ_j are drawn from the distribution $\text{Gamma}(a, b)$. If i indexes a data dimension (i.e. rows correspond to rows of the input matrix), the λ_is are tied. This allows the variance parameters to generalize to additional rows. If i indexes a latent dimension, the λ_is are all independent draws. This allows the variances of latent dimensions to be estimated. The same holds for the λ_js.

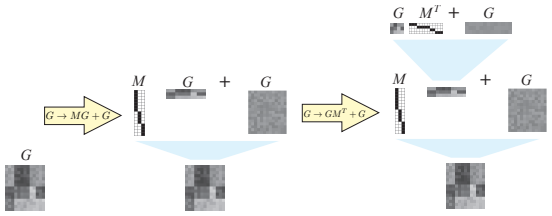

Figure 1: A synthetic example showing how an input matrix with block structure can be co-clustered by fitting the matrix decomposition structure $M(GM^T + G) + G$. Rows and columns are sorted for visualization purposes.

The starting symbol in our grammar is G, a structureless model where the entries are assumed to be independent Gaussians. Other models (expressions) are generated by repeatedly applying one of the following production rules:

low-rank approximation	$G \to GG + G$	(1)
clustering	$G \to MG + G \mid GM^T + G$	(2)
	$M \to MG + G$	(3)
linear dynamics	$G \to CG + G \mid GC^T + G$	(4)
sparsity	$G \to \exp(G) \circ G$	(5)
binary factors	$G \to BG + G \mid GB^T + G$	(6)
	$B \to BG + G$	(7)
	$M \to B$	(8)

For instance, any occurrence of G in a model may be replaced by $GG + G$ or $MG + G$. Repeated application of these production rules allows us to build hierarchical models by capturing additional dependencies between variables which were previously modeled as independent.

3.1 Examples

We now turn to several examples in which our simple components and production rules give rise to a rich variety of models from unsupervised learning. While the model space is symmetric with respect to rows and columns, for purposes of exposition, we will adopt the convention that the rows of the input matrix correspond to data points and columns corresponds to observed attributes.

We always begin with the model G, which assumes the entries of the matrix are *i.i.d.* Gaussian. Applying productions in our grammar allows us to capture additional structure. For instance, starting with Rule 2(a) gives the model $MG + G$, which clusters the rows (data points). In more detail, the M represents the cluster assignments, the first G represents the cluster centers, and the second G represents within-cluster variation. These three matrices are sampled independently, the assignment matrix is multiplied by the center matrix, and the within-cluster variation is added to the result. By applying Rule 2(b), the clustering model can be extended to co-clustering (Kemp et al., 2006), where the columns (attributes) form clusters as well. In our framework, this can be represented as $M(GM^T + G) + G$. We

need not stop here: for instance, there may be coherent covariation even within individual clusters. One can capture this variation by applying Rule 3 to get the Bayesian Clustered Tensor Factorization (BCTF) (Sutskever et al., 2009) model $(MG+G)(GM^T+G)+G$. This process is shown in cartoon form in Figure 1.

For an example from vision, consider a matrix X, where each row is a small (e.g. 12×12) patch sampled from an image and vectorized. Image patches can be viewed as lying near a low-dimensional subspace spanned by the lowest frequency Fourier coefficients (Bossomaier and Snyder, 1986). This can be captured by the low-rank model $GG+G$. In a landmark paper, Olshausen and Field (1996) found that image patches are better modeled as a linear combination of a small number of components drawn from a larger dictionary. In other words, X is approximated as the product WA, where each row of A is a basis function, and W is a sparse matrix giving the linear reconstruction coefficients for each patch. By fitting this "sparse coding" model, they obtained a dictionary of oriented edges similar to the receptive fields of neurons in the primary visual cortex. If we apply Rule (5), we obtain a Bayesian version of sparse coding, $(\exp(G) \circ G)G + G$, similar to the model proposed by Berkes et al. (2008). Intuitively, the latent Gaussian coefficients are multiplied elementwise by "scale" variables to give a heavy-tailed distribution. Many researchers have designed models to capture the dependencies between these scale variables, and such "Gaussian scale mixture" models represent the state-of-the art for low-level vision tasks such as denoising (Portilla et al., 2003) and texture synthesis (Portilla and Simoncelli, 2000). One such GSM model is that of Karklin and Lewicki (2008), who fit a low-rank model to the scale variables. By applying Rule (1) to the sparse coding structure, we can represent their model in our framework as $(\exp(GG+G)\circ G)G+G$. This model has been successful at capturing higher-level textural properties of a scene and has properties similar to complex cells in the primary visual cortex.

Figure 2 gives several additional examples of matrix decomposition models and highlights the relationships between them. We emphasize that our goal is not to reproduce existing models exactly, but to develop a formalism powerful enough to express a wide variety of statistical assumptions about the latent factors underlying the data.

We note that many of the above models are not typically viewed as matrix decomposition structures. Describing them as such results in a compact notation for defining them and makes clearer the relationships between the different models. The above examples have in common that complex models can be derived by incrementally adding structure to a sequence of simpler models (in a way that parallels the path researchers took to discover them). This observation motivates our proposed procedures for inference and structure learning.

4 Posterior inference of component matrices

Searching over matrix decomposition structures requires a generic and unified approach for posterior sampling of the latent matrices. Unfortunately, for most of the structures we consider, this posterior is complicated and multimodal, and escaping from local modes requires carefully chosen special-purpose sampling operators. Engineering such operators for thousands of different models would be undesirable.

Fortunately, the compositional nature of our model space allows us to focus the engineering effort on the relatively small number of production rules. In particular, observe that in a realization of the generative process, the value of an expression depends only on the values of its subexpressions. This suggests the following initialization procedure: when applying a production rule P to a matrix S, sample from the posterior for P's generative model conditioned on it evaluating (exactly) to S. Many of our production rules correspond to simple machine learning models for which researchers have already expended much time developing efficient inference algorithms:

1. **Low rank.** To apply the rule $G \to GG+G$, we fit the probabilistic matrix factorization (Salakhutdinov and Mnih, 2008) model using block Gibbs sampling over the two factors. While PMF assumes a fixed latent dimension, we choose the dimension automatically by placing a Poisson prior on the dimension and moving between states of differing dimension using reversible jump MCMC (Green, 1995).

2. **Clustering.** To apply the clustering rule to rows: $G \to MG + G$, or to columns: $G \to GM^T + G$, we perform collapsed Gibbs sampling over the cluster assignments in a Dirichlet process mixture model.

3. **Binary factors.** To apply the rule $G \to BG + G$ or $G \to GB^T + G$, we perform accelerated collapsed Gibbs sampling (Doshi-Velez and Ghahramani, 2009) over the binary variables in a linear-Gaussian Indian Buffet Process (Griffiths and Ghahramani, 2005) model, using split-merge proposals (Meeds et al., 2006) to escape local modes.

4. **Markov chains.** The rule $G \to CG + G$ is equivalent to estimating the state of a random walk given noisy observations, which is done using Rauch-Tung-Striebel (RTS) smoothing.

The remaining production rules begin with a random decomposition of S. While some of these algorithms involve fitting Bayesian nonparametric models, once the dimensionality is chosen, the model is converted to a finite model of fixed dimensionality (as defined in section 3). The

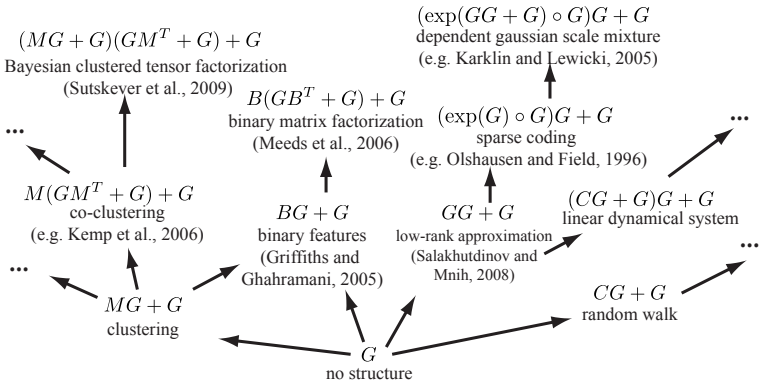

Figure 2: Examples of existing machine learning models which fall under our framework. Arrows represent models reachable using a single production rule. Only a small fraction of the 2496 models reachable within 3 steps are shown, and not all possible arrows are shown.

smart initialization step is followed by generic Gibbs sampling over the entire model. We note that our initialization procedure generalizes "tricks of the trade" whereby complex models are initialized from simpler ones (Kemp et al., 2006; Miller et al., 2009).

In addition to simplifying the engineering, this procedure allows us to reuse computations between different structures. Most of the computation time is in the initialization steps. Each of these steps only needs to be run once on the full matrix, specifically when the first production rule is applied. Subsequent initialization steps are performed on the component matrices, which are considerably smaller. This allows a large number of high level structures to be fit for a fraction of the cost of fitting them from scratch.

5 Scoring candidate structures

Performing model selection requires a criterion for scoring individual structures which is informative yet tractable. To motivate our method, we first discuss two popular choices: marginal likelihood of the input matrix and entrywise mean squared error (MSE). Marginal likelihood, the probability of the data with all the latent variables integrated out, is widely used in Bayesian model selection. Unfortunately, this requires integrating out all of the latent component matrices, whose posterior distribution is highly complex and multimodal. While elegant solutions exist for particular models, estimating the data marginal likelihood generically is still extremely difficult. At the other extreme, one can hold out a subset of the entries of the matrix and compute the mean squared error for predicting these entries. MSE is easier to implement, but we found that it was unable to distinguish many of the the more complex structures in our grammar.

As a compromise between these two approaches, we chose to evaluate predictive likelihood of held-out rows and columns. That is, for each row (or column) x of the matrix, we evaluate $p(x|X_O)$, where X_O denotes an "observed" sub-matrix. Like marginal likelihood, this tests the model's ability to predict entire rows or columns. However, it can be efficiently approximated in our class of models using a small but carefully chosen toolbox corresponding to the component matrix priors in our grammar. We discuss the case of held-out rows; columns are handled analogously.

First, by expanding out the products in the expression, we can write the decomposition uniquely in the form

$$X = U_1 V_1 + \cdots + U_n V_n + E, \tag{1}$$

where E is an *i.i.d.* Gaussian "noise" matrix and the U_i's are any of the following: (1) a component matrix G, M, or B, (2) some number of Cs followed by G, (3) a Gaussian scale mixture. The held-out row x can therefore be represented as:

$$x = V_1^T u_1 + \cdots + V_n^T u_n + e. \tag{2}$$

The predictive likelihood is given by:

$$p(x|X_O) = \int p(U_O, V|X_O) p(u|U_O) p(x|u,V)\, dU_O\, du\, dV \tag{3}$$

where U_O is shorthand for $(U_{O1}, \ldots, U_{On})$ and u is shorthand for $(u_1, \ldots, u_n)$.

In order to evaluate this integral, we generate samples from the posterior $p(U_O, V|X)$ using the techniques described in Section 4, and compute the sample average of

$$p_{pred}(x) \triangleq \int p(u|U_O) p(x|u,V)\, du \tag{4}$$

If the term U_i is a Markov chain, the predictive distribution $p(u_i|U_O)$ can be computed using Rauch-Tung-Striebel smoothing; in the other cases, u and U_O are related only

through the hyperparameters of the component prior. Either way, each term $p(u_i|U_O)$ can be summarized as a Gaussian, multinomial, Bernoulli, or Gaussian scale mixture distribution.

It remains to marginalize out the latent representation u of the held-out row. While this can be done exactly in some simple models, it is intractable in general (for instance, if u is Bernoulli or a Gaussian scale mixture). It is important that the approximation to the integral be a lower bound, because otherwise an overly optimistic model could be chosen even when it is completely inappropriate.

Our approach is a hybrid of variational and sampling techniques. We first lower bound the integral (4) in an approximate model $\tilde{p}$ where the Gaussian scale mixture components are approximated as Gaussians. This is done using using the variational Bayes bound

$$\log \tilde{p}_{pred}(x) \geq E_q[\log \tilde{p}_{pred}(x, u)] + \mathcal{H}(q).$$

The approximating distribution $q(u)$ is such that all of the discrete components are independent, while the Gaussian components are marginalized out. The ratio $p_{pred}(x)/\tilde{p}_{pred}(x)$ is then estimated using annealed importance sampling (AIS) (Neal, 2001). Because AIS is an unbiased estimator which always takes positive values, by Markov's inequality we can regard it as a stochastic lower bound. Therefore, this small toolbox of techniques allows us to (stochastically) lower bound the predictive likelihood across a wide variety of matrix decomposition models.

6 Search over structures

We aim to find a matrix decomposition structure which is a good match to a dataset, as measured by the predictive likelihood criterion of Section 5. Since the space of models is large and inference in many of the models is expensive, we wish to avoid exhaustively evaluating every model. Instead, we adopt a greedy search procedure inspired by the process of scientific discovery. In particular, consider a common heuristic researchers use to build probabilistic models: we begin with a model which has already been applied to a problem, look for additional dependencies not captured by the model, and refine the model to account for those dependencies.

In our approach, refining a model corresponds to applying one of the productions. This suggests the following greedy search procedure, which iteratively "expands" the best-scoring unexpanded models by applying all possible production rules and scoring the resulting models. In particular we first expand the structureless model G. Then, in each step, we expand the K best-performing models from the previous step by applying all possible productions. We then score all the resulting models. The procedure stops when no model achieves sufficient improvement over the best model from the previous step. We refer to the models reached in i productions as the Level i models; for instance, $GG+G$ is a Level 1 model and $(MG+G)G+G$ is a Level 2 model.

The effectiveness of this search procedure depends whether the score of a simple structure is a strong indicator of the best score which can be obtained from the structures derived from it. In our experiments, the scores of the simpler structures turned out to be a powerful heuristic: while our experiments used $K = 3$, in most all cases, the correct (or best-scoring) structure would have been found with a purely greedy search ($K = 1$). This results in enormous savings because of the compositional nature of our search space: while the number of possible structures (up to a given level) grows quickly in the number of production rules, the number of structures evaluated by this search procedure is merely linear.

The search procedure returns a high-scoring structure for each level in our grammar. There remains a question of when to stop. Choosing between structures of differing complexity imposes a tradeoff between goodness of fit and other factors such as interpretability and tractability of inference, and inevitably the choice is somewhat subjective. In practice, a user may wish to run our procedure up to a fixed level and analyze the sequence of models chosen, as well as the predictive likelihood improvement at each level. However, for the purposes of evaluating our system, we need it to return a single answer. In all of our experiments, we adopt the following arbitrary but consistent criterion: prefer the higher level structure if its predictive log-likelihood score improves on the previous level by at least one nat per row and column.[2]

7 Experiments

7.1 Synthetic data

We first validated our structure learning procedure on synthetic data where the correct model was known. We generated matrices of size 200×200 from all of the models in Figure 2, with 10 latent dimensions. The noise variance σ^2 was varied from 0.1 to 10, while the signal variance was fixed at 1.[3] The structures selected by our procedure are shown in Table 1.

[2] More precisely, if $\frac{S_i - S_{i-1}}{N+D} > 1$, where S_i is the total predictive log-likelihood for the level i model summed over all rows and columns, and N and D are the numbers of rows and columns, respectively. We chose to normalize by $N+D$ because the predictive likelihood improvements between more abstract models tend to grow with the number of rows and columns in the input matrix, rather than the number of entries.

[3] Our grammar generates expressions of the form $\cdots + G$. We consider this final G term to be the "noise" and the rest to be the "signal," even though the models and algorithms do not distinguish the two.

	— Increasing noise ⟶			
	$\sigma^2 = 0.1$	$\sigma^2 = 1$	$\sigma^2 = 3$	$\sigma^2 = 10$

Table 1: The structures learned from 200×200 matrices generated from various distributions, with signal variance 1 and noise variance σ^2. Incorrect structures are marked with a 1, 2, or 3, depending how many decisions would need to be changed to find the correct structure. We observe that our approach typically finds the correct answer in low noise settings and backs off to simpler models in high noise settings.

We observe that seven of the ten structures were identified perfectly in both trials where the noise variance was no larger than the data variance ($\sigma^2 \leq 1$). When $\sigma^2 = 0.1$, the system incorrectly chose $(BG+G)G+G$ for the binary latent feature data, rather than $BG + G$. Similarly, it chose $(BG + G)(GB^T + G) + G$ rather than $(BG + G)B^T + G$ for binary matrix factorization. In both cases, the sampler learned an incorrect set of binary features, and the additional flexibility of the more complex model compensated for this. This phenomenon, where more structured models compensate for algorithmic failures in simpler models, has also been noted in the context of deep learning (Salakhutdinov and Murray, 2008).

Our system also did not succeed in learning the dependent Gaussian scale mixture structure $(\exp(GG+G)\circ G)G+G$ from synthetic data, instead generally falling back to the simpler sparse coding model $(\exp(G) \circ G)G + G$. For $\sigma^2 = 0.1$ the correct structure was in fact the highest scoring structure, but did not cross our threshold of 1 nat improvement over the previous level. We note that in every case, there were nearly 2500 incorrect structures to choose from, so it is notable that the correct model structure can be recovered most of the time.

In general, when the noise variance was much larger than the signal variance, the system gracefully fell back to simpler models, such as $GM^T + G$ instead of the BCTF model $(MG + G)(GM^T + G) + G$ (see Section 3.1). At the extreme, in the maximum noise condition, it chose the structureless model G much of the time. Overall, our procedure reliably learned most of the model structures in low-noise settings (impressive considering the extremely large space of possible wrong answers) and gracefully fell back to simpler models when necessary.

7.2 Real-world data

Next, we evaluated our system on several real-world datasets. We first consider two domains, motion capture and image statistics, where the core statistical assumptions are widely agreed upon, and verify that our learned structures are consistent with these assumptions. We then turn to domains where the correct structure is more ambiguous and analyze the representations our system learns.

In general, we do not expect every real-world dataset to have a unique best structure. In cases where the predictive likelihood score differences between multiple top-scoring models were not statistically significant, we report the set of top-scoring models and analyze what they have in common.

Motion capture. We first consider a human motion capture dataset (Hsu et al., 2005; Taylor et al., 2007) consisting of a person walking in a variety of styles. Each row of the matrix gives the person's orientation and displacement in one frame, as well as various joint angles. We used 200 frames (6.7 seconds), and 45 state variables. In the first step, the system chose the Markov chain model $CG + G$, which assumes that the components of the state evolve continuously but independently over time. Since a person's different joint angles are clearly correlated, the system next captured these correlations with the model $C(GG+G)+G$. This is slightly different from the popular linear dynamical system model $(CG + G)G + G$, but it is more physically correct in the sense that the LDS assumes the deviations of the observations from the low-dimensional subspace must be independent in different time steps, while our learned structure captures the temporal continuity in the deviations.

Natural image patches. We tested the system on the Sparsenet dataset of Olshausen and Field (1996), which consists of 10 images of natural scenes which were blurred and whitened. The rows of the input matrix corresponded to 1,000 patches of size 12×12. In the first stage, the model learned the low-rank representation $GG + G$, and in the second stage, it sparsified the linear reconstruction coefficients to give the sparse coding model $(\exp(G) \circ G)G + G$. In the third round, it modeled the dependencies between the scale variables by recursively giving them a low-rank representation, giving a dependent Gaussian scale mixture (GSM) model $(\exp(GG + G) \circ G)G + G$ reminiscent of Karklin and Lewicki (2008). A closely related model, $(\exp(GB^T + G) \circ G)G + G$, also achieved a score not significantly lower. Both of these structures resulted in a

	Level 1	Level 2	Level 3
Motion capture	$CG + G$	$C(GG + G) + G$	—
Image patches	$GG + G$	$(\exp(G) \circ G)G + G$	$(\exp(GG + G) \circ G)G + G$
20 Questions	$MG + G$	$M(GG + G) + G$	—
Senate votes	$GM^T + G$	$(MG + G)M^T + G$	—

Table 2: The best performing models at each level of our grammar for real-world datasets. These correspond to plausible structures for the datasets, as discussed in the text.

rank-one factorization of the scale matrix, similar to the radial Gaussianization model of Lyu and Simoncelli (2009) for neighboring wavelet coefficients.

Dependent GSM models (see Section 3.1) are the state-of-the-art for a variety of image processing tasks, so it is interesting that this structure can be learned merely from the raw data. We note that a single pass through the grammar reproduces an analogous sequence of models to those discovered by the image statistics research community as discussed in Section 3.1.

20 Questions. We now consider a dataset collected by Pomerleau et al. (2009) of Mechanical Turk users' responses to 218 questions from the 20 Questions game about 1000 concrete nouns (e.g. animals, foods, tools). The system began by clustering the entities using the flat clustering model $MG + G$. In the second stage, it found low-rank structure in the matrix of cluster centers, resulting in the model $M(GG+G)+G$. No third-level structure achieved more than 1 nat improvement beyond this. The low-rank representation had 8 dimensions, where the largest variance dimension corresponded to living vs. nonliving and the second largest corresponded to large vs. small. The 39 clusters, the 20 largest of which are shown in Figure 3, correspond to semantically meaningful categories.

We note that two other models expressing similar assumptions, $M(GB^T + G) + G$ and $(MG + G)G + G$, achieved scores only slightly lower. What these models have in common is a clustering of entities (but not questions) coupled with low-rank structure between entities and questions. The learned clusters and dimensions are qualitatively similar in each case.

Senate voting records. Finally, we consider a dataset of roll call votes from the 111th United States Senate (2009-2010). Rows correspond to Senators, and the columns correspond to all 696 votes, most of which were on procedural motions and amendments to bills. Yea votes were mapped to 1, Nay and Present were mapped to -1, and absences were treated as unobserved. In the first two stages, our procedure clustered the votes and Senators, giving the clustering model $GM^T + G$ and the co-clustering model $(MG+G)M^T+G$, respectively. Senators clustered along party lines, as did most of the votes, according to the party of the proposer. The learned representations are all visualized in Figure 4.

In the third stage, one of the best performing models was Bayesian clustered tensor factorization (BCTF) (see section 3.1), where Senators and votes are each clustered inside a low-rank representation.[4] This low-rank representation was rank 5, with one dominant dimension corresponding to the liberal-conservative axis. The BCTF model makes it clearer that the clusters of Senators and votes are not independent, but can be seen as occupying different points in a low-dimensional representation. This model improved on the previous level by less than our 1 nat cutoff.[5] The models in this sequence increasingly highlight the polarization of the Senate.

8 Discussion

We have presented an effective and practical method for automatically determining the model structure in a particular space of models, matrix decompositions, by exploiting compositionality. However, we believe our approach can be extended beyond the particular space of models presented here. Most straightforwardly, additional components can be added to capture other motifs of probabilistic modeling, such as tree embeddings and low-dimensional embeddings. More generally, it should be fruitful to investigate other model classes with compositional structure, such as tensor decompositions.

In either case, exploiting the structure of the model space becomes increasingly essential. For instance, the number of models reachable in 3 steps is cubic in the number of production rules, whereas the complexity of the greedy search is linear. For tensors, the situation is even more overwhelming: even if we restrict our attention to analogues of $GG+G$, a wide variety of provably distinct generalizations have been identified, including the widely used Tucker3 and PARAFAC decompositions (Kolda and Bader, 2007).

[4] The other models whose scores were not significantly different were: $(MG+G)M^T+BG+G$, $(MG+G)M^T+GM^T+G$, $G(GM^T + G) + GM^T + G$, and $(BG + G)(GM^T + G) + G$. All of these models include the clustering structure but account for additional variability within clusters.

[5] BCTF results in a more compact representation than the co-clustering model, but our predictive likelihood criterion doesn't reward this except insofar as overfitting hurts a model's ability to generalize to new rows and columns. We speculate that a fully Bayesian approach using marginal likelihood may lead to more compact structures.

1. Miscellaneous. key, chain, powder, aspirin, umbrella, quarter, cord, sunglasses, toothbrush, brush
2. Clothing. coat, dress, pants, shirt, skirt, backpack, tshirt, quilt, carpet, pillow, clothing, slipper, uniform
3. Artificial foods. pizza, soup, meat, breakfast, stew, lunch, gum, bread, fries, coffee, meatballs, yoke
4. Machines. bell, telephone, watch, typewriter, lock, channel, tuba, phone, fan, ipod, flute, aquarium
5. Natural foods. carrot, celery, corn, lettuce, artichoke, pickle, walnut, mushroom, beet, acorn
6. Buildings. apartment, barn, church, house, chapel, store, library, camp, school, skyscraper
7. Printed things. card, notebook, ticket, note, napkin, money, journal, menu, letter, mail, bible
8. Body parts. arm, eye, foot, hand, leg, chin, shoulder, lip, teeth, toe, eyebrow, feet, hair, thigh
9. Containers. bottle, cup, glass, spoon, pipe, gallon, pan, straw, bin, clipboard, carton, fork
10. Outdoor places. trail, island, earth, yard, town, harbour, river, planet, pond, lawn, ocean
11. Tools. knife, chisel, hammer, pliers, saw, screwdriver, screw, dagger, spear, hoe, needle
12. Stuff. speck, gravel, soil, tear, bubble, slush, rust, fat, garbage, crumb, eyelash
13. Furniture. bed, chair, desk, dresser, table, sofa, seat, ladder, mattress, handrail, bench, locker
14. Liquids. wax, honey, pint, disinfectant, gas, drink, milk, water, cola, paste, lemonade, lotion
15. Structural features. bumper, cast, fence, billboard, guardrail, axle, deck, dumpster, windshield
16. Non-solid things. surf, fire, lightning, sky, steam, cloud, dance, wind, breeze, tornado, sunshine
17. Transportation. airplane, car, train, truck, jet, sedan, submarine, jeep, boat, tractor, rocket
18. Herbivores. cow, horse, lamb, camel, pig, hog, calf, elephant, cattle, giraffe, yak, goat
19. Internal organs. rib, lung, vein, stomach, heart, brain, smile, blood, lap, nerve, lips, wink
20. Carnivores. bear, walrus, shark, crocodile, dolphin, hippo, gorilla, hyena, rhinocerous

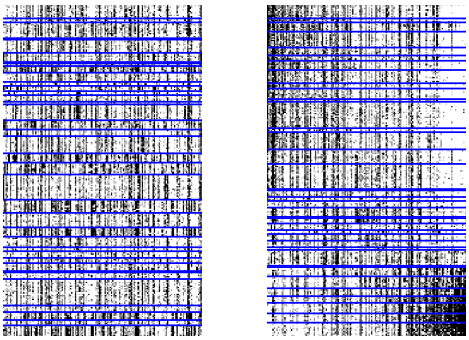

Figure 3: **(left)** The 20 largest clusters discovered by our Level 2 model $M(GG+G)+G$ for the 20 Questions dataset. Each line gives **our interpretation**, followed by random items from the cluster. **(right)** Visualizations of the Level 1 representation $MG+G$ and the Level 2 representation $M(GG+G)+G$. Rows = entities, columns = questions. 250 rows and 150 columns were selected at random from the original matrix. Rows and columns are sorted first by cluster, then by the highest variance dimension of the low-rank representation (if applicable). Clusters were sorted by the same dimension as well. Blue = cluster boundaries.

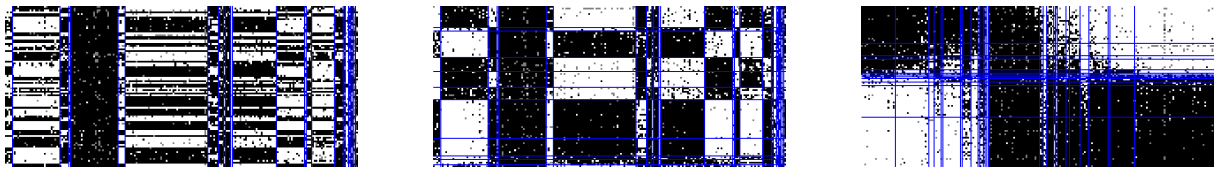

(a) Level 1: GM^T+G (b) Level 2: $(MG+G)M^T+G$ (c) Level 3: $(MG+G)(GM^T+G)+G$

Figure 4: Visualization of the representations learned from the Senate voting data. Rows = Senators, columns = votes. 200 columns were selected at random from the original matrix. Black = yes, white = no, gray = absence. Blue = cluster boundaries. Rows and columns are sorted first by cluster (if applicable), then by the highest variance dimension of the low-rank representation (if applicable). Clusters are sorted by the same dimension as well. The models in the sequence increasingly reflect the polarization of the Senate.

What is the significance of the grammar being context-free? While it imposes no restriction on the models themselves, it has the effect that the grammar "overgenerates" model structures. Our grammar licenses some nonsensical models: for instance, $G(MG+G)+G$, which attempts to cluster dimensions of a latent space which is defined only up to affine transformation. Reassuringly, we have never observed such models being selected by our search procedure — a useful sanity check on the output of the algorithm. The only drawback is that the system wastes some time evaluating meaningless models. Just as context-free grammars for English can be augmented with attributes to enforce contextual restrictions such as agreement, our grammar could be similarly extended to rule out unidentifiable models. Such extensions may become important if our approach is applied to a much larger space of models.

Our context-free grammar formalism unifies a wide variety of matrix decomposition models in terms of compositional application of a few production rules. We exploited this compositional structure to efficiently and generically sample from and evaluate a wide variety of latent variable models, both continuous and discrete, flat and hierarchical. Greedy search over our grammar allows us to select a model structure from raw data by evaluating only a small fraction of all models. This search procedure was effective at recovering the correct structure for synthetic data and sensible structures for real-world data. More generally, we believe this paper is a proof-of-concept for the practicality of selecting complex model structures in a compositional manner. Since many model spaces other than matrix factorizations are compositional in nature, we hope to spur additional research on automatically searching large, compositional spaces of models.

A Slice Sampler for Restricted Hierarchical Beta Process with Applications to Shared Subspace Learning

Abstract

Hierarchical beta process has found interesting applications in recent years. In this paper we present a modified hierarchical beta process prior with applications to hierarchical modeling of multiple data sources. The novel use of the prior over a hierarchical factor model allows factors to be shared across different sources. We derive a slice sampler for this model, enabling tractable inference even when the likelihood and the prior over parameters are non-conjugate. This allows the application of the model in much wider contexts without restrictions. We present two different data generative models – a linear Gaussian-Gaussian model for real valued data and a linear Poisson-gamma model for count data. Encouraging transfer learning results are shown for two real world applications – text modeling and content based image retrieval.

1 Introduction

Hierarchical modeling is becoming increasingly popular in Bayesian statistics – it allows joint modeling of multiple data sources, permitting shared patterns. A successful example of hierarchy in text modeling is the hierarchical Dirichlet process (HDP) [18]. HDP is used as a prior over a mixture model allowing shared mixture components (topics) across multiple data sources. Each data point from a data source is modeled using 1-out-of-K topics, shared across different sources. In many applications, where it may not be easy to separate out data into K mutually exclusive groups, an appropriate approach is factor analysis, where each data point is modeled using P-out-of-K factors. The benefits of joint modeling can still be retained by sharing these factors across different sources.

Previous works on nonparametric factor analysis have used beta processes. One of the earliest work develops the Indian buffet process (IBP) and uses it as a nonparametric prior over infinite binary matrices [6]. Similar works differing in inference methods are proposed in [15, 14, 5]. A significant contribution by Thibaux and Jordan [19] uncovers that the IBP is a predictive process for an underlying beta process with concentration parameter equaling one. In addition, they propose a hierarchical beta process (HBP) model and demonstrate its use for document classification in a *single* data source. The use of HBP can be extended to modeling multiple data sources by utilizing it as a nonparametric prior for *factor* models, in a similar way to HDP being used as a nonparametric prior for *mixture* models. However, when combining HBP with the factor model, inference is often intractable. This is mainly due to the need to integrate out the parameters when invoking new factors according to the HBP prior. For efficient computation of this integration, conjugacy is required between the parameter priors and the likelihood. However, the requirement of the conjugacy restricts the applicability of this model. One approach to deal with the non-conjugacy issues is through explicit representation of all the samples drawn from beta process. This requires representation of an infinite set of atoms - a practically impossible task. To circumvent this problem, one possible solution is to truncate the beta process. However, a pre-specified truncation level is arbitrary. To avoid this arbitrary truncation for a IBP based factor model, Teh et al [17] use a slice sampling technique, which turns the infinite representation problem into a finite representation problem. A similar approach for Dirichlet processes was taken by Walker [20]. However, a slice sampler for HBP based factor model is *yet* to be developed.

An attempt on nonparametric, hierarchical factor analysis using HBP was made in [8]. However, inference for this model has many *approximation* steps (refer section 3.1.2 in [8]), which risk sampling from incorrect posterior distributions. Thus *more accurate inference* methods *need to be developed.*

In this paper, we take the HBP prior and replace the upper beta process layer by an IBP prior, i.e. the concentration parameter of the underlying beta process is fixed to one. We refer to this modified hierarchical prior as the

Restricted Hierarchical Beta Process (R-HBP). This modification allows us to use the stick breaking construction of IBP [17] and explicitly represent the samples of the underlying beta process. To handle the resultant infinite representation problem, *we present a novel slice sampler* for the proposed R-HBP, deriving an infinite limit, necessary for tractable posterior over stick-weights of IBP. At the data source level, we still retain beta processes with arbitrary concentration parameters, allowing arbitrary sharing between data sources.

For the hierarchical factor analysis (i.e. factor analysis using R-HBP prior), we propose two different data models – a linear Gaussian data model for real-valued data and a Poisson-gamma model for count data. For the linear Poisson-gamma model, we present novel inference using auxiliary variables. Through synthetic experiments, we illustrate the behavior of our model, demonstrating that it correctly discovers all parameters including the dimensionalities of the factor subspaces. We further demonstrate the proposed models for two real world tasks – text modeling and content based image retrieval. For text modeling, which is demonstrated on NIPS 0-12 dataset (constructed from 12 years of NIPS proceedings), we successfully show the benefits of transfer learning. In addition, we show that linear Poisson-gamma model achieves much better perplexity than other models such as linear Gaussian model or HDP mixture model. For content based image retrieval, using NUS-WIDE animal dataset, we demonstrate that our method outperforms recent state-of-the-art methods.

Our main contributions are:

- A slice sampler for the proposed R-HBP model – we derive an infinite limit, which is necessary for tractable posterior over stick-weights of IBP.
- A novel, auxiliary variable, Gibbs sampler for the linear Poisson-gamma model.
- Demonstration of the proposed models for text modeling and content based image retrieval.

The rest of this paper is organized as follows: Section 2 presents brief background on the related nonparametric priors. Section 3 describes the modeling distributions for nonparametric hierarchical factor analysis. Section 4 presents the inference covering the novel slice sampling along with Gibbs sampling. Section 5 demonstrates the experiments using synthetic and real-world text and image data. Section 6 concludes this paper.

2 Preliminaries

2.1 Hierarchical Modeling using Beta Process

Let Ω be the set of all outcomes and $\mathscr{F}$ be its sigma algebra. We denote a beta process [10] as $B \sim \mathrm{BP}(\gamma_0, B_0)$ where γ_0 is a positive concentration parameter and B_0 is a base measure on Ω. The beta process is a completely random measure [13], implying that if $C_1, \ldots, C_n$ are the disjoint sets in Ω, the measures $B(C_1), \ldots, B(C_n)$ are independent random variables and the draws from a beta process are discrete with probability one. Using this property, a draw B from the beta process $\mathrm{BP}(\gamma_0, B_0)$ can be written as $B = \sum_k \beta_k \delta_{\phi_k}$ where $\phi_k \in \Omega$ is an atom drawn from B_0 and β_k is a random weight assigned to ϕ_k according to the following

$$\beta_k \sim \mathrm{beta}\left(\gamma_0 B_0(\phi_k), \gamma_0\left(1 - B_0(\phi_k)\right)\right), k = 1, 2, \ldots \quad (1)$$

If $B_0 = \sum_k \xi_k \delta_{\phi_k}$ (i.e. discrete), $B_0(\phi_k) = \xi_k$. For a continuous B_0, $\{(\phi_k, \beta_k)\}$ are i.i.d. draws from a Poisson process on the product space $\Omega \times [0,1]$ with a Lévy measure [12].

Building a hierarchy over beta processes, Thibaux and Jordan [19] introduced a hierarchical beta process (HBP) prior that allows the sharing of the atoms (drawn from a beta process) across multiple data sources. A hierarchical beta process is constructed in the following way : $B \sim \mathrm{BP}(\gamma_0, B_0)$ is a draw from a beta process with base measure B_0 and there emanate J child beta processes using B as their base measure (drawn as $A_j \sim \mathrm{BP}(\alpha_j, B)$, $j = 1, \ldots, J$). Finally, each A_j is used to parametrize a Bernoulli process denoted as $\mathbf{Z}_j^{i,:} \mid A_j \sim \mathrm{BeP}(A_j)$ where $\mathbf{Z}_j^{i,:}$ denotes i-th row of a binary matrix $\mathbf{Z}_j$. The support of random measure B is the same as that of base measure B_0 and is passed on to each A_j (for each j) allowing sharing of atoms across J-sources.

2.2 Indian Buffet Process and Stick-Breaking Construction

Indian buffet process (IBP) [6] is a nonparametric predictive prior developed as a generative model for infinite binary matrices. A key property of IBP is that it is exchangeable, i.e. if $\mathbf{Z} = [z_1, \ldots, z_N]$ (where z_i is a binary-valued infinite vector) then $p(z_1, \ldots, z_N) = p\left(z_{\sigma(1)}, \ldots, z_{\sigma(N)}\right)$ where σ is a permutation over $\{1, \cdots, N\}$. Given this exchangeability property, it is interesting to find out the underlying de Finetti stochastic process [4]. Investigating this question, Thibaux and Jordan [19] discovered that this underlying stochastic process is a beta process with concentration parameter equal to one, (i.e. $\gamma_0 = 1$ in Eq (1)). In most of the models, to construct the binary matrix $\mathbf{Z}$ from IBP, a sequential process [6] can be followed. However, this keeps the underlying beta process hidden. There are many applications where it is required to represent the underlying beta process explicitly. In such applications, one needs to know how to sample from the beta process underlying IBP. A solution to this problem was proposed by Teh et al [17] who derived stick-breaking construction for IBP and related this scheme to a similar stick breaking construction for Dirichlet processes.

Let us denote the beta process underlying IBP by $B \sim \mathrm{BP}(1, B_0)$ and assume that $\tau_0 = B_0(\Omega)$. Using an infi-

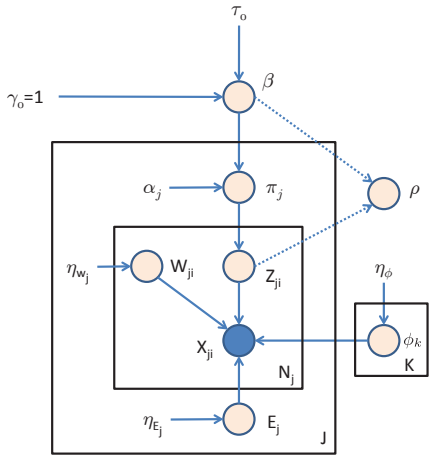

Figure 1: Directed graphical representation for the proposed nonparametric hierarchical factor model. The hyperparameters over $\mathbf{W}_j$, ϕ_k and $\mathbf{E}_j$ are denoted by η_{w_j},η_ϕ and η_{E_j} respectively.

nite set of atoms, we can write $B = \sum_l \beta_l \delta_{\phi_l}$. Now let $\{\beta_{(1)}, \beta_{(2)}, \ldots, \beta_{(K)}\}$ be the decreasing ordered representation of $\{\beta_1, \beta_2, \ldots, \beta_K\}$, where $\beta_l \sim \text{beta}\left(\frac{\tau_0}{K}, 1\right)$. Teh et al [17] showed that in the limit $K \to \infty$, the $\beta_{(k)}$ variables can be obtained from the following procedure

$$\nu_{(t)} \sim \text{beta}\,(\tau_0, 1)\,,\ \beta_{(k)} = \nu_{(k)}\beta_{(k-1)} = \Pi_{t=1}^{k}\nu_{(t)} \tag{2}$$

We shall denote the stick-breaking construction of Eq (2) as $\beta_{(k)} \sim \text{StickIBP}(\tau_0)$. A key property of this construction is that there exists a Markov relation [17] among $\{\beta_{(1)}, \beta_{(2)}, \ldots, \beta_{(K)}\}$, i.e. $\beta_{(k)}$ is conditionally independent of $\beta_{(1:k-2)}$ given $\beta_{(k-1)}$. Formally,

$$p\left(\beta_{(k)} \mid \beta_{(1:k-1)}\right) = \tau_0 \beta_{(k-1)}^{-\tau_0} \beta_{(k)}^{\tau_0 - 1} 1\left(0 \le \beta_{(k)} \le \beta_{(k-1)}\right) \tag{3}$$

where $1(Q)$ equals to one if Q is true and zero otherwise. Given top k variables $\{\beta_{(1)}, \beta_{(2)}, \ldots, \beta_{(k)}\}$, the other variables β_l have the following density function [17]

$$p\left(\beta_l \mid \beta_{(1:k)}\right) = \frac{\tau_0}{K} \beta_{(k)}^{-\left(\frac{\tau_0}{K}\right)} \beta_l^{\left(\frac{\tau_0}{K}\right)-1} 1\left(0 \le \beta_l \le \beta_{(k)}\right) \tag{4}$$

2.3 Restricted Hierarchical Beta Process

Restricted hierarchical beta process (R-HBP) is defined as a hierarchical beta process where the parent beta process has a concentration parameter equal to one. In other words, the parent beta process in a R-HBP is a beta process for which the predictive process is an Indian buffet process. Formally,

$$B \sim \text{BP}(1, B_0)\,, \quad A_j \sim \text{BP}(\alpha_j, B)\,, \quad \mathbf{Z}_j^{i,:} \mid A_j \sim \text{BeP}(A_j)$$

Alternatively, using Eqs (1-2), we can write the above as

$$\beta_{(k)} \sim \text{StickIBP}(\tau_0) \tag{5}$$

$$\pi_{jk} \sim \text{beta}\left(\alpha_j \beta_{(k)}, \alpha_j\left(1 - \beta_{(k)}\right)\right), \mathbf{Z}_j^{i,:} \sim \text{BeP}(\pi_j) \tag{6}$$

3 Hierarchical Factor Analysis using R-HBP

We now consider joint factor analysis [7, 8] and use the R-HBP prior to infer the dimensionalities of factor subspaces. Our goal is to model *multiple* data matrices $\mathbf{X}_1, ..., \mathbf{X}_J$ jointly using a factor matrix $\Phi = [\phi_1, ..., \phi_K]$ where $\phi_k \in \mathbb{R}^M$ denotes the k-th factor. Some of the factors in Φ may be *shared* amongst the various data sources whereas others factors are specific to *individual* sources. For each $j = 1, \ldots, J$, $\mathbf{X}_j \in \mathbb{R}^{M \times N_j}$ has a representation $\mathbf{H}_j \in \mathbb{R}^{N_j \times K}$ in the subspace spanned by Φ along with the factorization error $\mathbf{E}_j$. Formally,

$$\Pi : \begin{cases} \mathbf{X}_1 = & \Phi \mathbf{H}_1^{\mathsf{T}} + \mathbf{E}_1 \\ \cdots & \cdots \\ \mathbf{X}_J = & \Phi \mathbf{H}_J^{\mathsf{T}} + \mathbf{E}_J \end{cases} \tag{7}$$

We allow the number of factors (K) to grow infinitely when more data is observed. To infer the value of K, we represent the matrix $\mathbf{H}_j$ as an element-wise multiplication of two matrices $\mathbf{Z}_j$ and $\mathbf{W}_j$, i.e. $\mathbf{H}_j = \mathbf{Z}_j \odot \mathbf{W}_j$, where $\mathbf{Z}_j^{ik} = 1$ implies the presence of factor ϕ_k for i-th data point $\mathbf{X}_j^{:,i}$ from source j and $\mathbf{W}_j^{ik}$ represents the corresponding coefficient or weight of the factor ϕ_k. The collection of matrices $\mathbf{Z}_1, \ldots, \mathbf{Z}_J$ are now modeled using R-HBP prior. In particular, we model i-th row of $\mathbf{Z}_j$ as a draw from a Bernoulli process parametrized by a beta process A_j, i.e. $\mathbf{Z}_j^{i,:} \sim \text{BeP}(\pi_j)$ where $\pi_j \triangleq [\pi_{j1}, \ldots, \pi_{jK}]$ and π_{jk} is defined in Eq (6). We note that sampling π_{jk} according to Eq (6) allows sharing of the factors ϕ_k's across data sources. This is because $\beta_{(k)}$ (the stick-breaking weights of B, i.e. $\beta_{(k)} \sim \text{StickIBP}(\tau_0)$) are used for all data sources. For the factor analysis parameters, we propose two different models : a Gaussian-Gaussian model (GGM) for real-valued data and a Poisson-gamma model (PGM) for count data. The whole model can be summarized as

$$\text{PGM} : \begin{cases} \Phi^{ik} \sim \text{gamma}\left(a_\phi, b_\phi\right) \\ \mathbf{W}_j^{i,:} \sim \Pi_{k=1}^{K} \text{gamma}\left(a_{w_j}, b_{w_j}\right) \\ \mathbf{X}_j^{:,i} \mid \Phi, \mathbf{Z}_j^{i,:}, \mathbf{W}_j^{i,:} \\ \sim \text{Poisson}\left(\Phi\left(\mathbf{Z}_j^{i,:} \odot \mathbf{W}_j^{i,:}\right)^{\mathsf{T}} + \lambda_j\right) \end{cases} \tag{8}$$

$$\text{GGM} : \begin{cases} \Phi^{ik} \sim \mathcal{N}\left(0, \sigma_\phi^2\right), \mathbf{W}_j^{i,:} \sim \mathcal{N}\left(\mathbf{0}, \sigma_{w_j}^2 \mathbf{I}\right) \\ \mathbf{X}_j^{:,i} \mid \Phi, \mathbf{Z}_j^{i,:}, \mathbf{W}_j^{i,:} \sim \mathcal{N}\left(\Phi\left(\mathbf{Z}_j^{i,:} \odot \mathbf{W}_j^{i,:}\right)^{\mathsf{T}}, \sigma_{n_j}^2 \mathbf{I}\right) \end{cases} \tag{9}$$

For reference purposes, we call the above model as *Nonparametric Hierarchical Factor Analysis* (NHFA) and the two variants as NHFA-PGM and NHFA-GGM.

4 Model Inference

For inference, we use a combination of slice sampling and collapsed Gibbs sampling. The main variables of interest

for NHFA model are $\mathbf{Z}$, $\mathbf{W}$, Φ, π, β and α_j (see Figure 1). In addition, we introduce an auxiliary variable ρ. The purpose of this auxiliary variable is to turn the infinite representation of beta process into a finite representation. We integrate out π and sample $\mathbf{Z}$, $\mathbf{W}$, Φ and β. Notation-wise, we use $\beta = \{\beta_k : k = 1,\ldots,K\}$, $\pi = \{\pi_j : j = 1,\ldots,J\}$ and a superscript attached to a variable followed by a '$-$' sign (e.g. $\mathbf{m}^{-jk}$, $\mathbf{Z}_j^{i,-k}$ etc) means a set excluding the variable indexed by the superscript. In the following, we describe the inference steps. ***Further details on some of the derivations are provided in the supplementary material [9].***

The joint distribution of β and $\mathbf{Z}$ can be written as

$$p(\beta,\mathbf{Z},\rho) = p(\beta)\,p(\rho \mid \mathbf{Z},\beta)\int_{\pi} p(\mathbf{Z} \mid \pi)\,p(\pi \mid \beta)\,d\pi \tag{10}$$

Let us assume that the auxiliary variable ρ is uniformly distributed as

$$p(\rho \mid \mathbf{Z},\beta) = \frac{1}{\beta^*}1(0 \le \rho \le \beta^*) \tag{11}$$

where β^* (a function of $\beta_{(1:\infty)}$ and $\mathbf{Z}$) is equal to the stick weight of the smallest active factor, i.e.

$$\beta^* = \min_{k|\exists i,\, \mathbf{Z}_j^{ik}=1} \beta_{(k)} \tag{12}$$

Using Eq (11), the conditional of $\mathbf{Z}$ given ρ and β can be written as

$$p(\mathbf{Z} \mid \rho,\beta) \propto \frac{1}{\beta^*}1(0 \le \rho \le \beta^*)\int_{\pi} p(\mathbf{Z} \mid \pi)\,p(\pi \mid \beta)\,d\pi \tag{13}$$

We note that given ρ, $\forall i$, $\mathbf{Z}_j^{ik} = 0$ if $\beta_{(k)} < \rho$ and therefore, we only need to update $\mathbf{Z}_j^{ik}$ for those values of k such that $\beta_{(k)} \ge \rho$ [17]. We now proceed to derive the full conditional distributions required for Gibbs sampling.

4.1 Sampling ρ

Let $K^\dagger$ denote the index such that all active features have index $k < K^\dagger$. The index $K^\dagger$ is also represented although it is an inactive feature. We sample ρ according to Eq (11). If the new value of ρ is such that $\beta_{(K^\dagger)} \ge \rho$, then we extend the stick breaking representation until $\beta_{(K^\dagger)} < \rho$. For the extended representation, Φ and $\mathbf{W}$ can be sampled from their prior distributions while $\beta_{(k)}$ are sampled from the following conditional distribution

$$\begin{aligned} &p\left(\beta_{(k)} \mid \beta_{(k-1)}, \mathbf{Z}^{:,\ge k} = 0\right) \\ &\propto p\left(\beta_{(k)} \mid \beta_{(k-1)}\right) p\left(\mathbf{Z}^{:,\ge k} = 0 \mid \beta_{(k)}\right) \end{aligned} \tag{14}$$

where $\mathbf{Z}^{:,\ge k} \triangleq \left\{\mathbf{Z}_j^{ik'} \mid \forall j,i \text{ and } k' \ge k\right\}$. The likelihood term in the above expression can be computed as

$$\begin{aligned} &p\left(\mathbf{Z}^{:,\ge k} = 0 \mid \beta_{(k)}\right) \\ &= \Pi_{j=1}^{J} p\left(\mathbf{Z}_j^{:,k} = 0 \mid \beta_{(k)}\right) p\left(\mathbf{Z}_j^{:,>k} = 0 \mid \beta_{(k)}\right) \end{aligned} \tag{15}$$

In the above expression, the first term of the right hand side (R.H.S.) requires marginalizing out π_{jk} and is computed as

$$\begin{aligned} &p\left(\mathbf{Z}_j^{:,k} = 0 \mid \beta_{(k)}\right) \\ &= \int_0^1 p\left(\mathbf{Z}_j^{:,k} = 0 \mid \pi_{jk}\right) p\left(\pi_{jk} \mid \beta_{(k)}\right) d\pi_{jk} \\ &= \frac{\Gamma(\alpha_j)\,\Gamma\left(\alpha_j\bar{\beta}_{(k)} + N_j\right)}{\Gamma\left(\alpha_j\bar{\beta}_{(k)}\right)\Gamma(\alpha_j + N_j)} \end{aligned} \tag{16}$$

where $\bar{\beta}_{(k)} \triangleq 1 - \beta_{(k)}$. For each $k \ge 1$, let us use l_k to define the mapping $\beta_{l_k} = \bar{\beta}_{(k)}$and let $\mathbf{L}_k = \{1,\ldots,K\} \setminus \{l_1,\ldots,l_k\}$, then the second term in the right hand side (R.H.S.) of Eq (15) can be computed as the following

$$\begin{aligned} &p\left(\mathbf{Z}_j^{:,>k} = 0 \mid \beta_{(k)}\right) \\ &= \lim_{K\to\infty} \int p\left(\beta_{\mathbf{L}_k} \mid \beta_{(k)}\right) p\left(\mathbf{Z}_j^{:,\mathbf{L}_k} = 0 \mid \beta_{\mathbf{L}_k}\right) d\beta_{\mathbf{L}_k} \\ &= \lim_{K\to\infty} \int \Pi_{l\in\mathbf{L}_k} p\left(\beta_l \mid \beta_{(k)}\right) p\left(\mathbf{Z}_j^{:,l} = 0 \mid \beta_l\right) d\beta_{\mathbf{L}_k} \\ &= \lim_{K\to\infty} \left(\int_0^{\beta_{(k)}} p\left(\beta_l \mid \beta_{(k)}\right) p\left(\mathbf{Z}_j^{:,l} = 0 \mid \beta_l\right) d\beta_l\right)^{K-k} \end{aligned} \tag{17}$$

In the above limmand, we first simplify the integral to the following

$$\begin{aligned} &\int_0^{\beta_{(k)}} p\left(\beta_l \mid \beta_{(k)}\right) p\left(\mathbf{Z}_j^{:,l} = 0 \mid \beta_l\right) d\beta_l \\ &= \frac{\Gamma(\alpha_j)}{\Gamma(\alpha_j + N_j)} \sum_{u_{jk}=0}^{N_j} \begin{bmatrix} N_j \\ u_{jk} \end{bmatrix} \alpha_j^{u_{jk}} \\ &\times \frac{\Pi_{t"=1}^{u_{jk}} t"}{\Pi_{t'=1}^{u_{jk}}\left(\frac{\tau}{K} + t'\right)} \left[1 + \frac{\tau}{K}\sum_{p=1}^{u_{jk}} \frac{\Pi_{t=1}^{p-1}\left(\frac{\tau}{K} + t\right)}{p!}\bar{\beta}_{(k)}^{p}\right] \end{aligned} \tag{18}$$

where $\begin{bmatrix} n \\ m \end{bmatrix}$ denotes the unsigned Stirling numbers of the first kind. In the above expression, we note that the term $\frac{\Gamma(\alpha_j)}{\Gamma(\alpha_j+N_j)}\sum_{u_{jk}=0}^{N_j}\begin{bmatrix} N_j \\ u_{jk} \end{bmatrix}\alpha_j^{u_{jk}} \times (...)$ can be written as

$$\begin{aligned} &\frac{\Gamma(\alpha_j)}{\Gamma(\alpha_j + N_j)} \sum_{u_{jk}=0}^{N_j} \begin{bmatrix} N_j \\ u_{jk} \end{bmatrix} \alpha_j^{u_{jk}} \times \left(\text{ term involving } u_{jk}\right) \\ &= \sum_{u_{jk}=0}^{N_j} \frac{\begin{bmatrix} N_j \\ u_{jk} \end{bmatrix}\alpha_j^{u_{jk}}}{\sum_{u'_{jk}=0}^{N_j}\begin{bmatrix} N_j \\ u'_{jk} \end{bmatrix}\alpha_j^{u'_{jk}}} \times \left(\text{ term involving } u_{jk}\right) \\ &= \sum_{u_{jk}=0}^{N_j} \tilde{\omega}_{u_{jk}} \times \left(\text{ term involving } u_{jk}\right) \end{aligned}$$

where $\sum_{u_{jk}=0}^{N_j}\tilde{\omega}_{u_{jk}}$ is equal to 1. Continuing from Eq (18) and substituting it in Eq (17), we can write

$$\begin{aligned} &p\left(\mathbf{Z}_j^{:,>k} = 0 \mid \beta_{(k)}\right) \\ &= \lim_{K\to\infty} \left(\sum_{u_{jk}=0}^{N_j} \tilde{\omega}_{u_{jk}} \frac{\Pi_{t"=1}^{u_{jk}} t"}{\Pi_{t'=1}^{u_{jk}}\left(\frac{\tau}{K} + t'\right)}\left(1 + \frac{\tau}{K}R_{u_{jk}}\right)\right)^{K-k} \end{aligned}$$

which simplifies to (see *supplementary material [9]*)

$$
\begin{aligned}
& p\left(\mathbf{Z}_j^{:,>k}=0 \mid \beta_{(k)}\right) \\
&= \lim_{K\to\infty}\left(1+\sum_{u_{jk}=0}^{N_j}\tilde{\omega}_{u_{jk}}\frac{\tau\left(T_{u_{jk}}-H_{u_{jk}}\right)}{K+\tau H_{u_{jk}}}\right)^{K-k} \\
&= \exp\left(\tau\sum_{u_{jk}=0}^{N_j}\tilde{\omega}_{u_{jk}}\left(T_{u_{jk}}-H_{u_{jk}}\right)\right) \qquad (19)
\end{aligned}
$$

where we have defined $R_{u_{jk}} \triangleq \sum_{p=1}^{u_{jk}} \frac{\Pi_{t=1}^{p-1}\left(\frac{\tau}{K}+t\right)}{p!}\bar{\beta}_{(k)}^{p}$, $T_{u_{jk}} \triangleq \sum_{p=1}^{u_{jk}} \frac{\bar{\beta}_{(k)}^{p}}{p}$ and the harmonic number $H_{u_{jk}} = \sum_{h=1}^{u_{jk}} \frac{1}{h}$. Plugging the likelihood of (19) and (16) into Eq (15) and using Eq (14), we obtain

$$
\begin{aligned}
& p\left(\beta_{(k)} \mid \beta_{(k-1)}, \mathbf{Z}^{:,\geq k}=0\right) \\
& \propto \tau\beta_{(k-1)}^{-\tau}\beta_{(k)}^{\tau-1}1\left(0\leq\beta_{(k)}\leq\beta_{(k-1)}\right)\times \\
& \Pi_{j=1}^{J}\frac{\Gamma\left(\alpha_j\bar{\beta}_{(k)}+N_j\right)}{\Gamma\left(\alpha_j\bar{\beta}_{(k)}\right)}\exp\left(\tau\sum_{u_{jk}=0}^{N_j}\tilde{\omega}_{u_{jk}}\left(T_{u_{jk}}-H_{u_{jk}}\right)\right) \\
& \propto \beta_{(k)}^{\tau-1}1\left(0\leq\beta_{(k)}\leq\beta_{(k-1)}\right)\times \\
& \Pi_{j=1}^{J}\sum_{v_{jk}=0}^{N_j}\begin{bmatrix}N_j\\ v_{jk}\end{bmatrix}\left(\alpha_j\bar{\beta}_{(k)}\right)^{v_{jk}}\exp\left(\tau\sum_{u_{jk}=0}^{N_j}\tilde{\omega}_{u_{jk}}\sum_{p=1}^{u_{jk}}\frac{\bar{\beta}_{(k)}^{p}}{p}\right)
\end{aligned}
$$

Introducing the auxiliary variables $\mathbf{v}=\left(v_{jk}:\forall j,k\right)$, we get

$$
\begin{aligned}
& p\left(\beta_{(k)} \mid \beta_{(k-1)}, \mathbf{Z}^{:,\geq k}=0, \mathbf{v}\right) \\
& \propto \beta_{(k)}^{\tau-1}\left(\bar{\beta}_{(k)}\right)^{\sum_j v_{jk}}\exp\left(\tau\sum_{u_{jk}=0}^{N_j}\tilde{\omega}_{u_{jk}}\sum_{p=1}^{u_{jk}}\frac{\bar{\beta}_{(k)}^{p}}{p}\right) \\
& 1\left(0\leq\beta_{(k)}\leq\beta_{(k-1)}\right) \qquad (20)
\end{aligned}
$$

The auxiliary variable v_{jk} can be sampled as

$$
p\left(v_{jk} \mid \mathbf{v}^{-jk}\right) \propto \begin{bmatrix}N_j\\ v_{jk}\end{bmatrix}\left(\alpha_j\bar{\beta}_{(k)}\right)^{v_{jk}} \qquad (21)
$$

Sampling from Eq (20) can be obtained using Adaptive Rejection Sampling (ARS) procedure as the distribution is *log-concave* in $\beta_{(k)}$. Sampling of auxiliary variable v_{jk} is straight-forward as it is sampling from a discrete distribution with finite support.

4.2 Sampling $\mathbf{Z}_j$

Given other variables, $\mathbf{Z}_j^{ik}$ (for $k=1,\ldots,K^{\dagger}-1$) can be sampled from the following Gibbs conditional posterior distribution

$$
\begin{aligned}
& p\left(\mathbf{Z}_j^{ik}=1 \mid \mathbf{Z}_j^{i,-k}, \mathbf{Z}^{-ji}, \mathbf{W}_j^i, \beta, \Phi, \mathbf{X}_j^i, \rho\right) \\
& \propto p\left(\rho \mid \mathbf{Z}_j^{ik}=1, \mathbf{Z}_j^{i,-k}, \mathbf{Z}^{-ji}, \beta\right) \\
& \times p\left(\mathbf{Z}_j^{ik}=1 \mid \mathbf{Z}_j^{-i,k}, \beta_{(k)}\right) p\left(\mathbf{X}_j^i \mid \mathbf{Z}_j^{ik}=1, \mathbf{Z}_j^{i,-k}, \mathbf{W}_j^i, \Phi\right) \\
& = \frac{n_j^{-i,k}+\alpha_j\beta_{(k)}}{\beta^{*}} p\left(\mathbf{X}_j^i \mid \mathbf{Z}_j^{ik}=1, \mathbf{Z}_j^{i,-k}, \mathbf{W}_j^i, \Phi\right) \qquad (22)
\end{aligned}
$$

where $n_j^{-i,k}=\sum_{i'\neq i}\mathbf{Z}_j^{i'k}$. In the above posterior expression, we note the dependency of β^{*} on the sample of $\mathbf{Z}_j^{ik}$.

4.3 Sampling $\beta_{(k)}$

To sample from the posterior of each $\beta_{(k)}$, we use auxiliary variable sampling [3, 18]. We define $\mathbf{m}=\left(m_{jk}:\forall j,k\right), \mathbf{l}=\left(l_{jk}:\forall j,k\right)$ and $n_{jk}=\sum_i \mathbf{Z}_j^{i,k}$ where $m_{jk}\in\{0,1,\ldots,n_{jk}\}$, $l_{jk}\in\{0,1,\ldots,N_j-n_{jk}\}$, and sample $\beta_{(k)}$ (for $k=1,\ldots,K^{\dagger}$) and auxiliary variables $\mathbf{m},\mathbf{l}$ as below

$$
\begin{aligned}
& p\left(\beta_{(k)} \mid \beta^{-(k)}, \mathbf{m}, \mathbf{l}, \mathbf{Z}, \rho\right) \\
& \propto \beta_{(K^{\dagger})}^{\tau_0}\beta_{(k)}^{m_k-1}\left(1-\beta_{(k)}\right)^{l_k}1\left(\beta_{(k+1)}\leq\beta_{(k)}\leq\beta_{(k-1)}\right) \qquad (23)
\end{aligned}
$$

$$
p\left(m_{jk} \mid \mathbf{m}^{-jk}, \mathbf{l}, \beta, \mathbf{Z}, \rho\right) \propto \begin{bmatrix}n_{jk}\\ m_{jk}\end{bmatrix}\left(\alpha_j\beta_k\right)^{m_{jk}} \qquad (24)
$$

$$
p\left(l_{jk} \mid \mathbf{l}^{-jk}, \mathbf{m}, \beta, \mathbf{Z}, \rho\right) \propto \begin{bmatrix}\bar{n}_{jk}\\ l_{jk}\end{bmatrix}\left(\alpha_j\bar{\beta}_k\right)^{l_{jk}} \qquad (25)
$$

where $\mathbf{m}_k \triangleq \sum_j m_{jk}$, $\mathbf{l}_k \triangleq \sum_j l_{jk}$, $\bar{n}_{jk}=N_j-n_{jk}$. For detailed derivation, see *supplementary material [9]*.

4.4 Sampling Parameters Φ, $\mathbf{W}_j$ and λ_j for NHFA-PGM model

Under the model described in Eq (8), Gibbs conditional posterior of Φ can be written as

$$
\begin{aligned}
& p\left(\Phi^{i,:} \mid \mathbf{Z}_{1:J}, \mathbf{W}_{1:J}, \mathbf{X}_{1:J}, \lambda_{1:J}, a_\phi, b_\phi, \mathbf{s}\right) \\
& \propto \Pi_{k=1}^{K^{\dagger}}\left(\Phi^{ik}\right)^{a_\phi+\sum_{j,l}s_j^{ilk}-1}\exp\left\{-\left(b_\phi+\sum_{j,l}\mathbf{H}_j^{lk}\right)\Phi^{ik}\right\} \qquad (26)
\end{aligned}
$$

The auxiliary variables $\mathbf{s}=\left\{s_j^{ilk},\forall j,l\right\}_{k=1}^{K^{\dagger}+1}$ are drawn as

$$
\begin{aligned}
& p\left(s_j^{il1},\ldots s_j^{ilK^{\dagger}}, s_j^{il\left(K^{\dagger}+1\right)} \mid \text{rest}\right) \\
& \propto \frac{\mathbf{X}_j^{il}!}{s_j^{il1}!\ldots s_j^{ilK}!s_j^{il\left(K^{\dagger}+1\right)}!}\Pi_{k=1}^{K^{\dagger}}\left(\Phi^{ik}\mathbf{H}_j^{lk}\right)^{s_j^{ilk}}\lambda_j^{s_j^{il\left(K^{\dagger}+1\right)}} \\
& \qquad \text{s.t. } \sum_{p=1}^{K^{\dagger}+1}s_j^{ilp}=1 \qquad (27)
\end{aligned}
$$

Gibbs sampling update for $\mathbf{W}_{ji}$ conditioned on the remaining variables is given as

$$
\begin{aligned}
& p\left(\mathbf{W}_j^{l,:} \mid \mathbf{Z}_j, \Phi, \mathbf{X}_j, \lambda_j, a_{w_j}, b_{w_j}, \mathbf{t}\right) \\
& \propto \Pi_{k=1}^{K^{\dagger}}\left(\mathbf{W}_j^{lk}\right)^{a_{w_j}+\sum_i t_j^{ilk}-1} \\
& \times \exp\left\{-\left(b_{w_j}+\sum_i\left(\Phi\mathbf{D}_{\mathbf{Z}_j^{i,:}}\right)^{ik}\right)\mathbf{W}_j^{lk}\right\} \qquad (28)
\end{aligned}
$$

where $\mathbf{D}_{\mathbf{Z}_j^{l,:}}$ denotes a diagonal matrix constructed from $\mathbf{Z}_j^{l,:}$ and the auxiliary variables $\mathbf{t} = \left\{ t_j^{ilp}, \text{for each } i \right\}_{p=1}^{K^\dagger+1}$ are sampled as below

$$p\left(t_j^{il1}, \ldots t_j^{ilK^\dagger}, t_j^{il\left(K^\dagger+1\right)} \mid \text{rest}\right) \propto \frac{\mathbf{X}_j^{il}!}{t_j^{il1}! \ldots t_j^{ilK^\dagger}! t_j^{il\left(K^\dagger+1\right)}!} \Pi_{k=1}^{K^\dagger} \left(\Phi^{lk}\mathbf{H}_j^{lk}\right)^{t_j^{ilk}} \lambda_j^{t_j^{il\left(K^\dagger+1\right)}} \quad \text{s.t. } \sum_{p=1}^{K^\dagger+1} t_j^{ilp} = 1 \tag{29}$$

Gibbs sampling of λ_j remains similar to the variables Φ and $\mathbf{W}_j$. The required posterior distributions are given as

$$p\left(\lambda_j \mid \mathbf{Z}_{1:J}, \mathbf{W}_{1:J}, \Phi, \mathbf{X}_{1:J}, \mathbf{r}\right) \propto \lambda_j^{a_{\lambda_j} + \sum_{i=1}^{M}\sum_{l=1}^{N_j} r_j^{il} - 1} \exp\left\{-\left(b_{\lambda_j} + MN_j\right)\right\} \tag{30}$$

For each i, l, the auxiliary variables r_j^{il} can be sampled as

$$r_j^{il} \mid \text{rest} = \text{Binomial}\left(\mathbf{X}_j^{il}, \frac{\lambda_j}{\Phi^{i,:}\left(\mathbf{H}_j^{l,:}\right)^\top + \lambda_j}\right) \tag{31}$$

4.5 Sampling Parameters Φ, $\mathbf{W}_j$, σ_{w_j} and σ_{n_j} for NHFA-GGM model

Gibbs sampling updates for these parameters remains same as the updates described in [8].

4.6 Sampling α_j

Once again, Gibbs sampling updates for α_j remains same as the updates described in [8]. The hyperparameter α_j controls the variation of A_j (source-specific beta process) around B (parent beta process). As α_j vary from a low to high value, its concentration on the random distribution B increases. Since the random distribution B is shared across different data sources, this increases the probability of sharing more and more factors.

4.7 Predictive Likelihood

Let us denote the test data from the j-th source by matrix $\tilde{\mathbf{X}}_j$ and the corresponding matrix factorization as $\tilde{\mathbf{X}}_j = \Phi\left(\tilde{\mathbf{Z}}_j \odot \tilde{\mathbf{W}}_j\right) + \tilde{\mathbf{E}}_j$, then the Monte Carlo approximation of predictive likelihood can be written as

$$p\left(\tilde{\mathbf{X}}_j \mid \mathbf{X}_{1:J}\right) \approx \frac{1}{LR}\sum_{r=1}^{R}\sum_{l=1}^{L} p\left(\tilde{\mathbf{X}}_j \mid \Phi^{[l]}, \tilde{\mathbf{Z}}_j^{[r]}, \tilde{\mathbf{W}}_j^{[r]}\right) \tag{32}$$

where L is the number of training samples $\left\{\Phi^{[l]}\right\}$ and R is the number of test samples $\left\{\tilde{\mathbf{Z}}_j^{[r]}, \tilde{\mathbf{W}}_j^{[r]}\right\}$.

5 Experiments

We carry out a variety of experiments to demonstrate the effectiveness of the proposed NHFA model. To illustrate the behavior of our model, we first perform experiments with a synthetic dataset, for which the true dimensionality of subspaces and other parameters are known. Through these experiments, we show the correct recovery of these parameters. Next, we demonstrate the usefulness of our model for two real-world tasks – text modeling and content based image retrieval. For both synthetic and real-world tasks, the priors for hyperparameters are chosen as the following : $\tau_0 = 1$, $\alpha_j \sim \text{gamma}(1,1)$. For NHFA-GGM, both the shape and the scale parameters of gamma priors for σ_ϕ, σ_{nj} and σ_{wj} were set to 1. For NHFA-PGM, since we expect the results to be sparse we set the shape parameters of hyperparameters as $a_\phi = 1$, $a_{w_j} = 1$ whereas the scale parameters were sampled as : $b_\phi \sim \text{gamma}\left(1, 1/\mu_\phi\right)$, $b_{w_j} \sim \text{gamma}\left(1, 1/\mu_{w_j}\right)$, where $\mu_\phi \triangleq \frac{1}{MK}\sum_{i,k}\Phi^{ik}$ and $\mu_{w_j} \triangleq \frac{1}{N_j K}\sum_{l,k}\mathbf{W}_j^{lk}$. *Supplementary material* provides further details.

5.1 Experiments-I : Synthetic Data

We create a synthetic dataset similar to [8] so that we can show the benefits of our model vis-à-vis the model considered in [8]. For this dataset, we create twelve 100-D binary factors and distribute them across the two data sources termed as $\mathscr{D}_1$ and $\mathscr{D}_2$. The first four factors were used by the data points from $\mathscr{D}_1$, the next four factors were used by the data points from $\mathscr{D}_2$ while the last four factors were shared by data points across both $\mathscr{D}_1$ and $\mathscr{D}_2$. We generated the mixing configuration matrices $\mathbf{Z}_1$ and $\mathbf{Z}_2$ randomly with discrete support $\{0,1\}$. The weight/coefficient matrices of the two sources, i.e. $\mathbf{W}_1$ and $\mathbf{W}_2$ were sampled from gamma distribution with shape and scale parameters 1 and 2 respectively. The using these parameters along with noise (with rate parameter 0.1 for both sources), the data for both $\mathscr{D}_1$ and $\mathscr{D}_2$ were generated from Poisson distributions according to the generative model described in section 3.

To verify the correctness of the inference, we run the slice sampler along with Gibbs updates as detailed in section 4 starting with the value of $K^\dagger$ as one. We observe that the sampler converges to the true value of the number of factors (i.e. $K^\dagger = 12$) in less than 100 iterations. However, we run the sampler longer to verify that the mode of the posterior over the number of factors remains at this true value. It can be seen from Figure 2 that the model correctly learns all the factors and their scores automatically.

To compare the computational efficiency of our slice sampler with the approximate Gibbs sampler of [8], we see that both methods need to sample $\{\beta, \mathbf{Z}, \Phi, \mathbf{W}\}$. Sampling Φ and $\mathbf{W}$ remain identical in both cases. Only sampling of β and $\mathbf{Z}$ differ. In case of the approximate Gibbs sampler, β conditioned on $\{\mathbf{m}, \mathbf{l}, \mathbf{Z}\}$ is drawn from a beta distribution whereas in the slice sampler, β conditioned on $\{\rho, \mathbf{m}, \mathbf{l}, \mathbf{Z}\}$ uses adaptive rejection sampling (ARS) (see Eq (23)). Although not as fast as sampling from a beta distribution, ARS is quite efficient due to sampling in one dimensional space. When comparing sampling of $\mathbf{Z}$, the slice sampler is more efficient than the approximate Gibbs sampler. The main difference lies in sampling the number of new factors

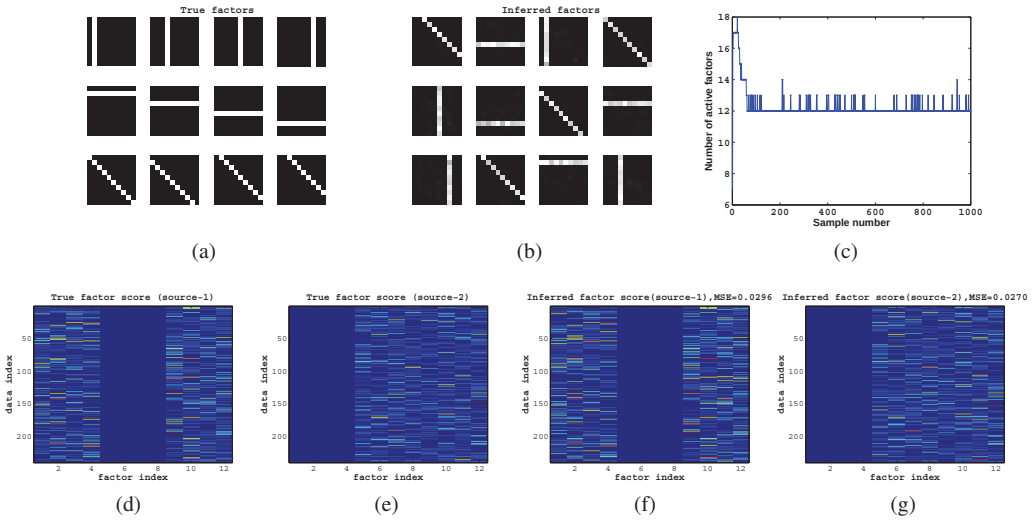

Figure 2: Synthetic data experiments (a) *true* factors (b) *inferred* factors (c) Number of active factors vs. Gibbs iterations (d) *true* factor scores for source-1 (e) *true* factor scores for source-2 (f) *inferred* factor scores for source-1 (g) *inferred* factor scores for source-2; for an easy comparison with (d) and (e), columns of (f) and (g) are permuted according to the mapping between (a) and (b).

for i-th data point from j-th source (say F_{ji}). In slice sampling, F_{ji} grows gradually based on the slice variable and requires sampling of F_{ji} new β_k variables using ARS. On the other hand, the approximate Gibbs sampler, to sample F_{ji}, approximates an intractable integral (Eq (3.22) in [8]) using Monte Carlo samples. For the synthetic experiments described above, slice sampler takes about *100 iterations* to converge and runs in **6.67** minutes. On the other hand, the approximate Gibbs sampler [8] requires about *1000 iterations* to converge to the true number of factors taking totally **52.3** minutes. This timing analysis is performed using a Windows PC with Intel i7@3.4 GHz and 8 GB RAM.

5.2 Experiments-II : Real Data

5.2.1 Results using NIPS 0-12 Dataset

Our first real-world dataset is the NIPS 0-12 dataset, which contains the articles from the proceedings of *Neural Information Processing Systems* (NIPS) conference published between 1988 and 1999. In this dataset[1], text articles are divided into nine different sections/tracks plus one miscellaneous section/track. We work with nine sections which are Cognitive Science (CS), Neuroscience (NS), Learning Theory (LT), Algorithms and Architecture (AA), Implementations (IM), Speech and Signal Processing (SSP), Visual Processing (VP), Applications (AP) and Control, Navigation and Planning (CNP). We treat each section as one data source and generate nine different term-document matrices. In doing so, we ensure that these matrices use a common dictionary for terms[2].

[1] A processed version of this dataset is made available by Y. W. Teh at http://www.gatsby.ucl.ac.uk/~ywteh/research/data.html.

[2] It is possible to make a common dictionary by merging the terms from all the sections.

Through this dataset, we intend to show the strength of our model for transfer learning. For this, we choose section VP as target data source while other sections (one at a time) as auxiliary data sources. We follow this scheme for *two* reasons. *First*, we believe that although there may be underlying sharing across different sections, each section has its own focus and differs in distribution. NHFA exploits the sharing across different sections while still retaining the focus of individual section by maintaining a hierarchy. *Second*, this allows us to compare our results with two baselines (i.e. Gupta et al [8] and Teh et al [18]) as they use the same dataset with similar settings.

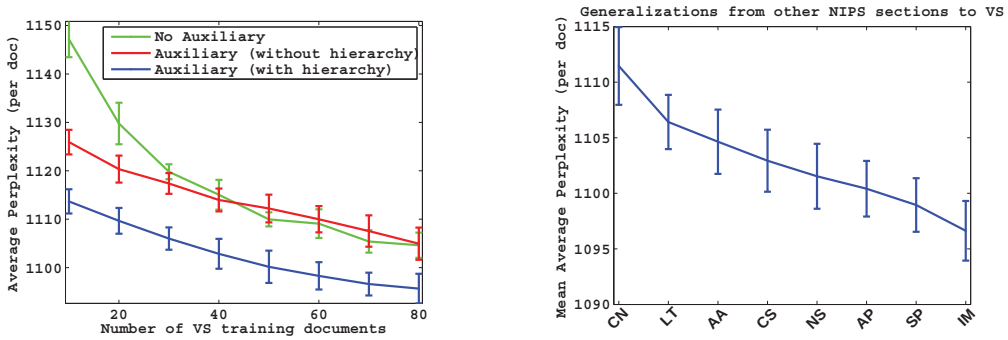
Out of 1564 articles in total across nine sections, we randomly select 80 articles from each section and use them for training. Similar to [8, 18], the test set is chosen from VP section (consisting of 44 articles) and kept fixed throughout the experimentation with NIPS 0-12 dataset. On average, the number of words per article are approximately 1000. We compute the perplexity on the test set and report the performance in terms of *perplexity per document*. Given the training data $\mathbf{X}_{1:J}$ and a test set $\tilde{\mathbf{X}}_j$ from j-th data source, perplexity per document (PPD) is defined as

$$\text{PPD}\left(\tilde{\mathbf{X}}_j\right) = \exp\left(-\frac{1}{\tilde{N}}\log\, p\left(\tilde{\mathbf{X}}_j \mid \mathbf{X}_{1:J}\right)\right) \qquad (33)$$

where $\tilde{N}$ denotes the number of documents in the test set.

Baseline Methods To compare the proposed model with other related works, we choose *three* baselines.

- Baseline-1a ["No auxiliary"]: This baseline is a linear Poisson-gamma based factor analysis model which totally relies on the target data and does not use any auxiliary data for training.



(a) (b)

Figure 3: Perplexity results using NIPS 0-12 dataset (a) perplexity for the test data from VP section vs. number of VP training documents (averaged over 10 runs); for Baseline-1a, Baseline-1b and the proposed NHFA-PGM (b) mean average perplexity for the test data from VP section (averaged over 10 runs) versus different NIPS auxiliary sections (except VP) using the proposed NHFA-PGM.

- Baseline-1b ["Auxiliary - without hierarchy"]: This baseline is a linear Poisson-gamma based factor analysis model similar to the first baseline but also uses auxiliary data simply by augmenting them with the target data and does not maintain any hierarchy.
- Baseline-2 [NHFA-GGM (approx.)]: This baseline is the hierarchical model recently proposed in Gupta et al [8]. This model attempts to learn both shared and individual subspace using a hierarchical model. The data distributions for this model are similar to the NHFA-GGM model proposed in section 2, however it uses a series of approximations for inference.
- Baseline-3 [HDP]: This baseline is the hierarchical Dirichlet process proposed in [18]. This model uses a hierarchy for sharing topics across different groups.

Experimental Results We run the proposed NHFA-PGM and the baseline models and compute the perplexity per doc (PPD) values over 10 independent runs. For each run, we select VP section as the target source while other sections as auxiliary (one at a time) and compute perplexity values for increasing number of target training articles varying from 10 to 80 at a step of 10. By doing this, our intention is to see at what point, the auxiliary data ceases to improve the generalization performance.

Figure 3 depicts the perplexity results for the proposed model and compares with baseline-1a and baseline-1b. It can be seen from Figure 3a that the proposed NHFA-PGM model achieves significantly lower perplexity compared to the two baselines irrespective of the number of training articles from VP section. When comparing the results between the baseline-1a and the baseline 1b, one can see that as long as the number of training documents from VP section are less than 50, the performance of baseline-1b is better than that of baseline 1a. This goes according to our intuition as the auxiliary source help learning some patterns. But, as soon as there are enough training articles from the VP section, simply combining auxiliary data does not help and the performance of baseline-1b goes lower than that of baseline-1a. This clearly shows that the baseline-1b is prone to negative transfer learning whereas the same is not true for the proposed NHFA-PGM model which retains low perplexity values compared to baseline-1a. Figure 3b focuses on the results of NHFA-PGM model and provides the mean average perplexity for each auxiliary section (a single figure measure computed by averaging the perplexity values along increasing number of training documents). It can be seen from the figure that the top three auxiliary sections that help maximum generalization are IM, SP and AP in decreasing order of performance.

Table 1 lists a comparison of the proposed NHFA-PGM and NHFA-GGM models with baseline-2 and baseline-3. One can clearly see that since the NIPS 0-12 data matrices are count data, both NHFA-PGM and the baseline-3 achieve significantly lower perplexity compared to NHFA-GGM and baseline-2. The proposed NHFA-PGM clearly outperforms the baseline-3, suggesting that Poisson-gamma model may be a better fit to the count data than topic models. When comparing the perplexity values of baseline-2 and NHFA-GGM, NHFA-GGM achieves better performance. This gain in performance is attributed to the exact inference made possible by slice sampling.

Method	*Average Log Perplexity (per doc)*
NHFA-GGM (approx.) [8]	6232.5 ± 164.0
Proposed NHFA-GGM	5945.3 ± 16.8
HDP [18]	2862.5 ± 268.3
Proposed NHFA-PGM	$\mathbf{1102.9 \pm 6.5}$

Table 1: Comparison of various hierarchical models in terms of average log perplexity per doc (PPD) using NIPS 0-12 dataset.

5.2.2 Results using NUS-WIDE Animal Dataset

Our second dataset is a subset of the NUS-WIDE [2] dataset. This subset comprises of 3411 images involving 13 animals. We use six different low-level features [2] namely 64-D color histogram, 144-D color correlogram, 73-D edge direction histogram, 128-D wavelet texture, 225-D block-wise color moments. We construct a real-valued feature matrix for each animal category and treat it as a separate data source under our hierarchical framework. This is done with a belief that features of different animal categories vary in their distributions. Out of 3411 images, 2054 images are used for training while the remaining images are held for testing. This is done for comparing with [21, 22, 1, 8] where an *identical* training and test settings were used.

Unlike NIPS 0-12 data, the feature matrices for NUS-WIDE images are real valued. Therefore, we use NHFA-GGM model (instead of NHFA-PGM model) to learn the factor matrix Φ and $\mathbf{H}_j$ (for $j = 1,\ldots,13$). Having learnt the matrix Φ, we construct the test matrix $\tilde{\mathbf{X}}$ from the test data and compute its subspace coefficient matrix $\tilde{\mathbf{H}} = \left[\tilde{\mathbf{h}}_1,\ldots,\tilde{\mathbf{h}}_{\tilde{N}}\right]$ such that $\tilde{\mathbf{X}} \approx \Phi\tilde{\mathbf{H}}$. To retrieve the similar images for the r-th test image, cosine similarity between its subspace coefficient vector $\tilde{\mathbf{h}}_r$ and the subspace coefficient matrices of the training data (i.e. $\mathbf{H}_j$ for each $j = 1,\ldots,13$) is computed. The retrieved images are ranked in decreasing order of their similarity values.

Evaluation Measures and Baselines To evaluate the performance of the proposed method, we use standard precision-scope curve[3] and mean average precision (MAP). We compare the result of the proposed NHFA-GGM with the recent state-of-the-art multi-view learning techniques [1, 21, 22] and "NHFA-GGM (approx.)" model [8] (the model used as baseline-2 for NIPS 0-12 experiments).

Experimental Results Table 2 compares the proposed NHFA-GGM with the recent works [1, 21, 22, 8] on image retrieval using NUS-WIDE animal dataset. This comparison is based on the mean average precision (MAP) values presented in [1, 8]. We note that the dataset used for generating these results (including the test set) is *identical*. For the works in [1, 21, 22], the MAP values are reported using 60 topics. The NHFA-GGM (approx.) model of [8] is a nonparametric model and reports the total number of shared and individual factors varying between 5 to 8. On the contrary, our proposed NHFA-GGM, which is exact version of NHFA-GGM (approx.), uses 30 to 40 factors typically. It can be clearly seen from the Table 2, that NHFA-GGM outperforms all the baselines. Focusing on the exact and approximate models, we report the precision scope curve which shows that NHFA-GGM model achieves clearly higher precision at initial scope levels which is often quite important in search applications as users are typically more interested in top few search results.

[3] Precision scope (P@N) curve reports precision values for top N retrieved items.

Method	*Mean Average Precision (MAP)*
DWH [21]	0.153
TWH [22]	0.158
MMH [1]	0.163
NHFA-GGM (approx.) [8]	0.1789 ± 0.0128
Proposed NHFA-GGM	$\mathbf{0.1945 \pm 0.0115}$

Table 2: Comparison of image retrieval results with recent state-of-the art multi-view learning and hierarchical modeling techniques using NUS-WIDE animal dataset.

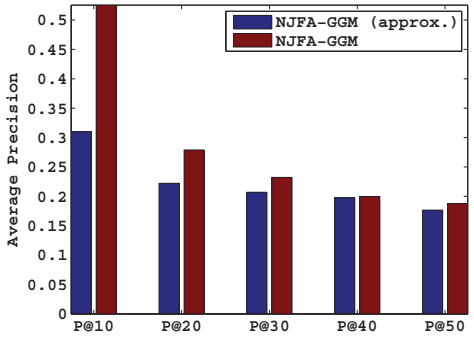


Figure 4: Comparison of the retrieval performances in terms of precision-scope (P@N) curve for NHFA-GGM and NHFA-GGM (approx.)[8].

6 Conclusion

We have presented a novel slice sampler for restricted hierarchical beta process (R-HBP). A key feature of the proposed sampler is that it keeps the inference tractable, even when the prior and the likelihood are non-conjugate – therefore, it can be applied for joint modeling of multiple data sources in more elaborate settings. Another key feature of this sampler is that it offers an exact inference and does not need a series of approximations used by standard Gibbs samplers [11, 16, 8]. We have combined this sampler with two hierarchical factor analysis data models – linear Poisson-gamma model and linear Gaussian-Gaussian model for modeling count data and real-valued data respectively. To show the utility of the proposed models, we applied them for learning shared and individual subspaces across multiple data sources where unlike parametric models, the subspace dimensionalities were learned automatically. Using two real world datasets (NIPS 0-12 and NUS-WIDE animal datasets), we have demonstrated that our method outperforms recent state-of-the-art methods for text modeling and content based image retrieval. Further, the slice sampling derived in this paper is general and can be utilized for other matrix factorizations.

Semantic Understanding of Professional Soccer Commentaries

Hannaneh Hajishirzi, Mohammad Rastegari, Ali Farhadi, and Jessica K. Hodgins
{hannaneh.hajishirzi, mrastega, afarhadi, jkh}@cs.cmu.edu

Abstract

This paper presents a novel approach to the problem of semantic parsing via learning the correspondences between complex sentences and rich sets of events. Our main intuition is that correct correspondences tend to occur more frequently. Our model benefits from a discriminative notion of similarity to learn the correspondence between sentence and an event and a ranking machinery that scores the popularity of each correspondence. Our method can discover a group of events (called *macro-events*) that best describes a sentence. We evaluate our method on our novel dataset of professional soccer commentaries. The empirical results show that our method significantly outperforms the state-of-the-art.

1 Introduction

This paper addresses the problem of understanding professional commentaries of soccer games. Computational understanding of such domains has crucial impact in automatic generation of commentaries and also in game analysis and strategic planning. To this end, one needs to infer the semantics of natural language text; this is an extremely challenging problem. Understanding professional soccer commentaries further introduces interesting and challenging issues. For example, commentators do not typically talk about all the events of the game, selecting what is important. Also, they use a variety of phrases to report similar events. For example, a simple event of "A passes to B" can be commentated in several different ways: "A feeds B", "A and B in a nice combination", "A, what a beautiful way to B". Further, in some cases, commentators create a group of events and only mention a *macro-event*. For example, instead of saying "A passes to B, B passes to C, and C passes to D", the commentators report this whole sequence of events as "Team X is coming forward" or "nice attack by X". Also, professional commentators report several statistics and related information about the league, players, stadium, and weather during less interesting segments of a play.

A general solution to understanding such a complex phenomenon requires infering about game-related events, reasoning in terms of very complex paraphrases, and also forming high-level understandings of game events. Most recent work in semantic parsing of natural language translates individual sentences into the underlying meaning representations. Meaning representations are usually logical forms represented with events or relations among entities. The problem of semantic parsing can be formulated as learning to map between sentences and meaning representation in a supervised fashion [Zettlemoyer and Collins, 2005]. One can decrease the amount of supervision in specific controlled domains, such as RoboCup soccer [Chen *et al.*, 2010; Hajishirzi *et al.*, 2011] and Windows help instructions [Branavan *et al.*, 2009]. Recently, [Liang *et al.*, 2009] introduce a general semantic parsing technique that is not restricted to a specific domain, but is not scalable to large datasets due to the complexity of the model. In this paper, we introduce an algorithm that does not require domain-specific knowledge and is scalable to larger datasets.

We formulate the problem of understanding soccer commentaries as learning to align sentences in commentaries to a list of events in the corresponding soccer game. Our approach does not need expensive supervision in terms of correspondences between sentences and events. Similar to previous work [Liang *et al.*, 2009; Chen *et al.*, 2010], we use loose temporal alignments between sentences in commentaries and events of games. We pair sentences with several events that occur in the rough temporal vicinities of the sentences. Each pair consists of a sentence and a corresponding event. We then try to distinguish between correct and incorrect pairs. We rank pairs based on how consistently they appear in other places. We use a discriminative notion of similarity to reason about repetitions of pairs of sentences and events. The core intuition is that,

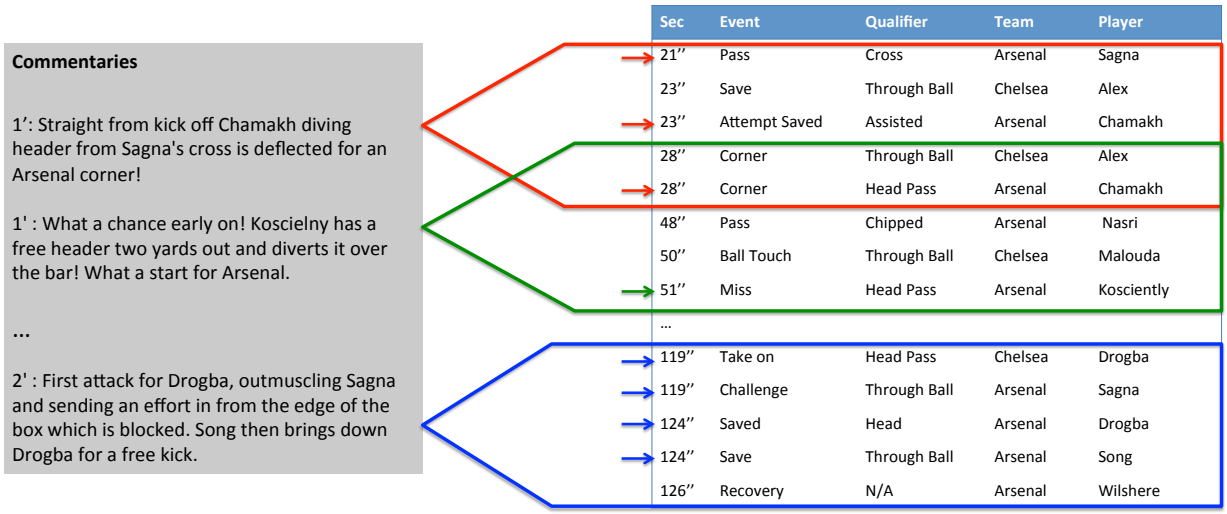

Figure 1: Examples of sentences in the commentaries with corresponding buckets of events. The correct correspondences in each bucket are marked with arrows.

under appropriate similarity metrics, correct pairs of sentences and events appear more often across several games. Our model is capable of forming macro-events and matching a group of events to a sentence. Experimental evaluations show that our method significantly outperforms the state of the art in our dataset and a benchmark of RoboCup soccer dataset. Our qualitative results demonstrate how our method can form macro-events and reason about complex paraphrases. We also introduce a dataset of eight English Primier League games with their commentaries and the accurate log of the game events. For evaluation purposes, we manually aligned sentences with events. Our dataset is publicly available.

1.1 Related Works

There are several approaches that learn to map natural language texts to meaning representations. Some researchers use full supervision in general and controlled domains [Zettlemoyer and Collins, 2005; Ge and Mooney, 2006; Snyder and Barzilay, 2007] . More recent work reduces the amount of required supervision in mapping sentences to meaning representations in controlled domains. [Kate and Mooney, 2007] introduce an Expectation Maximization (EM) approach with weak supervision in the GeoQuery and Child corpora. [Branavan *et al.*, 2009; Vogel and Jurafsky, 2010] use a reinforcement learning approach to map Windows help or navigational instructions to real events in the world. The supervision is weakly provided through interactions with a physical environment. [Chen *et al.*, 2010; Hajishirzi *et al.*, 2011] introduce EM-like approaches to map RoboCup soccer commentaries to real events of the game. They use weak supervision through the temporal alignments between sentences and events or the domain knowledge about soccer events. [Poon and Domingos, 2009] introduce an unsupervised method that finds is-a relationships among the entities in the domain by taking advantage of clustering structures of sentences and arguments. Most previous work take advantage of the special properties of the underlying domains and cannot be applied to the commentaries of real soccer games due to the complexity of the domain.

The closest work to ours are [Liang *et al.*, 2009; Bordes *et al.*, 2010] that introduce an interesting generative approach and a ranking system to map texts to meaning representations, respectively. The generative approach of [Liang *et al.*, 2009] is general, but it is not scalable as we demonstrate in our experiments. The system of [Bordes *et al.*, 2010] uses different models and objectives for ranking functions. Also, these two methods, as well as most previous work, has a one-to-one restriction in mapping between segments and events. This is not a well-suited assumption for real-world domains like professional soccer commentaries. One exception is the work of [Branavan *et al.*, 2010] that finds high-level comments which is specific to Windows instructions.

2 Problem Definition

The input to our problem is a representation of temporal evolution of the world state (sequence of events) and a natural language text (sequence of sentences). We use a rough alignment between every sentence S_i and a list of events $B(S_i)$; we call this list of events a *bucket* associated with the sentence S_i. We form a *pair* by combining a sentence S_i with an event in the corresponding bucket $B(S_i)$. The sentence S_i may describe zero, one, or more events in the bucket $B(S_i)$. Our objective is to find events in $B(S_i)$ that correspond to the sentence S_i. Figure 1 shows three example sentences and a portion of corresponding buckets in the dataset. Due to very loose alignments between sentences

and events one has to consider a rather big bucket size.

Every event $e(\vec{x})$ is represented by an event type e and a list of arguments $\vec{x}$. The arguments of an event can take two different types: string and categorical. String arguments correspond to lexical properties, such as player names, that can be easily found through a lexical analysis. Often only a part of the argument appears in the text. For instance, "Steven Gerrard" might be referred as "Gerard" or "Steven". Categorical arguments correspond to discrete values in the domain such as `zone` (`back, left, front, right`). These arguments might be addressed in many different ways and cannot be identified with lexical search. In fact, identical words to the categorical values do not convey any information. For ease of notations, we call each event e_j, discarding all the arguments.

Professional Soccer Commentaries Dataset (PSC) This paper introduces a dataset of professional soccer commentaries aligned with real events that occur in each match. We also provide ground-truth alignments between sentences in the commentaries and events of the game for evaluation purposes only. Our model does not use any domain specific knowledge, but we focus on soccer domain in this paper.

Commentaries: Commentaries are English texts, generated by professional soccer commentators. We collect the professionally generated commentaries for matches in the 2010-2011 season of English Premier League from `Espn.net`.

Soccer Events: The events are all actions that occur around the ball and are labeled by human annotators. We use the F24 soccer data feed collected for the EPL by Opta [Opta, 2012]. The F24 data is a time-coded feed that lists all events within the game with a player, team, event type, minute, and second for each event. Each event has a type together with a series of arguments describing it. The data include different types of events, such as goals, shots, passes (with start/end point), tackles, clearances, cards, free kicks, corners, offsides, substitutions and stoppages. This data is currently used for real-time online visualizations of events, as well as post-analysis for prominent television shows and newspaper articles.

Ground Truth Alignments: For evaluation purposes only, we generate the ground truth labels which denote the correct mapping between sentences in the commentary and events in the F24 Opta feed. Every sentence can be matched with zero, one, or more events in the bucket.

The commentaries, list of events with their time stamp, and the features are publicly available at: `http://vision.ri.cmu.edu/data-sets/psc/psc.html`.

This domain is much more complex than the RoboCup soccer, weather, or Windows instruction datasets used by previous work. The sentences are more complex. The commentator uses different phrases to refer to an identical event type. Most of the arguments in the events are categorical, which cannot be aligned using lexical analysis. For some buckets, there are no events that correspond to the sentence because the sentence is either a general statement about the game or is about game statistics, weather, etc. For many buckets, multiple events correspond to the sentence. Figure 3 shows examples of sentences with 2, 3, or 4 corresponding events that our approach finds correctly.

3 Approach

The problem of semantic understanding of commentaries can be formulated as establishing alignments between a sentence and a set of events. This, in fact, reduces to figuring out which events in the bucket $B(S_i)$ correspond to the sentence S_i. Every sentence can be aligned with multiple events in the corresponding bucket. Providing supervision at the level of sentence-event alignments is tedious and expensive. Instead, we use the weak supervision in the rough alignments between sentences and events.

To set up notations, assume that the input to our system includes s sentences represented by $S_i, i \in \{1 \dots s\}$, and each sentence S_i corresponds to a bucket of events $B(S_i)$. Without loss of generality, we can assume that each bucket has n events: $B(S_i) = \{e_1^i, e_2^i, ..., e_n^i\}$. Each sentence S_i can be aligned with a group of events, meaning that each sentence S_i can be matched to a member of the power set of $B(S_i)$, called $\mathcal{P}(B(S_i))$. The cardinality of this set is $2^{|B(S_i)|}$. The problem of finding a group of events that best aligns to the sentence S_i can be formalized as:

$$\arg \max_{\mathcal{E}_i \in \mathcal{P}(B(S_i))} \rho(S_i, \mathcal{E}_i) \quad | \mathcal{E}_i | \leq k \tag{1}$$

where ρ is a ranking function that scores *pairs* of sentences and events based on the quality of the correspondence and $\mathcal{E}$ is a group of events (called macro-event) of a cardinality less than or equal to k. This is obviously a search in an exponential space. Later, we show that Equation 1 is a form of budgeted submodular maximizations. We also show how we can search this space more efficiently.

Before going into the details of our search method, we need to specify a ranking function, ρ. The main role of ρ is to score the quality of each pair; each pair includes a sentence and an event in the corresponding bucket. The core idea is that under an "appropriate" notion of similarity, a good pair tends to appear more consistently across the data. For that, one needs to somehow count the number of appearances of a pair. Simple counting does not work because exact sentences and events may not appear more than once. However, the underlying pattern of correspondence between a sentence and an event may appear rather frequently. Therefore, we need a way of capturing the patterns of correspondences for pairs and then score them based on the popularity of the patterns in the dataset.

3.1 Learning Pair Models

We adopt a discriminative approach that learns the characteristic correspondence patterns that distinguishes a pair from all other pairs. Recently in computer vision, Exemplar Support Vector Machines (ESVM) has shown great success in learning what is unique about an image that can distinguish it from all other images [Malisiewicz *et al.*, 2011; Shrivastava *et al.*, 2011]. The main idea is very simple, yet surprisingly effective. To learn what is unique about each example, one can fit an SVM with only one positive instance and large number of negative instances. The main intuition is that an example can be defined as what it is not, rather than what it is like. Despite being susceptible to overfitting, the proposed hard negative mining method gets away from this issue.

This framework suits our problem setting very well because we learn for all pairs of sentences and events in each bucket and do not need training labels for which pairs are correct. We extend this approach to learn models of pairs (called *PairModel*). A *PairModel* demonstrates how to weigh features of a pair against each other in a discriminative manner. If a learned model for a pair produces a positive score when applied to another pair, then two pairs share analogous patterns of correspondences.

Feature Vector: The features for each pair $p_{ij} = (S_i, e^i_j)$ of a sentence S_i and event e^i_j are $\vec{\Phi}_{ij} = (\vec{\Phi}_{S_i}, \vec{\Phi}_{e^i_j}, \vec{\Phi}_{st_i})$. $\vec{\Phi}_{S_i}$ is a binary vector representing the sentence S_i, where each element in the vector shows the presence of a word in the vocabulary. The vocabulary consists of frequent words in the domain except the words that can occur in the string arguments. For instance, the vocabulary does not include the `player names`. $\vec{\Phi}_{e^i_j}$ is a binary vector representation of the event e^i_j that includes the event type together with its arguments. Each element in the vector represents the presence of the corresponding event type or the argument value in e^i_j. $\vec{\Phi}_{st_i}$ is a binary vector with one element for every string type in the event arguments. Every element in the vector st_i denotes if the string argument is matched with a word in the sentence. For instance, the feature vector has an argument to demonstrate whether or not the `player name` (argument of the event e^i_j) has occurred in the sentence S_i.

Pair Model: For each pair $p_{ij} = (S_i, e^i_j)$, we fit a linear SVM to a set of pairs with $p_{ij} = (S_i, e^i_j)$ as a positive training example and a large number of pairs as negative examples. The negative examples are selected in a way that encourages weak similarities between patterns of correspondences compared to the positive example. To do that, we try to make sure that none of the examples in the negative set contains the identical sentence or event to the positive example. If the events (resp. sentences) are similar (in Euclidean distance) to the event (resp. sentence) of the positive example, we make sure that sentences (resp. events) are very different (more details in Algorithm 1 and Section 4.1). We balance the examples by weighting them accordingly. The algorithm is sketched in Algorithm 1.

The output of the *PairModel* M_{ij} learned for the pair $p_{ij} = (S_i, e^i_j)$ is a weight vector $\vec{\Theta}_{ij}$. The confidence of applying M_{ij} over a new pair $p_{kl} = (S_k, e^k_l)$ is computed as *Conf*$(M_{ij}, p_{kl}) = \vec{\Theta}_{ij} \cdot \vec{\Phi}_{kl}$. This confidence compares the patterns of correspondence between S_i and e^i_j and patterns of correspondence between S_k and e^k_l. The *PairModel* tries to weight the features that are most important to discriminate the corresponding pair from the rest. High confidence means that those important features are "on" in an example; therefore, it is following the same pattern. Figure 2 demonstrates three *PairModels*, the top-weight words for each pair, and the nearest sentence under the learned patterns of correspondences. Non-discriminative measures of similarity like Cosine or Euclidean are not desirable because they treats all the dimensions in the same way. For comparisons and experimental evaluations please see Section 4.

A *PairModel* M_{ij} *likes* the pair p_{kl} by *Conf*(M_{ij}, p_{kl}). We score the similarity between two pairs by looking at their mutual *likeness* meaning that they both share analogous patterns of correspondence. We can now start reasoning about the popularity of *PairModels* by aggregating all mutual likeness scores. To propagate the mutual likeness information we adopt a strategy similar to Google PageRank.

3.2 Ranking Pairs

The input to this module are all of the pairs and their learned models, and the output is the popularity scores of the pairs relative to each other. A pair $p_{ij} = (S_i, e^i_j)$ is likely to be a correct match if the pattern of correspondence extracted by M_{ij} occurs frequently relative to other pairs; this means that p_{ij} is popular . A pair is frequent if many popular pairs like that pair with high confidence. This resembles similar problems in ranking Web pages.

We adopt an approach similar to the PageRank algorithm [Brin and Page, 1998] utilized by Google to order the importance of webpages. PageRank examines the graph of webpages (called Webgraph) and assigns a high score to a web page if many important pages link to the page.

Here, we are interested in computing relative scores of the pairs. We build a graph of pairs by assigning a node to each pair. Unlike the Webgraph, the edges are undirected and weighted. We assign a weighted edge between a pair p_{ij} and a pair p_{kl}, if they mutually like each other (i.e., *Conf*$(M_{ij}, p_{kl}) > 0$ and *Conf*$(M_{kl}, p_{ij}) > 0$). We call this edge the *popularity* link. The graph also has self loops; i.e., a node can also be connected to itself if *Conf*$(M_{ij}, p_{ij}) > 0$. This self loop encodes how com-

petent each *PairModel* is. The weight of an edge between pairs denotes the degree of confidence that each pair likes the other. Calibrating pairmodels against each other is an issue. For that, we use the rank of each pair among all the other pairs to model the degree of confidence. More formally, the weight of the edge between p_{ij} and p_{kl} is $1/(rank(M_{kl}, p_{ij}).rank(M_{ij}, p_{kl}))$ where $rank(M_{kl}, p_{ij})$ shows the order of p_{ij} among all the pairs p with $\mathit{Conf}(M_{ij}, p) > 0$.

Our approach, *PairRank* (sketched in Algorithm 3), first builds the adjacency matrix of the graph using the edges and their weights. The ranking function $\rho(p_{ij})$ iteratively computes the popularity score of a pair according to Equation 2. At every iteration, $\rho(p_{ij})$ is the expected sum (with probability d) of the score of the adjacent pairs (computed at the previous iteration) and the self confidence value:

$$\rho(p_{ij}) = (1-d)\mathit{Conf}(M_{ij}, p_{ij}) + d \sum_{p_{kl} \in T(p_{ij})} \frac{\rho(p_{kl})}{edge(p_{ij}, p_{kl})} \quad (2)$$

where $edge(p_{ij}, p_{kl}) = rank(M_{ij}, p_{kl}).rank(M_{kl}, p_{ij})$, $T(p_{ij})$ is the set of adjacent nodes to p_{ij}, d is a damping factor, and $\rho(p_{ij})$ is initialized by random values.

At iteration 1, only popularity links with length 1 are considered; $\rho(p_{ij})$ only adds up the scores of the pairs that are directly linked to p_{ij}. In next iterations, longer popularity paths are considered; the effect of indirectly linked pairs to p_{ij} is included in the scores of neighboring pairs. We are not interested in adding the effect of pairs with high distances from p_{ij}. We control the expected length of the popularity paths with a damping factor d.

At the end of each iteration, we divide $\rho(p_{ij})$ by the frequency of the type of the event e^i_j to discount the biases in the dataset. For instance, there are 8,597 events with type `pass` in the dataset. However, only 451 (5.2%) of the `pass` events occur in the ground-truth events. The last step of each iteration is to normalize the scores of all the pairs.

3.3 Searching for Good Correspondences

Now that we learn *PairModels* and rank the pairs based on their popularity, we return to our main goal of aligning sentences with events. If we knew that each sentence only corresponds to one event we could report the $\arg\max$ of the outputs of the *PairRank* scores. However, most of the times sentences correspond to groups of events merged together, called macro-events.

Dealing with macro events requires learning *PairModels* and performing the *PairRank* on pairs with macro-events. To pair a sentence S with a macro-event $\mathcal{E}$ we need to define how to merge events to form macro-events. Assume that we want to merge (S, e_1) and (S, e_2) to form the pair $(S, \mathcal{E})$. A *PairModel* for $(S, \mathcal{E})$ should learn the correspondences between the sentence S and all the events in $\mathcal{E}$. To learn the *PairModel* for $(S, \mathcal{E})$, we use (S, e_1) and (S, e_2) as positive examples and generate negative examples as before (Algorithm 1). This results in a *PairModel* M. The confidence of the *PairModel* M over a pair $\mathrm{P}_k = (S_k, \acute{\mathcal{E}})$ is the maximum confidence of the M on pairs of the sentence with every event in the macro event $\acute{\mathcal{E}}$ (Algorithm 2). $Conf(M, \mathrm{P}_k) = \max_{e^k_j} Conf(M, p_{kj} = (s_k, e^k_j))$.

To score the popularity of every pair with macro-event, we run the *PairRank* method by adding one node per each pair with macro-event. The edge weights to the new node are computed as the maximum score of all the events in the macro-event (Algorithm 2).

As mentioned before, the search space for each sentence is the exponential space of all possible ways of merging events in each bucket (Equation 1). However, the good news is that our main objective function in Equation 1 is submodular. Because by definition, the ranking function works as a maximization of a set function over the examples that form the macro-event. This results in $\rho(S_i, \mathcal{E}_j) + \rho(S_i, e_k) \geq \rho(S_i, (\mathcal{E}_j \oplus e_k)) + \rho(S_i, (\mathcal{E}_j \ominus e_k))$. We denote the operation of merging two events by $\oplus$ and the inverse operation by $\ominus$. These operators resemble the union and intersections over sets. Now we can adopt a greedy approximation of Equation 1 with reasonable error bounds [Goundan and Schulz, 2009; Dey *et al.*, 2012; Krause *et al.*, 2008]. The core intuition is that instead of searching the exponential space of all possible ways of merging events, we start with the best scoring event and merge events that maximizes the marginal benefits of merging them. We keep merging until we observe no benefit of doing so. More formally, our recursive greedy solution is:

$$\mathcal{E}^l = \mathcal{E}^{l-1} \oplus \mathcal{A}^*$$
$$\mathcal{A}^* = \arg \max_{A \in B(S) \setminus D} \rho(S, \mathcal{E}^l \oplus A) - \rho(S, \mathcal{E}^l) \quad (3)$$

where $\mathcal{E}^0 = \emptyset$, $\mathcal{E}^l$ is the macro-event, of cardinality at most l, that we want to grow using the merging procedure $\oplus$, and D is the set of all elements in $\mathcal{E}^l$. We stop this procedure after k steps or when merging events does not help (Algorithm 4).

To elaborate more, assume that for the sentence S we are given the bucket of events $B(S) = \{e_1, e_2, e_3\}$. We start with the best scoring event in $B(S)$, let's say e_1. We then look for the event that maximizes the marginal benefit (Equation 3), let's say e_2. We now check to see if there is any gain in forming macro-events. If there is no gain we stop and report e_1 as the answer. Otherwise, we form the macro-event $e_{12} = e_1 \oplus e_2$ by merging the two events together, ($\mathcal{E}^2 = e_{12}$). We now can go to the next layer and search for the next event that maximizes the marginal benefit, let's say e_3. If adding e_3 helps, we form a new macro-event, $\mathcal{E}^3 = e_{123} = e_{12} \oplus e_3$. This procedure may result in aligning sentences with macro-events of cardinality up to k. In our experiments we set the $k = 4$.

Algorithm 1. *PairModel*$(S, \mathcal{E})$
- Input: pair $(S, \mathcal{E})$

1. $\vec{\Phi} \leftarrow$ feature vector for (S, e_j) $\forall e_j$ in $\mathcal{E}$
2. $Pos \leftarrow \cup_j (S, e_j)$ $\forall e_j$ in $\mathcal{E}$
   // Generate Negative Examples
3. $\forall$ pairs: sort $D_e \leftarrow Dist(e, e_k)$, sort $D_S \leftarrow Dist(S, S_k)$
4. $Neg_1 \leftarrow (S_k, e_l) : S_k \in D_{S1:N}, e_l \in D_{e_{end-N:end}}$
5. $Neg_2 \leftarrow (S_k, e_l) : S_k \in D_{Send-N:end}, e_l \in D_{e_{1:N}}$
6. $Neg \leftarrow Neg_1 \cup Neg_2$
7. return $SVM(Pos, Neg)$ with the weight vector $\vec{\Theta}$

Algorithm 2. *ComputeConf*(p_{ij}, p_{kl})
- Input: pairs $p_{ij} = (S_i, \mathcal{E}_j^i)$ and $p_{kl} = (S_k, \mathcal{E}_l^k)$ with feature vector Φ_{kl}

1. $M_{ij} \leftarrow$ *PairModel*(p_{ij}) (Alg. 1)
2. $\vec{\Theta}_{ij} \leftarrow$ weight vector of M_{ij}
3. *Conf*$(M_{ij}, p_{kl}) \leftarrow \max_{e_l \in \mathcal{E}_l^k} \vec{\Theta}_{ij}.\vec{\Phi}_{kl}$

Algorithm 3. *PairRank*$(pairs)$
- Output: ranks of all the pairs

//Build adjacency matrix
1. for pairs p_{ij}, p_{kl}:
   (a) *ComputeConf*(p_{ij}, p_{kl}) (Alg. 2)
   (b) $\vec{P}_i \leftarrow$ scores of applying M_{ij} on all pairs
   (c) $\vec{P}_k \leftarrow$ scores of applying M_{kl} on all pairs
   (d) $edge(p_{ij}, p_{kl}) \leftarrow (rank(p_{kl})$ in $\vec{P}_i)$ and $(rank(p_{ij})$ in $\vec{P}_k)$

//Iteration t
2. while $|\vec{\rho}_t - \vec{\rho}_{t-1}| \geq \epsilon$
   (a) for every pair $p_{ij} = (S_i, e_j^i)$
      i. $\rho_t(p_{ij}) \leftarrow$ Equation 2
      ii. $\rho_t(p_{ij}) \leftarrow \frac{\rho_t(p_{ij})}{\text{frequency}(e_j^i.type)}$
      iii. $\rho_t(p_{ij}) \leftarrow \frac{\rho_t(p_{ij})}{sum(\vec{\rho})}$
3. return $\vec{\rho}_t$

Algorithm 4. *ReturnMacroEvent*$(pairs,k)$
- Output: best macro event for each bucket

1. Iteration $l = 0$:
   (a) $\mathcal{E} = \emptyset$
   (b) $\vec{\rho} \leftarrow$ *PairRank*$(pairs)$
   (c) $\mathcal{A}^* \leftarrow$ highest ranked pair in each bucket according to $\vec{\rho}$
2. Iteration l:
   (a) $\mathcal{E} \leftarrow \mathcal{E} \oplus \mathcal{A}^*$
   (b) $\vec{\rho}_1 \leftarrow$ *PairRank*$(pairs \cup \mathcal{A}^*)$
   (c) for e_i in every bucket:
      i. $\vec{\rho}_2 \leftarrow$ *PairRank*$(pairs \cup \mathcal{E} \oplus e_i)$
      ii. $\Delta_{e_i} \leftarrow \rho_2(S, \mathcal{E} \oplus e_i) - \rho_1(S, \mathcal{E})$
   (d) $\mathcal{A}^* \leftarrow \arg\max_{e_i} \vec{\Delta}$
3. repeat until $l \leq k$
4. return $\mathcal{E}$ for each bucket

4 Experiments

We evaluate our method on how accurately it aligns sentences in professional soccer commentaries with events in the actual games. We use our professional soccer dataset as the main testbed and compare our method with state-of-the-art methods and several different baselines. For comparison, we also test our model on a benchmark dataset of RoboCup soccer [Chen and Mooney, 2008].

4.1 Professional Soccer Commentaries

Our dataset consists of time-stamped commentaries and event logs of 8 games in 2010-2011 season of English Premier League. For evaluation purposes, we label ground-truth annotations for the correspondences between sentences and events throughout the dataset. There are 935 sentences, 14,845 events, 2,147 words, and 306 players in total. Each sentence on average has 16.62 words. For each sentence in the commentaries, we assign a bucket by selecting events that occur in an interval of 150 seconds around the time the sentence has been generated. We then pair each sentence with all of the events in the corresponding bucket. This results in 38,332 pairs. On average, there are 42 pairs in each bucket. Of course, not all of these pairs are correct correspondences. There are in total 1,404 pairs labeled as correct matches in the ground-truth labels. On average there are 2 correct pairs in each bucket.

Each event is represented with an event type followed by a list of its arguments. There are 55 event types and several arguments defined in the event logs. Examples of the arguments are the `time` that the event occurred, the `player name` that is the agent of the event, the `team name`, the `outcome` of the event, and the `body part`. Most of the arguments are categorical. The only string field is the `player name` that can provide useful information for finding initial guesses for correct correspondences. However, identical player names occur in multiple events in each bucket.

We apply our method (Algorithm 4) on this dataset. We start by pairing sentences with events in the corresponding buckets. This step is followed by learning *PairModels* for every pair $p_{ij} = (S_i, e_j^i)$ that has at least one matching player name between the sentence S_i and the event e_j^i. The features for the pair p_{ij} are $\Phi_{ij} = (\Phi_{S_i}, \Phi_{e_j^i}, \Phi_{st})$ where Φ_{S_i} and $\Phi_{e_j^i}$ are binary vectors representing the sentence and the event, and Φ_{st} is an integer value corresponding to the number of players matched between the sentence and 3 consecutive events. At the first step, each *PairModel* M_{ij} is trained using one positive example (S_i, e_j^i) and 100 negative examples generated automatically as follows. We sort all sentences according to their Euclidean distance to the sentence S_i and all events based on their Euclidean distance to the event e_j^i. We generate negative examples from the sentences and events that are not identical to S_i and e_j^i. Half of the negative pairs are generated from the sentences with lowest distance to S_i and events with highest distance to e_j^i. The other half are generated by pairing sentences with highest distance to S_i and events with lowest distance to e_j^i. We make sure that no pairs with matching player names between sentences and events exist in the negative set. This way we try to make sure that negative examples do not contain the same patterns of correspondences as the positive examples.

Sentence	Chelsea looking for a penalty as Malouda's header hits Koscielny, not a chance as it hit him in the stomach.	First attack for Drogba, outmuscling Sagna and sending an effort in from the edge of the box which is blocked, and Song then brings down Drogba for a free kick	Two poor efforts for the price of one from the free kick as Nasri's shot hits the wall before Vermaelen fires wide.
Event	**E:**Foul **Q:**Head Pass **T:**Chelsea **P:**Malouda	**E:**Challenge **Q:** Through Ball **T:**Arsenal **P:**Sagna	**E:**Miss **Q:** Pass **T:**Arsenal **P:**Sagna
Top Weights	'penalty', 'looking', 'hits', 'Foul', 'header', 'chance', 'chelsea', 'city', 'clear','half'	'box', 'first','edge','block', 'attack','effort', 'kick', 'free','wide', break	'shot', 'wide', 'two', 'hits', 'poor','one' 'free', 'kick', 'Miss', 'chelsea'
Top Sentences	Alex Song is too strong for Malouda, who goes down looking for a foul. Nothing given by the referee.	Foul by Arshavin as he blocks Essien's attack. He's lucky to escape a card there.	A choppy start from both sides with possession swapping hands regularly. Wilshere gets stuck into Jovanovic and gives away a free kick.

Figure 2: Qualitative analysis of *PairModels*: Each column corresponds to a *PairModel* trained with a sentence on the first row and the event in the second row as the positive example. The learned *PairModel* assigns high values to the features corresponding to the words in the third row. The closest sentence under the learned pattern of correspondences between the sentence and the event in the pair is shown in the fourth row.

We then fit linear SVMs [Fan *et al.*, 2008] to the positive and negative examples for each pair. We use LibLinear with $c = 100$. We weight positive instances to avoid the affects of unbalanced data. We then apply the *PairRank* with the damping factor $d = 0.5$ to rank the pairs based on their consistency. To create macro-events we run Algorithm 4 with $k = 4$.

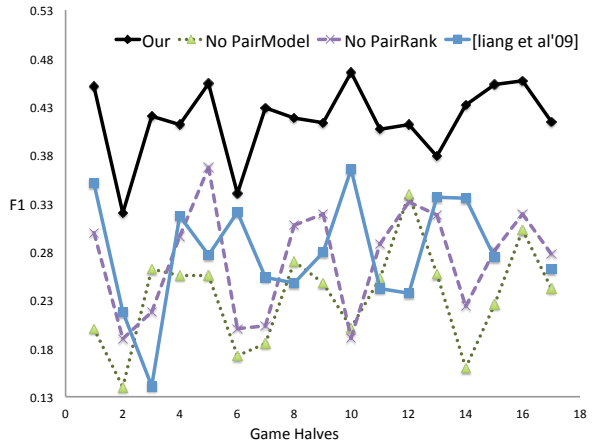

Figure 4: Our method outperforms the state-of-the-art on all the games.

Method	F_1	AUC	Precision	Recall
No PairModel	23.3	36.4	37.3	17.1
No PairRank	27.3	37.4	**39.4**	21.1
MIL	11.0	36.8	37.3	7.0
[Liang *et al.*, 2009]	27.6	N/A	27.2	28.4
Our approach	**41.4**	**46.8**	33.9	**54.0**

Table 1: Average performance of different approaches over all games in our dataset.

4.1.1 Comparisons

We compare the performance of our method with the state-of-the-art method of [Liang *et al.*, 2009], a Multiple Instance Learning (MIL) method of [Andrews *et al.*, 2002], and two baselines.As the main testbed, we use our professional soccer dataset where we have 16 half games (8 games). Figure 4 plots the comparisons mentioned above on all 16 half games. We use F_1 as the measure of performance per half game. Table 1 contains the results of all the aforementioned methods using F_1 and AUC measures averaged over all half games.

[Liang *et al.*, 2009] This approach uses a generative model that learns the correspondence between sentences and events. We use their publicly available code and run their method for 5 iterations. To have a generous comparison, we report the best results achieved during 5 iterations (sometimes the best performance is achieved earlier than 5 iterations). Table 1 shows the average accuracy of this method over all the games. Our model outperforms this method by more than 14% in F_1. Due to the complexity of the model, [Liang *et al.*, 2009] cannot take advantage of the full capacity of the domain. It runs out of memory on a machine with $8GB$ of memory when using 6 arguments. The reason is that this approach grows exponentially with the number of arguments whereas our approach grows linearly. To be compatible, we decrease the number of arguments of every event to 3 arguments `team, player-name, qualifier`, in all the comparisons. Even after decreasing the number of arguments, the method of [Liang *et al.*, 2009] still runs out of memory for one game that consist of long sentences (half-game 16). Due to memory limitations, this method is not applicable to all games at the same time; we perform all comparisons on half game basis.

Multiple Instance Learning (MIL): Finding correct correspondences given the rough alignments between sentences and events can be formulated as a multiple instance learning problem. Pairs of sentences with all the events in the corresponding bucket can be considered as bags. A positive bag includes at least one correct pair. Negative bags do not include any correct pairs. We utilize the same procedure that we used to generate negative pairs to produce neg-

Figure 3: Qualitative exampels of macro-events discovered by our method in correspondence to sentences. For instance, in sentence 4 the commentator is implicitly describing a foul occurred in the game which led to a card but there is no explicit mention of 'Foul' nor 'Card' in the sentence. However, our method can discover both events correctly.

ative bags. We use the publicly available implementation of mi-SVM [Andrews *et al.*, 2002] for comparisons. Table 1 compares the performance of our method with that of MIL. Our method outperforms MIL significantly (by about 30% in F_1). We postulate that, the complex structure in the correspondences between sentences and events cannot be discovered by latent methods like mi-SVM.

No PairModel Baseline: To analyze the importance of discriminative notion of correspondences, we also compare our method with a baseline that uses a non-discriminative notion of correspondences between sentences and events. In our model, we replace the *PairModel* with a non-discriminative similarity metric (such as Cosine or Euclidean). In our experiments, we did not find any considerable difference between the non-discriminative distances. Table 1 shows performance numbers using Euclidean distance. Replacing the *PairModel* with non-discriminative distances decreases the performance by 16%.

No PairRank Baseline: We also replace the PairRank component in our model with a voting scheme. In this baseline, we compute the confidence scores of applying all *PairModels* on all pairs. We then compute the score of each pair by counting the number of non-negative confidence values. Replacing the *PairRank* model with a voting scheme decreases the performance by 13%.

We also analyze the importance of incorporating macro-events. To this purpose, we enforce our model to produce macro-events at multiple different lengths. Figure 5 plots the F_1 measures against the maximum cardinality of macro events. Forming macro-events up to the cardinality 4 dramatically boosts the performance. Our experiments do not show any boost by adding longer macro-events.

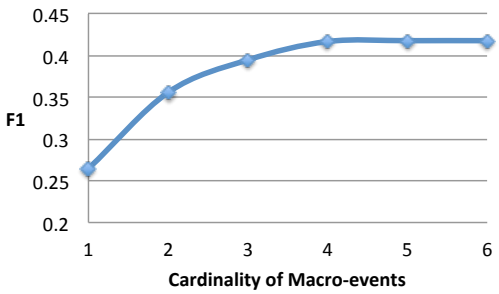

Figure 5: Average F_1 over all games by increasing the number of iterations.

4.1.2 Qualitative Examples

Figure 3 shows examples of macro-events discovered by our method in correspondence to the sentences in the first column. The correspondences are not obvious and show deep understanding of sentences in commentaries. To further analyze the intermediate result of our model, we looked at the top scoring dimensions in the features for specific events. For example for event `Foul`, the highest weights correspond to 'Foul','free','kick','card', 'dangerous', and 'late'. For the event `Save`, the highest dimensions corresponds to 'Save','goal', 'shot','block','ball'.

4.2 RoboCup Soccer Commentary

We also compare our approach with the state-of-the-art methods in the RoboCup soccer dataset [Chen and Mooney, 2008]. The data is based on commentaries of four championship games of the RoboCup simulation league. Each game is associated with a sequence of human comments in English and the Robocup soccer events that happen in the original game tagged with time. Sentences are on average 5.7 words long. There are 17 events, including actions with the ball or other game information. The buckets are generated by mapping sentences and the events that occurred within 5 time steps of when the comments were recorded. There are in total 1,919 pairs and average of 2.4 events per bucket. It is assumed that every sentence is matched with at most one event. Following previous approach, we adopt the scheme of 4 fold cross validation and report the micro-averaged results for four games in terms of F_1. Table 2 demonstrates that our method outperforms the state-of-the-art. [Hajishirzi *et al.*, 2011] uses domain knowledge about soccer events instead of buckets information. [Chen *et al.*, 2010] can achieve the F_1 of 79.1% by initializing with the output generated by [Liang *et al.*, 2009]. We cannot directly compare [Bordes *et al.*, 2010] to other methods in the table because a) they use Bigram and Trigram features. This gives a strong boost for games like the game 3 where most sentences are 3 or 4 words long. b) they use post processing heuristics to find sentences with no matching events. With the same heuristics our model can go up to an F1 of 84.57 (cf. 83.0 of [Bordes *et al.*, 2010]).

Approach	F_1
[Chen and Mooney, 2008]	67.0
[Chen *et al.*, 2010]	73.5
[Liang *et al.*, 2009]	75.7
[Hajishirzi *et al.*, 2011]	77.9
Our approach	**81.6**

Table 2: The average F_1 scores of 4 fold cross validation in the Roboup dataset.

5 Discussion and Future Work

In this paper, we present an approach that can form macro-events that best describe sentences given a bucket of events that correspond to each sentence. Our method takes advantage of a discriminative notion of correspondence coupled with a ranking technique to find popular pairs in our professional soccer dataset. To avoid exponential searches over all possible ways of merging events in a bucket we use a greedy approximation with reasonable bounds. We update the macro-events incrementally by combining events that provide maximum marginal benefits. Our experiments show significant improvement over the state-of-the-art methods. In fact, our method achieves an F_1 measure of 41.4% comparing to the state of the art performance of 27.6% in professional soccer commentaries. Also, our method outperforms state-of-the-art on RoboCup dataset.

Our method can assign a macro-event to a part of the text that cannot be further segmented. For instance, the first part of the sentence 1 in Figure 3 is mapped to both pass and corner. We argue that we need to first align sentences with macro-events and then start the segmentation with a relaxed one-to-one assumption. Discovering strategy-level macro events still remains open. For example our method cannot align attack or coming forward with series of passes. We believe that we can make progress by augmenting our method with more powerful Natural Language Processing tools that improves lexical analysis. Also, our method cannot address the cases where there is no event corresponding to a sentence. Our formulation forces at least one event per sentence. This is not desirable for many domains including soccer commentaries where there are several sentences that do not correspond to any ball-related event in the game. Our ultimate goal is to build an automatic commentary generation for professional soccer games. This paper is one step forward toward that big goal.

Acknowledgments

The authors would like to thank Opta for providing the data on event logs of the soccer games, Emma Brunskill for the useful discussions, and anonymous reviewers for their insightful comments on the paper. Ali Farhadi is supported by the ONR-MURI grant N000141010934.

Weighted Sets of Probabilities and Minimax Weighted Expected Regret: New Approaches for Representing Uncertainty and Making Decisions*

Abstract

We consider a setting where an agent's uncertainty is represented by a set of probability measures, rather than a single measure. Measure-by-measure updating of such a set of measures upon acquiring new information is well-known to suffer from problems; agents are not always able to learn appropriately. To deal with these problems, we propose using *weighted sets of probabilities*: a representation where each measure is associated with a *weight*, which denotes its significance. We describe a natural approach to updating in such a situation and a natural approach to determining the weights. We then show how this representation can be used in decision-making, by modifying a standard approach to decision making—minimizing expected regret—to obtain *minimax weighted expected regret* (MWER). We provide an axiomatization that characterizes preferences induced by MWER both in the static and dynamic case.

1 Introduction

Agents must constantly make decisions; these decisions are typically made in a setting with uncertainty. For decisions based on the outcome of the toss of a fair coin, the uncertainty can be well characterized by probability. However, what is the probability of you getting cancer if you eat fries at every meal? What if you have salads instead? Even experts would not agree on a single probability.

Representing uncertainty by a single probability measure and making decisions by maximizing expected utility leads to further problems. Consider the following stylized problem, which serves as a running example in this paper. The baker's delivery robot, T-800, is delivering $1,000$ cupcakes from the bakery to a banquet. Along the way, T-800 takes a tumble down a flight of stairs and breaks some of the cupcakes. The robot's map indicates that this flight of stairs must be either ten feet or fifteen feet high. For simplicity, assume that a fall of ten feet results in one broken cupcake, while a fall of fifteen feet results in ten broken cupcakes.

	1 broken	10 broken
$cont$	10,000	-10,000
$back$	0	0
$check$	5,001	-4,999

Table 1: Payoffs for the robot delivery problem. Acts are in the leftmost column. The remaining two columns describe the outcome for the two sets of states that matter.

T-800's choices and their consequences are summarized in Table 1. Decision theorists typically model decision problems with states, acts, and outcomes: the world is in one of many possible states, and the decision maker chooses an *act*, a function mapping states to outcomes. A natural state space in this problem is $\{$*good,broken*$\}^{1000}$, where each state is a possible state of the cupcakes. However, all that matters about the state is the number of broken cakes, so we can further restrict to states with either one or ten broken cakes.

T-800 can choose among three acts: $cont$: continue the delivery attempt; $back$: go back for new cupcakes; or $check$: open the container and count the number of broken cupcakes, and then decide to continue or go back, depending on the number of broken cakes. The client will tolerate one broken cupcake, but not ten broken cupcakes. Therefore, if T-800 chooses $cont$, it obtains a utility of $10,000$ if there is only one broken cake, but a utility of $-10,000$ if there are ten broken cakes. If T-800 chooses to go $back$, then it gets a utility of 0. Finally, checking the cupcakes costs $4,999$ units of utility but is reliable, so if T-800 chooses $check$, it ends up with a utility of $5,001$ if there is one broken cake, and a utility of $-4,999$ if there are ten broken cakes.

*Work supported in part by NSF grants IIS-0534064, IIS-0812045, and IIS-0911036, by AFOSR grants FA9550-08-1-0438 and FA9550-09-1-0266, and by ARO grant W911NF-09-1-0281.

If we try to maximize expected utility, we must assume some probability over states. What measure should be used? There are two hypotheses that T-800 entertains: (1) the stairs are ten feet high and (2) the stairs are fifteen feet high. Each of these places a different probability on states. If the stairs are ten feet high, we can take all of the $1,000$ states where there is exactly one broken cake to be equally probable, and take the remaining states to have probability 0; if the stairs are fifteen feet high, we can take all of the $C(1000, 10)$ states where there are exactly ten broken cakes to be equally probable, and take the remaining states to have probability 0. One way to model T-800's uncertainty about the height of the stairs is to take each hypothesis to be equally likely. However, not having any idea about which hypothesis holds is very different from believing that all hypotheses are equally likely. It is easy to check that taking each hypothesis to be equally likely makes $check$ the act that maximizes utility, but taking the probability that the stairs are fifteen feet high to be .51 makes $back$ the act that maximizes expected utility, and taking the probability that the stairs are ten feet high to be .51 makes $cont$ the act that maximizes expected utility. What makes any of these choices the "right" choice?

It is easy to construct many other examples where a single probability measure does not capture uncertainty, and does not result in what seem to be reasonable decisions, when combined with expected utility maximization. A natural alternative, which has often been considered in the literature, is to represent the agent's uncertainty by a *set* of probability measures. For example, in the delivery problem, the agent's beliefs could be represented by two probability measures, $\Pr_1$ and $\Pr_{10}$, one for each hypothesis. Thus, $\Pr_1$ assigns uniform probability to all states with exactly one broken cake, and $\Pr_{10}$ assigns uniform probability to all states with exactly ten broken cakes.

But this representation also has problems. Consider the delivery example again. In a more realistic scenario, why should T-800 be sure that there is exactly either one broken cake or ten broken cakes? Of course, we can replace these two hypotheses by hypotheses that say that the probability of a cake being broken is either .001 or .01, but this doesn't solve the problem. Why should the agent be sure that the probability is either exactly .001 or exactly .01? Couldn't it also be .0999? Representing uncertainty by a set of measures still places a sharp boundary on what measures are considered possible and impossible.

A second problem involves updating beliefs. How should beliefs be updated if they are represented by a set of probability measures? The standard approach for updating a single measure is by conditioning. The natural extension of conditioning to sets of measure is measure-by-measure updating: conditioning each measure on the information (and also removing measures that give the information probability 0).

However, measure-by-measure updating can produce some rather counterintuitive outcomes. In the delivery example, suppose that a passer-by tells T-800 the information E: the first 100 cupcakes are good. Assuming that the passer-by told the truth, intuition tells us that there is now more reason to believe that there is only one broken cupcake.

However, $\Pr_1 \mid E$ places uniform probability on all states where the first 100 cakes are good, and there is exactly one broken cake among the last 900. Similarly, $\Pr_{10} \mid E$ places uniform probability on all states where the first 100 cakes are good, and there are exactly ten broken cakes among the last 900. $\Pr_1 \mid E$ still places probability 1 on there being one broken cake, just like $\Pr_1$, $\Pr_{10} \mid E$ still places probability 1 on there being ten broken cakes. There is no way to capture the fact that T-800 now views the hypothesis $\Pr_{10}$ as less likely, even if the passer-by had said instead that the first 990 cakes are all good!

Of course, both of these problems would be alleviated if we placed a probability on hypotheses, but, as we have already observed, this leads to other problems. In this paper, we propose an intermediate approach: representing uncertainty using *weighted sets of probabilities*. That is, each probability measure is associated with a weight. These weights can be viewed as probabilities; indeed, if the set of probabilities is finite, we can normalize them so that they are effectively probabilities. Moreover, in one important setting, we update them in the same way that we would update probabilities, using likelihood (see below). On the other hand, these weights do not act like probabilities if the set of probabilities is infinite. For example, if we had a countable set of hypotheses, we could assign them all weight 1 (so that, intuitively, they are all viewed as equally likely), but there is no uniform measure on a countable set.

More importantly, when it comes to decision making, we use the weights quite differently from how we would use second-order probabilities on probabilities. Second-order probabilities would let us define a probability on events (by taking expectation) and maximize expected utility, in the usual way. Using the weights, we instead define a novel decision rule, *minimax weighted expected regret (MWER)*, that has some rather nice properties, which we believe will make it widely applicable in practice. If all the weights are 1, then MWER is just the standard *minimax expected regret (MER)* rule (described below). If the set of probabilities is a singleton, then MWER agrees with (subjective) expected utility maximization (SEU). More interestingly perhaps, if the weighted set of measures converges to a single measure (which will happen in one important special case, discussed below), MWER converges to SEU. Thus, the weights give us a smooth, natural way of interpolating between MER and SEU.

In summary, weighted sets of probabilities allow us to represent ambiguity (uncertainty about the correct probability

distribution). Real individuals are sensitive to this ambiguity when making decisions, and the MWER decision rule takes this into account. Updating the weighted sets of probabilities using likelihood allows the initial ambiguity to be resolved as more information about the true distribution is obtained.

We now briefly explain MWER, by first discussing MER. MER is a probabilistic variant of the minimax regret decision rule proposed by Niehans [10] and Savage [13]. Most likely, at some point, we've second-guessed ourselves and thought "had I known this, I would have done that instead". That is, in hindsight, we regret not choosing the act that turned out to be optimal for the realized state, called the *ex post* optimal act. The *regret* of an act a in a state s is the difference (in utility) between the ex post optimal act in s and a. Of course, typically one does not know the true state at the time of decision. Therefore the regret of an act is the worst-case regret, taken over all states. The *minimax regret* rule orders acts by their regret.

The definition of regret applies if there is no probability on states. If an agent's uncertainty is represented by a single probability measure, then we can compute the *expected regret* of an act a: just multiply the regret of an act a at a state s by the probability of s, and then sum. It is well known that the order on acts induced by minimizing expected regret is identical to that induced by maximizing expected utility (see [8] for a proof). If an agent's uncertainty is represented by a set $\mathcal{P}$ of probabilities, then we can compute the expected regret of an act a with respect to each probability measure $\Pr \in \mathcal{P}$, and then take the worst-case expected regret. The MER (Minimax Expected Regret) rule orders acts according to their worst-case expected regret, preferring the act that minimizes the worst-case regret. If the set of measures is the set of *all* probability measures on states, then it is not hard to show that MER induces the same order on acts as (probability-free) minimax regret. Thus, MER generalizes both minimax regret (if $\mathcal{P}$ consists of all measures) and expected utility maximization (if $\mathcal{P}$ consists of a single measure).

MWER further generalizes MER. If we start with a *weighted* set of measures, then we can compute the weighted expected regret for each one (just multiply the expected regret with respect to $\Pr$ by the weight of $\Pr$) and compare acts by their worst-case weighted expected regret.

Sarver [12] also proves a representation theorem that involves putting a multiplicative weight on a regret quantity. However, his representation is fundamentally different from MWER. In his representation, regret is a factor only when comparing two *sets* of acts; the ranking of individual acts is given by expected utility maximization. By way of contrast, we do not compare sets of acts.

It is standard in decision theory to axiomatize a decision rule by means of a representation theorem. For example, Savage [14] showed that if an agent's preferences $\succeq$ satisfied several axioms, such as completeness and transitivity, then the agent is behaving as if she is maximizing expected utility with respect to some utility function and probabilistic belief.

If uncertainty is represented by a set of probability measures, then we can generalize expected utility maximization to *maxmin expected utility (MMEU)*. MMEU compares acts by their worst-case expected utility, taken over all measures. MMEU has been axiomatized by Gilboa and Schmeidler [7]. MER was axiomatized by Hayashi [8] and Stoye [16]. We provide an axiomatization of MWER. We make use of ideas introduced by Stoye [16] in his axiomatization of MER, but the extension seems quite nontrivial.

We also consider a dynamic setting, where beliefs are updated by new information. If observations are generated according to a probability measure that is stable over time, then, as we suggested above, there is a natural way of updating the weights given observations, using ideas of likelihood. The idea is straightforward. After receiving some information E, we update each probability $\Pr \in \mathcal{P}$ to $\Pr \mid E$, and take its weight to be $\alpha_{\Pr} = \Pr(E)/\sup_{\Pr' \in \mathcal{P}} \Pr'(E)$. Thus, the weight of $\Pr$ after observing E is modified by taking into account the likelihood of observing E assuming that $\Pr$ is the true probability. We refer to this method of updating weights as *likelihood updating*.

If observations are generated by a stable measure (e.g., we observe the outcomes of repeated flips of a biased coin) then, as the agent makes more and more observations, the weighted set of probabilities of the agent will, almost surely, look more and more like a single measure. The weight of the measures in $\mathcal{P}$ closest to the measure generating the observations will converge to 1, and the weight of all other measures will converge to 0. This would not be the case if uncertainty were represented by a set of probability measures and we did measure-by-measure updating, as is standard. As we mentioned above, this means that MWER will converge to SEU.

We provide an axiomatization for dynamic MWER with likelihood updating. We remark that a dynamic version of MMEU with measure-by-measure updating has been axiomatized by Jaffray [9], Pires [11], and Siniscalchi [15].

Likelihood updating is somewhat similar in spirit to an updating method implicitly proposed by Epstein and Schneider [5]. They also represented uncertainty by using (unweighted) sets of probability measures. They choose a threshold α with $0 < \alpha < 1$, update by conditioning, and eliminate all measures whose relative likelihood does not exceed the threshold. This approach also has the property that, over time, all that is left in $\mathcal{P}$ are the measures closest to the measure generating the observations; all other measures are eliminated. However, it has the drawback that it introduces a new, somewhat arbitrary, parameter α.

Chateauneuf and Faro [2] also consider weighted sets of probabilities (they model the weights using what they call *confidence functions*), although they impose more constraints on the weights than we do. They then define and provide a representation of a generalization of MMEU using weighted sets of probabilities that parallels our generalization of MER. Chateauneuf and Faro do not discuss the dynamic situation; specifically, they do not consider how weights should be updated in the light of new information.

The rest of this paper is organized as follows. Section 2 introduces the weighted sets of probabilities representation, and Section 3 introduces the MWER decision rule. Axiomatic characterizations of static and dynamic MWER are provided in Sections 4 and 5, respectively. We conclude in Section 6. All proofs can be found in the full paper (http://cs.cornell.edu/home/halpern/papers/mwr.pdf).

2 Weighted Sets of Probabilities

A set $\mathcal{P}^+$ of *weighted probability measures* on a set S consists of pairs $(\Pr, \alpha_{\Pr})$, where $\alpha_{\Pr} \in [0,1]$ and $\Pr$ is a probability measure on S.[1] Let $\mathcal{P} = \{\Pr : \exists \alpha (\Pr, \alpha) \in \mathcal{P}^+\}$. We assume that, for each $\Pr \in \mathcal{P}$, there is exactly one α such that $(\Pr, \alpha) \in \mathcal{P}^+$. We denote this number by $\alpha_{\Pr}$, and view it as the *weight of* $\Pr$. We further assume for convenience that weights have been normalized so that there is at least one measure $\Pr \in \mathcal{P}$ such that $\alpha_{\Pr} = 1$.[2] We remark that, just as we do, Chateaunef and Faro [2] take weights to be in the interval $[0,1]$. They impose additional requirements on the weights. For example, they require that the weight of a convex combination of two probability measures is at least as high as the weight of each one. This does not seem reasonable in our applications. For example, an agent may know that one of two measures is generating his observations, and give them both weight 1, while giving all other distributions weight 0.

As we observed in the introduction, one way of updating weighted sets of probabilities is by using likelihood updating. We use $\mathcal{P}^+ \mid E$ to denote the result of applying likelihood updating to $\mathcal{P}^+$. Define $\overline{\mathcal{P}}^+(E) = \sup\{\alpha_{\Pr} \Pr(E) : \Pr \in \mathcal{P}\}$; if $\overline{\mathcal{P}}^+(E) > 0$, set $\alpha_{\Pr|E} = \sup_{\{\Pr' \in \mathcal{P} : \Pr'|E = \Pr|E\}} \frac{\alpha_{\Pr'} \Pr'(E)}{\overline{\mathcal{P}}^+(E)}$. Note that given a measure $\Pr \in \mathcal{P}$, there may be several distinct measures $\Pr'$ in $\mathcal{P}$ such that $\Pr' \mid E = \Pr \mid E$. Thus, we take the weight of $\Pr \mid E$ to be the sup of the possible candidate values of $\alpha_{\Pr|E}$. By dividing by $\overline{\mathcal{P}}^+(E)$, we guarantee that $\alpha_{\Pr|E} \in [0,1]$, and that there is some measure $\Pr$ such that $\alpha_{\Pr|E} = 1$, as long as there is some pair $(\alpha_{\Pr}, \Pr) \in \mathcal{P}$ such that $\alpha_{\Pr} \Pr(E) = \overline{\mathcal{P}}^+(E)$. If $\overline{\mathcal{P}}^+(E) > 0$, we take $\mathcal{P}^+ \mid E$ to be

$$\{(\Pr \mid E, \alpha_{\Pr|E}) : \Pr \in \mathcal{P}\}.$$

If $\overline{\mathcal{P}}^+(E) = 0$, then $\mathcal{P}^+ \mid E$ is undefined.

In computing $\mathcal{P}^+ \mid E$, we update not just the probability measures in $\mathcal{P}$, but also their weights. The new weight combines the old weight with the likelihood. Clearly, if all measures in $\mathcal{P}$ assign the same probability to the event E, then likelihood updating and measure-by-measure updating coincide. This is not surprising, since such an observation E does not give us information about the relative likelihood of measures. We stress that using likelihood updating is appropriate only if the measure generating the observations is assumed to be stable. For example, if observations of heads and tails are generated by coin tosses, and a coin of possibly different bias is tossed in each round, then likelihood updating would not be appropriate.

It is well known that, when conditioning on a single probability measure, the order that information is acquired is irrelevant; the same observation easily extends to sets of probability measures. As we now show, it can be further extended to weighted sets of probability measures.

Proposition 1. *Likelihood updating is consistent in the sense that for all* $E_1, E_2 \subseteq S$, $(\mathcal{P}^+ \mid E_1) \mid E_2 = (\mathcal{P}^+ \mid E_2) \mid E_1 = \mathcal{P}^+ \mid (E_1 \cap E_2)$, *provided that* $\mathcal{P}^+ \mid (E_1 \cap E_2)$ *is defined.*

3 MWER

We now define MWER formally. Given a set S of states and a set X of outcomes, an *act* f (over S and X) is a function mapping S to X. For simplicity in this paper, we take S to be finite. Associated with each outcome $x \in X$ is a utility: $u(x)$ is the utility of outcome x. We call a tuple (S, X, u) a *(non-probabilistic) decision problem*. To define regret, we need to assume that we are also given a set $M \subseteq X^S$ of feasible acts, called the *menu*. The reason for the menu is that, as is well known (and we will demonstrate by example shortly), regret can depend on the menu. Moreover, we assume that every menu M has utilities bounded from above. That is, we assume that for all menus M, $\sup_{g \in M} u(g(s))$ is finite. This ensures that the regret of each act is well defined.[3] For a menu M and act

[1] In this paper, for ease of exposition, we take the state space S to be finite, and assume that all sets are measurable. We can easily generalize to arbitrary measure spaces.

[2] While we could take weights to be probabilities, and normalize them so that they sum to 1, if $\mathcal{P}$ is finite, this runs into difficulties if we have an infinite number of measures in $\mathcal{P}$. For example, if we are tossing a coin, and $\mathcal{P}$ includes all probabilities on heads from $1/3$ to $2/3$, using a uniform probability, we would be forced to assign each individual probability measure a weight of 0, which would not work well in the definition of MWER.

[3] Stoye [17] assumes that, for each menu M, there is a finite set A_M of acts such that M consists of all the convex combinations of the acts in A_M. Our assumption is clearly much weaker than Stoye's.

$f \in M$, the regret of f with respect to M and decision problem (S, X, u) in state s is

$$reg_M(f, s) = \left(\max_{g \in M} u(g(s))\right) - u(f(s)).$$

That is, the regret of f in state s (relative to menu M) is the difference between $u(f(s))$ and the highest utility possible in state s (among all the acts in M). The regret of f with respect to M and decision problem (S, X, u) is the worst-case regret over all states:

$$\max_{s \in S} reg_M(f, s).$$

We denote this as $reg_M^{(S,X,u)}(f)$, and usually omit the superscript (S, X, u) if it is clear from context. If there is a probability measure $\Pr$ over the states, then we can consider the *probabilistic decision problem* $(S, X, u, \Pr)$. The *expected regret* of f with respect to M is

$$reg_{M,\Pr}(f) = \sum_{s \in S} \Pr(s) reg_M(f, s).$$

If there is a set $\mathcal{P}$ of probability measures over the states, then we consider the $\mathcal{P}$-decision problem $(S, X, u, \mathcal{P})$. The maximum expected regret of $f \in M$ with respect to M and $(S, X, u, \mathcal{P})$ is

$$reg_{M,\mathcal{P}}(f) = \sup_{\Pr \in \mathcal{P}} \left(\sum_{s \in S} \Pr(s) reg_M(f, s)\right).$$

Finally, if beliefs are modeled by weighted probabilities $\mathcal{P}^+$, then we consider the $\mathcal{P}^+$-decision problem $(S, X, u, \mathcal{P}^+)$. The maximum weighted expected regret of $f \in M$ with respect to M and $(S, X, u, \mathcal{P}^+)$ is

$$reg_{M,\mathcal{P}^+}(f) = \sup_{\Pr \in \mathcal{P}} \left(\alpha_{\Pr} \textstyle\sum_{s \in S} \Pr(s) reg_M(f, s)\right).$$

The MER decision rule is thus defined for all $f, g \in X^S$ as

$$f \succeq_{M,\mathcal{P}}^{S,X,u} g \text{ iff } reg_{M,\mathcal{P}}^{(S,X,u)}(f) \leq reg_{M,\mathcal{P}}^{(S,X,u)}(g).$$

That is, f is preferred to g if the maximum expected regret of f is less than that of g. We can similarly define $\succeq_{M,reg}$, $\succeq_{M,\Pr}^{S,X,u}$, and $\succeq_{M,\mathcal{P}^+}^{S,X,u}$ by replacing $reg_{M,\mathcal{P}}^{(S,X,u)}$ by $reg_M^{(S,X,u)}$, $reg_{M,\Pr}^{(S,X,u)}$, and $reg_{M,\mathcal{P}^+}^{(S,X,u)}$, respectively. Again, we usually omit the superscript (S, X, u) and subscript $\Pr$ or $\mathcal{P}^+$, and just write $\succeq_M$, if it is clear from context.

To see how these definitions work, consider the delivery example from the introduction. There are $1,000$ states with one broken cake, and $C(1000, 10)$ states with ten broken cakes. The regret of each action in a state depends only on the number of broken cakes, and is given in Table 2. It is easy to see that the action that minimizes regret is *check*, with *cont* and *back* having equal regret. If we represent uncertainty using the two probability measures $\Pr_1$ and $\Pr_{10}$,

	1 broken cake		10 broken cakes	
	Payoff	Regret	Payoff	Regret
cont	10,000	0	-10,000	10,000
back	0	10,000	0	0
check	5,001	4,999	-4,999	4,999

Table 2: Payoffs and regrets for delivery example.

	1 broken cake		10 broken cakes	
	Payoff	Regret	Payoff	Regret
cont	10,000	10,000	-10,000	10,000
back	0	20,000	0	0
check	5,001	14,999	-4,999	4,999
new	20,000	0	-20,000	20,000

Table 3: Payoffs and regrets for the delivery problem with a new choice added.

the expected regret of each of the acts with respect to $\Pr_1$ (resp., $\Pr_{10}$) is just its regret with respect to states with one (resp. ten) broken cakes. Thus, the action that minimizes maximum expected regret is again *check*.

As we said above, the ranking of acts based on MER or MWER can change if the menu of possible choices changes. For example, suppose that we introduce a new choice in the delivery problem, whose gains and losses are twice those of *cont*, resulting in the payoffs and regrets described in Table 3. In this new setting, *cont* has a lower maximum expected regret $(10,000)$ than *check* $(14,999)$, so MER prefers *cont* over *check*. Thus, the introduction of a new choice can affect the relative order of acts according to MER (and MWER), even though other acts are preferred to the new choice. By way of contrast, the decision rules MMEU and SEU are *menu-independent*; the relative order of acts according to MMEU and SEU is not affected by the addition of new acts.

We next consider a dynamic situation, where the agent acquires information. Specifically, in the context of the delivery problem, suppose that T-800 learns E—the first 100 items are good. Initially, suppose that T-800 has no reason to believe that one hypothesis is more likely than the other, so assigns both hypotheses weight 1. Note that $P_1(E) = 0.9$ and $\Pr_{10}(E) = C(900, 10)/C(1000, 10) \approx 0.35$. Thus, $\mathcal{P}^+ \mid E = \{(\Pr_1 \mid E, 1), (\Pr_{10} \mid E, C(900, 10)/(.9C(1000, 10))\}$.

We can also see from this example that MWER interpolates between MER and expected utility maximization. Suppose that a passer-by tells T-800 that the first N cupcakes are good. If $N = 0$, MWER with initial weights 1 is the same as MER. On the other hand, if $N \geq 991$, then the likelihood of $\Pr_{10}$ is 0, and the only measure that has effect is $\Pr_1$, which means minimizing maximum weighted expected regret is just maximizing expected utility with respect to $\Pr_1$. If $0 < N < 991$, then the likelihoods (hence weights)

of $\Pr_1$ and $\Pr_{10}$ are 1 and $\frac{C(1000-N,10)}{C(1000,10)} \times \frac{1000}{1000-N} < ((999-N)/999)^9$. Thus, as N increases, the weight of $\Pr_{10}$ goes to 0, while the weight of $\Pr_1$ stays at 1.

4 An axiomatic characterization of MWER

We now provide a representation theorem for MWER. That is, we provide a collection of properties (i.e., axioms) that hold of MWER such that a preference order on acts that satisfies these properties can be viewed as arising from MWER. To get such an axiomatic characterization, we restrict to what is known in the literature as the *Anscombe-Aumann* (AA) framework [1], where outcomes are restricted to lotteries. This framework is standard in the decision theory literature; axiomatic characterizations of SEU [1], MMEU [7], and MER [8, 16] have already been obtained in the AA framework. We draw on these results to obtain our axiomatization.

Given a set Y (which we view as consisting of *prizes*), a *lottery* over Y is just a probability with finite support on Y. Let $\Delta(Y)$ consist of all finite probabilities over Y. In the AA framework, the set of outcomes has the form $\Delta(Y)$. So now acts are functions from S to $\Delta(Y)$. (Such acts are sometimes called *Anscombe-Aumann acts*.) We can think of a lottery as modeling objective uncertainty, while a probability on states models subjective uncertainty; thus, in the AA framework we have both objective and subjective uncertainty. The technical advantage of considering such a set of outcomes is that we can consider convex combinations of acts. If f and g are acts, define the act $\alpha f+(1-\alpha)g$ to be the act that maps a state s to the lottery $\alpha f(s)+(1-\alpha)g(s)$.

In this setting, we assume that there is a utility function U on prizes in Y. The utility of a lottery l is just the expected utility of the prizes obtained, that is,

$$u(l) = \sum_{\{y \in Y:\, l(y)>0\}} l(y)U(y).$$

This makes sense since $l(y)$ is the probability of getting prize y if lottery l is played. The expected utility of an act f with respect to a probability $\Pr$ is then just $u(f) = \sum_{s \in S} \Pr(s)u(f(s))$, as usual. We also assume that there are at least two prizes y_1 and y_2 in Y, with different utilities $U(y_1)$ and $U(y_2)$.

Given a set Y of prizes, a utility U on prizes, a state space S, and a set $\mathcal{P}^+$ of weighted probabilities on S, we can define a family $\succeq_{M,\mathcal{P}^+}^{S,\Delta(Y),u}$ of preference orders on Anscombe-Aumann acts determined by weighted regret, one per menu M, as discussed above, where u is the utility function on lotteries determined by U. For ease of exposition, we usually write $\succeq_{M,\mathcal{P}^+}^{S,Y,U}$ rather than $\succeq_{M,\mathcal{P}^+}^{S,\Delta(Y),u}$.

We state the axioms in a way that lets us clearly distinguish the axioms for SEU, MMEU, MER, and MWER. The axioms are universally quantified over acts f, g, and h, menus M and M', and $p \in (0,1)$. We assume that $f, g \in M$ when we write $f \succeq_M g$.[4] We use l^* to denote a constant act that maps all states to l.

Axiom 1. *(Transitivity)* $f \succeq_M g \succeq_M h \Rightarrow f \succeq_M h$.

Axiom 2. *(Completeness)* $f \succeq_M g$ *or* $g \succeq_M f$.

Axiom 3. *(Nontriviality)* $f \succ_M g$ *for some acts* f *and* g *and menu* M.

Axiom 4. *(Monotonicity) If* $(f(s))^* \succeq_{\{(f(s))^*,(g(s))^*\}} (g(s))^*$ *for all* $s \in S$, *then* $f \succeq_M g$.

Axiom 5. *(Mixture Continuity) If* $f \succ_M g \succ_M h$, *then there exists* $q, r \in (0,1)$ *such that*

$$\begin{array}{ll} & qf + (1-q)h \succ_{M \cup \{qf+(1-q)h\}} g \\ \textit{and} & g \succ_{M \cup \{rf+(1-r)h\}} rf + (1-r)h. \end{array}$$

Menu-independent versions of Axioms 1–5 are standard. Clearly (menu-independent versions of) Axioms 1, 2, 4, and 5 hold for MMEU, MER, and SEU; Axiom 3 is assumed in all the standard axiomatizations, and is used to get a unique representation.

Axiom 6. *(Ambiguity Aversion)*

$$f \sim_M g \Rightarrow pf + (1-p)g \succeq_{M \cup \{pf+(1-p)g\}} g.$$

Ambiguity Aversion says that the decision maker weakly prefers to hedge her bets. It also holds for MMEU, MER, and SEU, and is assumed in the axiomatizations for MMEU and MER. It is not assumed for the axiomatization of SEU, since it follows from the Independence axiom, discussed next. Independence also holds for MWER, provided that we are careful about the menus involved. Given a menu M and an act h, let $pM+(1-p)h$ be the menu $\{pf+(1-p)h : p \in M\}$.

Axiom 7. *(Independence)*

$$f \succeq_M g \textit{ iff } pf + (1-p)h \succeq_{pM+(1-p)h} pg + (1-p)h.$$

Independence holds in a strong sense for SEU, since we can ignore the menus. The menu-independent version of Independence is easily seen to imply Ambiguity Aversion. Independence does not hold for MMEU.

Although we have menu independence for SEU and MMEU, we do not have it for MER or MWER. The following two axioms are weakened versions of menu independence that do hold for MER and MWER.

[4] Stoye [17] assumed that menus were convex, so that if $f, g \in M$, then so is $pf + (1-p)g$. We do not make this assumption, although our results would still hold if we did (with the axioms slightly modified to ensure that menus are convex). While it may seem reasonable to think that, if f and g are feasible for an agent, then so is $pf + (1-p)g$, this not always the case. For example, it may be difficult for the agent to randomize, or it may be infeasible for the agent to randomize with probability p for some choices of p (e.g., for p irrational).

Axiom 8. *(Menu independence for constant acts) If l^* and $(l')^*$ are constant acts, then $l^* \succeq_M (l')^*$ iff $l^* \succeq_{M'} (l')^*$.*

In light of this axiom, when comparing constant acts, we omit the menu.

An act h is *never strictly optimal relative to* M if, for all states $s \in S$, there is some $f \in M$ such that $(f(s))^* \succeq (h(s))^*$.

Axiom 9. *(Independence of Never Strictly Optimal Alternatives (INA)) If every act in M' is never strictly optimal relative to M, then $f \succeq_M g$ iff $f \succeq_{M \cup M'} g$.*

Axiom 10. *(Boundedness of menus) For every menu M, there exists a lottery $\bar{l} \in \Delta(Y)$ such that for all $f \in M$ and $s \in S$, $(f(s))^* \preceq \bar{l}^*$.*

The boundedness axiom enforces the assumption that we made earlier that every menu has utilities that are bounded from above. Recall that this assumption is necessary for regret to be finite.

Theorem 1. *For all Y, U, S, and $\mathcal{P}^+$, the family of preference orders $\succeq^{S,Y,U}_{M,\mathcal{P}^+}$ satisfies Axioms 1–10. Conversely, if a family of preference orders $\succeq_M$ on the acts in $\Delta(Y)^S$ satisfies Axioms 1–10, then there exist a weighted set $\mathcal{P}^+$ of probabilities on S and a utility U on Y such that $\succeq_M = \succeq^{S,Y,U}_{M,\mathcal{P}^+}$. Moreover, U is unique up to affine transformations, and $\mathcal{P}^+$ can be taken to be* maximal*, in the sense that if $\succeq_M = \succeq^{S,Y,U}_{M,(\mathcal{P}')^+}$, and $(\alpha, \Pr) \in (\mathcal{P}')^+$, then there exists $\alpha' \geq \alpha$ such that $(\alpha', \Pr) \in \mathcal{P}^+$.*

Showing that $\succeq^{S,Y,U}_{M,\mathcal{P}^+}$ satisfies Axioms 1–10 is fairly straightforward; we leave details to the reader. The proof of the converse is quite nontrivial, although it follows the lines of the proof of other representation theorems. We provide an outline of the proof here; details can be found in the full paper (http://cs.cornell.edu/home/halpern/papers/mwr.pdf).

Using standard techniques, we can show that the axioms guarantee the existence of a utility function U on prizes that can be extended to lotteries in the obvious way, so that $l^* \succeq (l')^*$ iff $U(l) \geq U(l')$. We then use techniques of Stoye [17] to show that it suffices to get a representation theorem for a single menu, rather than all menus: the menu consisting of all acts f such that $U(f(s)) \leq 0$ for all states $s \in S$. This allows us to use techniques in the spirit of those used by by Gilboa and Schmeidler [6] to represent (unweighted) MMEU. However, there are technical difficulties that arise from the fact that we do not have a key axiom that is satisfied by MMEU: C-independence (discussed below). The heart of the proof involves dealing with the lack of C-independence; We leave details of the proof to the full paper.

In standard representation theorems, not only is the utility function unique (up to affine transformations, so that we can replace U by $aU + b$, where $a > 0$ and b are constants), but the probability (or set of probabilities) is unique as well. We were not able to find natural conditions on weighted sets of probabilities that guarantee uniqueness. In the case of sets of probabilities, we need to assume that the set is convex and closed to get uniqueness. But there seems to be no natural notion of convexity for a set $\mathcal{P}^+$ of weighted probabilities, and the requirement that $\mathcal{P}^+$ be closed seems unreasonable. For example, if $\mathcal{P}^+$ consists of a single probability measure $\Pr$ with weight $\alpha_{\Pr} = 1$, then there are sequences $\Pr_n \to \Pr$ with $\alpha_{\Pr_n} = 0$, and yet $\alpha_{\Pr} = 1$. To see why something like convexity is needed for uniqueness, consider the delivery example and the expected regrets in Table 2, and the distribution $0.5\Pr_1 + 0.5\Pr_{10}$. The weighted expected regret of any act with respect to $0.5\Pr_1 + 0.5\Pr_{10}$ is bounded above by the maximum weighted expected regret of that act with respect to $\Pr_1$ and $\Pr_{10}$. Therefore, adding $0.5\Pr_1 + 0.5\Pr_{10}$ to $\mathcal{P}^+$, with any weight in $(0, 1]$, yields another representation for the MWER preferences. Although we do not get a unique set $\mathcal{P}^+$ in the representation, the maximality requirement allows us to view the set $\mathcal{P}^+$ as canonical in a certain sense.

It is instructive to compare Theorem 1 to other representation results in the literature. Anscombe and Aumann [1] showed that the menu-independent versions of axioms 1–5 and 7 characterize SEU. The presence of Axiom 7 (menu-independent Independence) greatly simplifies things. Gilboa and Schmeidler [7] showed that axioms 1–6 together with one more axiom that they call *Certainty-independence* characterizes MMEU. Certainty-independence, or C-independence for short, is a weakening of independence (which, as we observed, does not hold for MMEU), where the act h is required to be a constant act. Since MMEU is menu-independent, we state it in a menu-independent way.

Axiom 11. *(C-Independence) If h is a constant act, then $f \succeq g$ iff $pf + (1-p)h \succeq pg + (1-p)h$.*

As we observed, in general, we have Ambiguity Aversion (Axiom 6) for regret. *Betweenness* [3] is a stronger notion than ambiguity aversion, which states that if an agent is indifferent between two acts, then he must also be indifferent among all convex combinations of these acts. While betweenness does not hold for regret, Stoye [16] gives a weaker version that does hold. A menu M has *state-independent outcome distributions* if the set $L(s) = \{y \in \Delta(Y) : \exists f \in M, f(s) = y\}$ is the same for all states s.

Axiom 12. *If h is a constant act, and M has state-independent outcome distributions, then*

$$h \sim_M f \Rightarrow pf + (1-p)h \sim_{M \cup \{pf+(1-p)h\}} f.$$

The assumption that the menu has state-independent outcome distributions is critical in Axiom 12.

Stoye [16] shows that Axioms 1–9 together with Axiom 12

	SEU	REG	MER	MWER	MMEU
Ax. 1-6,8-10	✓	✓	✓	✓	✓
Ind	✓	✓	✓	✓	
C-Ind	✓				✓
Ax. 12	✓	✓	✓		
Symmetry	✓	✓			

Table 4: Characterizing axioms for several decision rules.

characterize MER.[5] Non-probabilistic regret (which we denote REG) can be viewed as a special case of MER, where $\mathcal{P}$ consists of all distributions. This means that it satisfies all the axioms that MER satisfies. As Stoye [17] shows, REG is characterized by Axioms 1–9 and one additional axiom, which he calls Symmetry. We omit the details here.

The assumption that the menu has state-independent outcome distributions is critical in Axiom 12. In the full paper, we give an example showing that the variant of Axiom 12 without the state-independent outcome distribution requirement does not hold.

Table 4 describes the relationship between the axioms characterizing the decision rules.

5 Characterizing MWER with Likelihood Updating

We next consider a more dynamic setting, where agents learn information. For simplicity, we assume that the information is always a subset E of the state space. If the agent is representing her uncertainty using a set $\mathcal{P}^+$ of weighted probability measures, then we would expect her to update $\mathcal{P}^+$ to some new set $\mathcal{Q}^+$ of weighted probability measures, and then apply MWER with uncertainty represented by $\mathcal{Q}^+$. In this section, we characterize what happens in the special case that the agent uses likelihood updating, so that $\mathcal{Q}^+ = (\mathcal{P}^+ \mid E)$.

For this characterization, we assume that the agent has a family of preference orders $\succeq_{E,M}$ indexed not just by the menu M, but by the information E. Each preference order $\succeq_{E,M}$ satisfies Axioms 1–10, since the agent makes decisions after learning E using MWER. Somewhat surprisingly, all we need is one extra axiom for the characterization; we call this axiom MDC, for 'menu-dependent dynamic consistency'.

To explain the axiom, we need some notation. As usual, we take fEh to be the act that agrees with f on E and with h off of E; that is

$$fEh(s) = \begin{cases} f(s) & \text{if } s \in E \\ h(s) & \text{if } s \notin E. \end{cases}$$

[5] Stoye actually worked with choice correspondences; see Section 6.

In the delivery example, the act $check$ can be thought of as $(cont)E(back)$, where E is the set of states where there is only one broken cake.

Roughly speaking, MDC says that you prefer f to g once you learn E if and only if, for any act h, you also prefer fEh to gEh before you learn anything. This seems reasonable, since learning that the true state was in E is conceptually similar to knowing that none of your choices matter off of E.

To state MDC formally, we need to be careful about the menus involved. Let $MEh = \{fEh : f \in M\}$. We can identify unconditional preferences with preferences conditional on S; that is, we identify $\succeq_M$ with $\succeq_{S,M}$. We also need to restrict the sets E to which MDC applies. Recall that conditioning using likelihood updating is undefined for an event such that $\overline{\mathcal{P}}^+(E) = 0$. That is, $\alpha_{\Pr} \Pr(E) = 0$ for all $\Pr \in \mathcal{P}$. As is commonly done, we capture the idea that conditioning on E is possible using the notion of a *non-null* event.

Definition 1. *An event E is* null *if, for all $f, g \in \Delta(Y)^S$ and menus M with $fEg, g \in M$, we have $fEg \sim_M g$.*

MDC. For all non-null events E, $f \succeq_{E,M} g$ iff $fEh \succeq_{MEh} gEh$ for some $h \in M$.[6]

The key feature of MDC is that it allows us to reduce all the conditional preference orders $\succeq_{E,M}$ to the unconditional order $\succeq_M$, to which we can apply Theorem 1.

Theorem 2. *For all Y, U, S, and $\mathcal{P}^+$, the family of preference orders $\succeq^{S,Y,U}_{M,\mathcal{P}^+|E}$ for events E such that $\overline{\mathcal{P}}^+(E) > 0$ satisfies Axioms 1–10 and MDC. Conversely, if a family of preference orders $\succeq_{E,M}$ on the acts in $\Delta(Y)^S$ satisfies Axioms 1–10 and MDC, then there exist a weighted set $\mathcal{P}^+$ of probabilities on S and a utility U on Y non-null E, $\succeq_{E,M} = \succeq^{S,Y,U}_{M,\mathcal{P}^+|E}$. Moreover, U is unique up to affine transformations, and $\mathcal{P}^+$ can be taken to be maximal.*

Proof. Since $\succeq_M = \succeq_{S,M}$ satisfies Axioms 1–10, there must exist a weighted set $\mathcal{P}^+$ of probabilities on S and a utility function U such that $f \succeq_M g$ iff $f \succeq^{S,Y,U}_{M,\mathcal{P}^+} g$. We now show that if E is non-null, then $\overline{\mathcal{P}}^+(E) > 0$, and $f \succeq_{E,M} g$ iff $f \succeq^{(S,X,u)}_{M,\mathcal{P}^+|E} g$.

For the first part, it clearly is equivalent to show that if $\overline{\mathcal{P}}^+(E) = 0$, then E is null. So suppose that $\overline{\mathcal{P}}^+(E) = 0$. Then $\alpha_{\Pr} \Pr(E) = 0$ for all $\Pr \in \mathcal{P}$. This means that $\alpha_{\Pr} \Pr(s) = 0$ for all $\Pr \in \mathcal{P}$ and $s \in E$. Thus, for all acts

[6] Although we do not need this fact, it is worth noting that the MWER decision rule has the property that $fEh \succeq_{MEh} gEh$ for some act h iff $fEh \succeq_{MEh} gEh$ for all acts h. Thus, this property follows from Axioms 1–10.

f and g,

$$\begin{aligned} & reg_{M,\mathcal{P}^+}(fEg) \\ = \; & \sup_{\Pr\in\mathcal{P}} \left(\alpha_{\Pr} \textstyle\sum_{s\in S} \Pr(s) reg_M(fEg, s)\right) \\ = \; & \sup_{\Pr\in\mathcal{P}} \left(\alpha_{\Pr} \left(\textstyle\sum_{s\in E} \Pr(s) reg_M(f, s)\right)\right. \\ & \left. + \textstyle\sum_{s\in E^c} \Pr(s) reg_M(g, s)\right) \\ = \; & \sup_{\Pr\in\mathcal{P}} \left(\alpha_{\Pr} \textstyle\sum_{s\in S} \Pr(s) reg_M(g, s)\right) \\ = \; & reg_{M,\mathcal{P}^+}(g). \end{aligned}$$

Thus, $fEg \sim_M g$ for all acts f, g and menus M containing fEg and g, which means that E is null.

For the second part, we first show that if $\overline{\mathcal{P}}^+(E) > 0$, then for all $f, h \in M$, we have that

$$reg_{MEh,\mathcal{P}^+}(fEh) = \overline{\mathcal{P}}^+(E) reg_{M,\mathcal{P}^+|E}(f).$$

We proceed as follows:

$$\begin{aligned} & reg_{MEh,\mathcal{P}^+}(fEh) \\ = \; & \sup_{\Pr\in\mathcal{P}} \left(\alpha_{\Pr} \textstyle\sum_{s\in S} \Pr(s) reg_{MEh}(fEH, s)\right) \\ = \; & \sup_{\Pr\in\mathcal{P}} \left(\alpha_{\Pr} \Pr(E) \textstyle\sum_{s\in E} \Pr(s \mid E) reg_M(f, s)\right. \\ & \left. + \alpha_{\Pr} \textstyle\sum_{s\in E^c} \Pr(s) reg_{\{h\}}(h, s)\right) \\ = \; & \sup_{\Pr\in\mathcal{P}} \left(\alpha_{\Pr} \Pr(E) \textstyle\sum_{s\in E} \Pr(s|E) reg_M(s, f)\right) \\ = \; & \sup_{\Pr\in\mathcal{P}} \left(\overline{\mathcal{P}}^+(E) \alpha_{\Pr|E} \textstyle\sum_{s\in E} \Pr(s|E) reg_M(f, s)\right) \\ & [\text{since } \alpha_{\Pr|E} = \sup_{\{\Pr'\in\mathcal{P}:\Pr'|E=\Pr|E\}} \tfrac{\alpha_{\Pr'} \Pr'(E)}{\overline{\mathcal{P}}^+(E)}] \\ = \; & \overline{\mathcal{P}}^+(E) \cdot reg_{M,\mathcal{P}^+|E}(f). \end{aligned}$$

Thus, for all $h \in M$,

$$\begin{aligned} & reg_{MEh,\mathcal{P}^+}(fEh) \le reg_{MEh,\mathcal{P}^+}(gEh) \\ \text{iff } & \overline{\mathcal{P}}^+(E) \cdot reg_{M,\mathcal{P}^+|E}(f) \le \overline{\mathcal{P}}^+(E) \cdot reg_{M,\mathcal{P}^+|E}(g) \\ \text{iff } & reg_{M,\mathcal{P}^+|E}(f) \le reg_{M,\mathcal{P}^+|E}(g). \end{aligned}$$

It follows that the order induced by $\Pr^+$ satisfies MDC.

Moreover, if 1–10 and MDC hold, then for the weighted set $\mathcal{P}^+$ that represents $\succeq_M$, we have

$$\begin{aligned} & f \succeq_{E,M} g \\ \text{iff} \quad & \text{for some } h \in M, fEh \succeq_{MEh} gEh \\ \text{iff} \quad & reg_{M,\mathcal{P}^+|E}(f) \le reg_{M,\mathcal{P}^+|E}(g), \end{aligned}$$

as desired. □

Analogues of MDC have appeared in the literature before in the context of updating preference orders. In particular, Epstein and Schneider [4] discuss a menu-independent version of MDC, although they do not characterize updating in their framework. Sinischalchi [15] also uses an analogue of MDC in his axiomatization of measure-by-measure updating of MMEU. Like us, he starts with an axiomatization for unconditional preferences, and adds an axiom called *constant-act dynamic consistency* (CDC), somewhat analogous to MDC, to extend the axiomatization of MMEU to deal with conditional preferences.

6 Conclusion

We proposed an alternative belief representation using *weighted sets of probabilities*, and described a natural approach to updating in such a situation and a natural approach to determining the weights. We also showed how weighted sets of probabilities can be combined with regret to obtain a decision rule, MWER, and provided an axiomatization that characterizes static and dynamic preferences induced by MWER.

We have considered preferences indexed by menus here. Stoye [17] used a different framework: *choice functions*. A choice function maps every finite set M of acts to a subset M' of M. Intuitively, the set M' consists of the 'best' acts in M. Thus, a choice function gives less information than a preference order; it gives only the top elements of the preference order. The motivation for working with choice functions is that an agent can reveal his most preferred acts by choosing them when the menu is offered. In a menu-independent setting, the agent can reveal his whole preference order; to decide if $f \succ g$, it suffices to present the agent with a choice among $\{f, g\}$. However, with regret-based choices, the menu matters; the agent's most preferred choice(s) when presented with $\{f, g\}$ might no longer be the most preferred choice(s) when presented with a larger menu. Thus, a whole preference order is arguably not meaningful with regret-based choices. Stoye [17] provides a representation theorem for MER where the axioms are described in terms of choice functions. The axioms that we have attributed to Stoye are actually the menu-based analogue of his axioms. We believe that it should be possible to provide a characterization of MWER using choice functions, although we have not yet proved this.

Finally, we briefly considered the issue of dynamic consistency and consistent planning. As we showed, making this precise in the context of regret involves a number of subtleties. We hope to return to this issue in future work.

Acknowledgments: We thank Joerg Stoye and Edward Lui for useful comments.

Abstract

Sequential decision problems are often approximately solvable by simulating possible future action sequences. *Metalevel* decision procedures have been developed for selecting *which* action sequences to simulate, based on estimating the expected improvement in decision quality that would result from any particular simulation; an example is the recent work on using bandit algorithms to control Monte Carlo tree search in the game of Go. In this paper we develop a theoretical basis for metalevel decisions in the statistical framework of Bayesian *selection problems*, arguing (as others have done) that this is more appropriate than the bandit framework. We derive a number of basic results applicable to Monte Carlo selection problems, including the first finite sampling bounds for optimal policies in certain cases; we also provide a simple counterexample to the intuitive conjecture that an optimal policy will necessarily reach a decision in all cases. We then derive heuristic approximations in both Bayesian and distribution-free settings and demonstrate their superiority to bandit-based heuristics in one-shot decision problems and in Go.

1 Introduction

The broad family of sequential decision problems includes combinatorial search problems, game playing, robotic path planning, model-predictive control problems, Markov decision processes (MDP), whether fully or partially observable, and a huge range of applications. In almost all realistic instances, exact solution is intractable and approximate methods are sought. Perhaps the most popular approach is to simulate a limited number of possible future action sequences, in order to find a move in the current state that is (hopefully) near-optimal. In this paper, we develop a theoretical framework to examine the problem of selecting *which* future sequences to simulate. We derive a number of new results concerning optimal policies for this selection problem as well as new heuristic policies for controlling Monte Carlo simulations. As described below, these policies outperform previously published methods for "flat" selection and game-playing in Go.

The basic ideas behind our approach are best explained in a familiar context such as game playing. A typical game-playing algorithm chooses a move by first exploring a tree or graph of move sequences and then selecting the most promising move based on this exploration. Classical algorithms typically explore in a fixed order, imposing a limit on exploration depth and using pruning methods to avoid irrelevant subtrees; they may also reuse some previous computations (see Section 6.2). Exploring unpromising or highly predictable paths to great depth is often wasteful; for a given amount of exploration, decision quality can be improved by directing exploration towards those actions sequences whose outcomes are helpful in selecting a good move. Thus, the *metalevel* decision problem is to choose what future action sequences to explore (or, more generally, what deliberative computations to do), while the *object-level* decision problem is to choose an action to execute in the real world.

That the metalevel decision problem can itself be formulated and solved decision-theoretically was noted by Matheson (1968), borrowing from the related concept of *information value theory* (Howard, 1966). In essence, computations can be selected according to the expected improvement in decision quality resulting from their execution. I. J. Good (1968) independently proposed using this idea to control search in chess, and later defined "Type II rationality" to refer to agents that optimally solve the metalevel decision problem before acting. As interest in probabilistic and decision-

theoretic approaches in AI grew during the 1980s, several authors explored these ideas further (Dean and Boddy, 1988; Doyle, 1988; Fehling and Breese, 1988; Horvitz, 1987). Work by Russell and Wefald (1988, 1991a,b) formulated the metalevel sequential decision problem, employing an explicit model of the results of computational actions, and applied this to the control of game-playing search in Othello with encouraging results.

An independent thread of research on metalevel control began with work by Kocsis and Szepesvári (2006) on the UCT algorithm, which operates in the context of *Monte Carlo tree search* (MCTS) algorithms. In MCTS, each computation takes the form of a simulation of a randomized sequence of actions leading from a leaf of the current tree to a terminal state. UCT is primarily a method for selecting a leaf from which to conduct the next simulation, and forms the core of the successful MoGo algorithm for Go playing (Gelly and Silver, 2011). The UCT algorithm is based on the the theory of bandit problems (Berry and Fristedt, 1985) and the asymptotically near-optimal UCB1 bandit algorithm (Auer et al., 2002). UCT applies UCB1 recursively to select actions to perform within simulations.

It is natural to consider whether the two independent threads are consistent; for example, are bandit algorithms such as UCB1 approximate solutions to some particular case of the metalevel decision problem defined by Russell and Wefald? The answer, perhaps surprisingly, is no. The essential difference is that, in bandit problems, every trial involves executing a real object-level action with real costs, whereas in the metareasoning problem the trials are *simulations* whose cost is usually independent of the utility of the action being simulated. Hence, as Audibert et al. (2010) and Bubeck et al. (2011) have also noted, UCT applies bandit algorithms to problems that are not bandit problems.

One consequence of the mismatch is that bandit policies are inappropriately biased away from exploring actions whose current utility estimates are low. Another consequence is the absence of any notion of "stopping" in bandit algorithms, which are designed for infinite sequences of trials. A metalevel policy needs to decide when to stop deliberating and execute a real action.

Analyzing the metalevel problem within an appropriate theoretical framework ought to lead to more effective algorithms than those obtained within the bandit framework. For Monte Carlo computations, in which samples are gathered to estimate the utilities of actions, the metalevel decision problem is an instance of the *selection problem* studied in statistics (Bechhofer, 1954; Swisher et al., 2003). Despite some recent work (Frazier and Powell, 2010; Tolpin and Shimony, 2012b), the theory of selection problems is less well understood than that of bandit problems. Most work has focused on the probability of selection error rather than optimal policies in the Bayesian setting (Bubeck et al., 2011). Accordingly, we present in Sections 2 and 3 a number of results concerning optimal policies for the general case as well as specific finite bounds on the number of samples collected by optimal policies for Bernoulli arms with beta priors. We also provide a simple counterexample to the intuitive conjecture that an optimal policy should not spend more on deciding than the decision is worth; in fact, it is possible for an optimal policy to compute forever. We also show by counterexample that optimal *index policies* (Gittins, 1989) may not exist for selection problems.

Motivated by this theoretical analysis, we propose in Sections 4 and 5 two families of heuristic approximations, one for the Bayesian case and one for the distribution-free setting. We show empirically that these rules give better performance than UCB1 on a wide range of standard (non-sequential) selection problems. Section 6 shows similar results for the case of guiding Monte Carlo tree search in the game of Go.

2 On optimal policies for selection

In a selection problem the decision maker is faced with a choice among alternative arms[1]. To make this choice, they may gather evidence about the utility of each of these alternatives, at some cost. The objective is to maximize the *net utility*, i.e., the expected utility of the final arm selected, less the cost of gathering the evidence. In the classical case (Bechhofer, 1954), evidence might consist of physical samples from a product batch; in a metalevel problem with Monte Carlo simulations, the evidence consists of outcomes of sampling computations:

Definition 1. *A **metalevel probability model** is a tuple $(U_1, \ldots, U_k, \mathcal{E})$ consisting of jointly distributed random variables:*

- *Real random variables $U_1, \ldots, U_k$, where U_i is the utility of arm i, and*
- *A countable set $\mathcal{E}$ of random variables, each variable $E \in \mathcal{E}$ being a computation that can be performed and whose value is the result of that computation, where $e \in E$ will denote that e is a potential value of the computation E.*

[1] Alternative actions are known as *arms* in the bandit setting; we borrow this terminology for uniformity.

For simplicity, in the below we'll assume the utilities U_i are bounded, without loss of generality in $[0, 1]$.

Example 1 (Bernoulli sampling)**.** *In the* ***Bernoulli metalevel probability model****, each arm will either succeed or not $U_i \in \{0, 1\}$, with an unknown latent frequency of success Θ_i, and a set of stochastic simulations of possible consequences $\mathcal{E} = \{E_{ij} | 1 \leq i \leq k, j \in \mathbb{N}\}$ that can be performed:*

$$\begin{aligned} \Theta_i &\overset{\text{iid}}{\sim} \text{Uniform}[0, 1] && \text{for } i \in \{1, \ldots, k\} \\ U_i \mid \Theta_i &\sim \text{Bernoulli}(\Theta_i) && \text{for } i \in \{1, \ldots, k\} \\ E_{ij} \mid \Theta_i &\overset{\text{iid}}{\sim} \text{Bernoulli}(\Theta_i) && \text{for } i \in \{1, \ldots, k\},\ j \in \mathbb{N} \end{aligned}$$

The ***one-armed Bernoulli metalevel probability model*** *has $k = 2$, $\Theta_1 = \lambda \in [0, 1]$ a constant, and $\Theta_2 \sim \text{Uniform}[0, 1]$.*

A metalevel probability model, when combined with a cost of computation $c > 0$,[2] defines a metalevel decision problem: what is the optimal strategy with which to choose a sequence of computations $E \in \mathcal{E}$ in order to maximize the agent's net utility? Intuitively, this strategy should choose the computations that give the most evidence relevant to deciding which arm to use, stopping when the cost of computation outweighs the benefit gained. We formalize the selection problem as a Markov Decision Process (see, e.g., Puterman (1994)):

Definition 2. *A (countable state, undiscounted)* ***Markov Decision Process*** *(MDP) is a tuple $M = (S, s_0, A_s, T, R)$ where: S is a countable set of states, $s_0 \in S$ is the fixed initial state, A_s is a countable set of actions available in state $s \in S$, $T(s, a, s')$ is the transition probability from $s \in S$ to $s' \in S$ after performing action $a \in A_s$, and $R(s, a, s')$ is the expected reward received on such a transition.*

To formulate the metalevel decision problem as an MDP, we define the states as sequences of computation outcomes and allow for a terminal state when the agent chooses to stop computing and act:

Definition 3. *Given a metalevel probability model*[3] *$(U_1, \ldots, U_k, \mathcal{E})$ and a cost of computation $c > 0$, a corresponding* ***metalevel decision problem*** *is any MDP $M = (S, s_0, A_s, T, R)$ such that*

$$\begin{aligned} S &= \{\bot\} \cup \{\langle e_1 \ldots, e_n\rangle : e_i \in E_i \text{ for all } i, \\ &\qquad \text{for finite } n \geq 0 \text{ and distinct } E_i \in \mathcal{E}\} \\ s_0 &= \langle\rangle \\ A_s &= \{\bot\} \cup \mathcal{E}_s \end{aligned}$$

where $\bot \in S$ is the unique terminal state, where $\mathcal{E}_s \subseteq \mathcal{E}$ is a state-dependent subset of allowed computations, and when given any $s = \langle e_1, \ldots, e_n\rangle \in S$, computational action $E \in \mathcal{E}$, and $s' = \langle e_1, \ldots, e_n, e\rangle \in S$ where $e \in E$, we have:

$$\begin{aligned} T(s, E, s') &= P(E = e \mid E_1 = e_1, \ldots, E_n = e_n) \\ T(s, \bot, \bot) &= 1 \\ R(s, E, s') &= -c \\ R(s, \bot, \bot) &= \max_i \mu_i(s) \end{aligned}$$

where $\mu_i(s) = \mathbb{E}[U_i \mid E_1 = e_1, \ldots, E_n = e_n]$.

Note that when stopping in state s, the expected utility of action i is by definition $\mu_i(s)$, so the optimal action to take is $i^* \in \text{argmax}_i\, \mu_i(s)$ which has expected utility $\mu_{i*}(s) = \max_i \mu_i(s)$.

One can optionally add an external constraint on the number of computational actions, or their total cost, in the form of a deadline or *budget*. This bridges with the related area of budgeted learning (Madani et al., 2004). Although this feature is not formalized in the MDP, it can be added by including either time or past total cost as part of the state.

Example 2 (Bernoulli sampling)**.** *In the Bernoulli metalevel probability model (Example 1), note that:*

$$\Theta_i \mid E_{i1}, \ldots, E_{in_i} \sim \text{Beta}(s_i + 1, f_i + 1) \quad (1)$$

$$E_{i(n_i+1)} \mid E_{i1}, \ldots, E_{in_i} \sim \text{Bernoulli}\left(\frac{s_i + 1}{n_i + 2}\right) \quad (2)$$

$$\mathbb{E}[U_i \mid E_{i1}, \ldots, E_{in_i}] = (s_i + 1)/(n_i + 2) \quad (3)$$

by standard properties of these distributions, where $s_i = \sum_{j=1}^{n_i} E_{in_i}$ is the number of simulated successes of arm i, and $f_i = n_i - s_i$ the failures. By Equation (1), the state space is the set of all k pairs (s_i, f_i); Equations (2) and (3) suffice to give the transition probabilities and terminal rewards, respectively. The one-armed Bernoulli case is similar, requiring as state just (s, f) defining the posterior over Θ_2.

Given a metalevel decision problem $M = (S, s_0, A_s, T, R)$ one defines policies and value functions as in any MDP. A (deterministic, stationary) **metalevel policy** π is a function mapping states $s \in S$ to actions to take in that state $\pi(s) \in A_s$.

[2] The assumption of a fixed cost of computation is a simplification; precise conditions for its validity are given by Harada (1997).

[3] Definition 1 made no assumption about the computational result variables $E_i \in \mathcal{E}$, but for simplicity in the following we'll assume that each E_i takes one of a countable set of values. Without loss of generality, we'll further assume the domains of the computational variables $E \in \mathcal{E}$ are disjoint.

The **value function** for a policy π gives the expected total reward received under that policy starting from a given state $s \in S$, and the **Q-function** does the same when starting in a state $s \in S$ and taking a given action $a \in A_s$:

$$V_M^\pi(s) = \mathbb{E}_M^\pi \left[\sum_{i=0}^{N} R(S_i, \pi(S_i), S_{i+1}) \mid S_0 = s \right] \quad (4)$$

where $N \in [0, \infty]$ is the random time the MDP is terminated, i.e., the unique time where $\pi(S_N) = \perp$, and similarly for the Q-function $Q_M^\pi(s, a)$.

As usual, an **optimal policy** π^*, when it exists, is one that maximizes the value from every state $s \in S$, i.e., if we define for each $s \in S$

$$V_M^*(s) = \sup_\pi V_M^\pi(s),$$

then an optimal policy π^* satisfies $V_M^{\pi^*}(s) = V_M^*(s)$ for all $s \in S$, where we break ties in favor of stopping.

The optimal policy must balance the cost of computations with the improved decision quality that results. This tradeoff is made clear in the value function:

Theorem 4. *The value function of a metalevel decision process $M = (S, s_0, A_s, T, R)$ is of the form*

$$V_M^\pi(s) = \mathbb{E}_M^\pi[-c\,N + \max_i \mu_i(S_N) \mid S_0 = s]$$

where N denotes the (random) total number of computations performed; similarly for $Q_M^\pi(s, a)$.

In many problems, including the Bernoulli sampling model of Example 2, the state space is infinite. Does this preclude solving for the optimal policy? Can infinitely many computations be performed?

There is in full generality an upper bound on the *expected* number of computations a policy performs:

Theorem 5. *The optimal policy's expected number of computations is bounded by the value of perfect information (Howard, 1966) times the inverse cost $1/c$:*

$$\mathbb{E}^{\pi^*}[N \mid S_0 = s] \leq \frac{1}{c} \left(\mathbb{E}[\max_i U_i \mid S_0 = s] - \max_i \mu_i(s) \right).$$

Further, any policy π with infinite expected number of computations has negative infinite value, hence the optimal policy stops with probability one.

Although the *expected* number of computations is always bounded, there are important cases in which the *actual* number is not, such as the following inspired by the sequential probability ratio test (Wald, 1945):

Example 3. *Consider the Bernoulli sampling model for two arms but with a different prior: $\Theta_1 = 1/2$, and Θ_2 is $1/3$ or $2/3$ with equal probability. Simulating arm 1 gains nothing, and after (s, f) simulated successes and failures of arm 2 the posterior odds ratio is*

$$\frac{P(\Theta_2 = 2/3 \mid s, f)}{P(\Theta_2 = 1/3 \mid s, f)} = \frac{(2/3)^s (1/3)^f}{(1/3)^s (2/3)^f} = 2^{s-f}.$$

Note that this ratio completely specifies the posterior distribution of Θ_2, and hence the distribution of the utilities and all future computations. Thus, whether it is optimal to continue is a function only of this ratio, and thus of $s - f$. For sufficiently low cost, the optimal policy samples when $s - f$ equals -1, 0, or 1. But with probability $1/3$, a state with $s - f = 0$ transitions to another state $s - f = 0$ after two samples, giving finite, although exponentially decreasing, probability to arbitrarily long sequences of computations.

However, in a number of settings, including the original Bernoulli model of Example 1, we can prove an upper bound on the number of computations. For reasons of space, and for its later use in Section 4, we prove here the bound for the one-armed Bernoulli model.

Before we can do this, we need to get an analytical handle on the optimal policy. The key is through a natural approximate policy:

Definition 6. *Given a metalevel decision problem $M = (S, s_0, A_s, T, R)$, the **myopic policy** $\pi^m(s)$ is defined to equal* $\operatorname{argmax}_{a \in A_s} Q^m(s, a)$ *where $Q^m(s, \perp) = \max_i \mu_i(s)$ and*

$$Q^m(s, E) = \mathbb{E}_M[-c + \max_i \mu_i(S_1) \mid S_0 = s, A_0 = E].$$

The myopic policy (known as the metalevel greedy approximation with single-step assumption in (Russell and Wefald, 1991a)) takes the best action, to either stop or perform a computation, under the assumption that at most one further computation can be performed. It has a tendency to stop too early, because changing one's mind about which real action to take often takes more than one computation. In fact, we have:

Theorem 7. *Given a metalevel decision problem $M = (S, s_0, A_s, T, R)$ if the myopic policy performs some computation in state $s \in S$, then the optimal policy does too, i.e., if $\pi^m(s) \neq \perp$ then $\pi^*(s) \neq \perp$.*

Despite this property, the stopping behavior of the myopic policy does have a close connection to that of the optimal policy:

Definition 8. *Given a metalevel decision problem $M = (S, s_0, A_s, T, R)$, a subset $S' \subseteq S$ of states is **closed under transitions** if whenever $s' \in S'$, $a \in A_{s'}$, $s'' \in S$, and $T(s', a, s'') > 0$, we have $s'' \in S'$.*

Theorem 9. *Given a metalevel decision problem $M = (S, s_0, A_s, T, R)$ and a subset $S' \subseteq S$ of states closed under transitions, if the myopic policy stops in all states $s' \in S'$ then the optimal policy does too.*

Using these results connecting the behavior of the optimal and myopic policies, we can prove our bound:

Theorem 10. *The one-armed Bernoulli decision process with constant arm $\lambda \in [0, 1]$ performs at most $\lambda(1-\lambda)/c - 3 \leq 1/4c - 3$ computations.*

Proof. Using Definition 6 and Example 2, we determine which states the myopic policy stops in by bounding $Q^m(s, E)$. For a state (s, f), let $\mu = (s+1)/(n+2)$ be the mean utility for arm 2, where $n = s + f$. Fixing n and maximizing over μ, we get sufficient condition for stopping Since the set of states satisfying Equation (5) is closed under

$$c \geq \frac{\lambda(1-\lambda)}{(n+3)} \qquad n \geq \frac{\lambda(1-\lambda)}{c} - 3 \qquad (5)$$

Since the set of states satisfying Equation (5) is closed under transitions (n only increases), by Theorem 7. Finally, note $\max_{\lambda \in [0,1]} \lambda(1-\lambda) = 1/4$. □

A key implication is that the *optimal* policy can be computed in time $O(1/c^2)$, i.e., quadratic in the inverse cost. This is particularly appropriate when the cost of computation is relatively high, such as in simulation experiments (Swisher et al., 2003), or when the decision to be made is critical.

3 Context effects and non-indexability

The Gittins index theorem (Gittins, 1979) is a famous structural result for bandit problems. It states that in bandit problems with independent reward distribution for each arm and geometric discounting, the optimal policy is an **index policy**: each arm is assigned a real-valued index based on its state only, such that it is optimal to sample the arm with greatest index.

The analogous result does *not* hold for metalevel decision problems, even when the action's values are independent (this formalized later in Definition 13):

Example 4 (Non-indexability)**.** *Consider a metalevel probability model with three actions. U_1 is equally likely to be -1.5 or 1.5 (low mean, high variance), U_2 is equally likely to be 0.25 or 1.75 (high mean, low variance), and $U_3 = \lambda$ has a known value (the context). The two computations are to observe exactly U_1 and U_2, respectively, each with cost 0.2. The corresponding metalevel MDP has 9 states and can be solved exactly. Figure 1 plots $Q^*_\lambda(s_0, U_i) - Q^*_\lambda(s_0, \perp)$ as a function of the known value λ. As the context λ varies the optimal action inverts from observing 1 to observing 2. Inversions like this are impossible for index policies.*

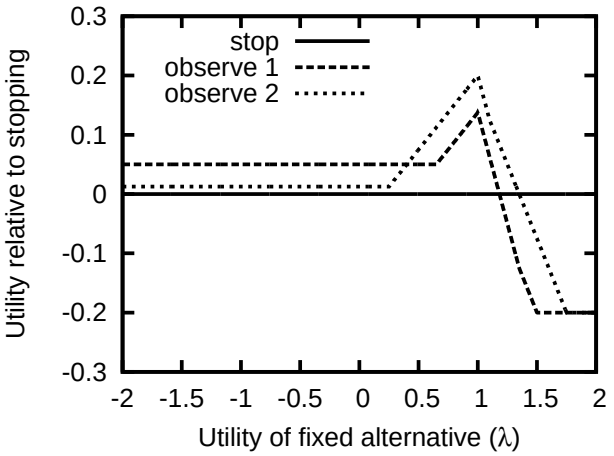

Figure 1: Optimal Q-values of computing relative to stopping as a function of the utility of the fixed alternative. Note the inversion where for low λ observing action 1 is strictly optimal, while for medium λ observing action 2 is strictly optimal.

There is, however, a restriction on what kind of influence the context can have:

Definition 11. *Given a metalevel decision problem $M = (S, s_0, A_s, T, R)$, and a constant $\lambda \in \mathbb{R}$, define $M_\lambda = (S, s_0, A_s, T, R_\lambda)$ to be M with an additional action of known value λ, defined by:*

$$R_\lambda(s, E, s') = R(s, E, s')$$
$$R_\lambda(s, \perp, \perp) = \max\{\lambda, R(s, \perp, \perp)\}$$

Note this is equivalent to adding an extra arm with constant value $U_{k+1} = \lambda$.

Theorem 12. *Given a metalevel decision problem $M = (S, s_0, A_s, T, R)$, there exists a real interval $I(s)$ for every state $s \in S$ such that it is optimal to stop in state s in M_μ iff $\mu \notin I(s)$. Furthermore, $I(s)$ contains $\max_i \mu_i(s)$ whenever it is nonempty.*

4 The blinkered policy

The myopic policy is an extreme approximation, often stopping far too early. A better approximation can be obtained, at least for the case where each computation can only affect the value of one action. The technical definition (closely related to *subtree independence* in Russell and Wefald's work) is as follows:

Definition 13. *A metalevel probability model $(U_1, \ldots, U_k, \mathcal{E})$ has **independent actions** if the computational variables can be partitioned $\mathcal{E} = \mathcal{E}_1 \cup \cdots \cup \mathcal{E}_k$*

such that such that the sets $\{U_i\} \cup \mathcal{E}_i$ *are independent of each other for different* i*.*

With independent actions, we can talk about metalevel policies that focus on computations affecting a single action. These policies are not myopic—they can consider arbitrarily many computations—but they are *blinkered* because they can look in only a single direction at a time:

Definition 14. *Given a metalevel decision problem* $M = (S, s_0, A_s, T, R)$ *with independent actions, the* ***blinkered policy*** π^b *is defined by* $\pi^b(s) = \text{argmax}_{a \in A_s} Q^b(s, a)$ *where* $Q^b(s, \bot) = \bot$ *and for* $E_i \in \mathcal{E}_i$

$$Q^b(s, E_i) = \sup_{\pi \in \Pi_i^b} Q^\pi(s, E_i) \tag{6}$$

where Π_i^b *is the set of policies* π *where* $\pi(s) \in \mathcal{E}_i$ *for all* $s \in S$*.*

Clearly, blinkered policies are better than myopic: $Q^m(s, a) \leq Q^b(s, a) \leq Q^*(s, a)$. Moreover, the blinkered policy can be computed in time proportional to the number of arms, by breaking the decision problem into separate subproblems:

Definition 15. *Given a metalevel decision problem* $M = (S, s_0, A_s, T, R)$ *with independent actions, a* ***one-action metalevel decision problem*** *for* $i = 1, \ldots, k$ *is the metalevel decision problem* $M^1_{i,\lambda} = (S_i, s_0, A_{s0}, T_i, R_i)$ *defined by the metalevel probability model* $(U_0, U_i, \mathcal{E}_i)$ *with* $U_0 = \lambda$*.*

Note that given a state s of a metalevel decision problem, we can form a state s_i by taking only the results of computations in $\mathcal{E}_i$ (see Definition 3). By action independence, $\mu_i(s)$ is a function only of s_i.

Theorem 16. *Given a metalevel decision problem* $M = (S, s_0, A_s, T, R)$ *with independent actions, let* M^1_{i,λ_i} *be the* i*th one-action metalevel decision problem for* $i = 1, \ldots, k$*. Then for any* $s \in S$*, whenever* $E_i \in A_s \cap \mathcal{E}_i$ *we have:*

$$Q^b_M(s, E_i) = Q^*_{M^1_{i,\mu^*_{-i}}}(s_i, E_i)$$

where $\mu^*_{-i} = \max_{j \neq i} \mu_j(s)$*.*

Theorem 16 shows that to compute the blinkered policy we need only compute the optimal policies for k separate one-action problems.

For the Bernoulli problem with k actions, the one-action metalevel decision problems are all one-action Bernoulli problems (Example 1). By Theorem 10 these policies perform at most $1/4c - 3$ computations. As a result, the blinkered policy can be numerically computed in time $O(D/c^2)$ independent of k by backwards induction, where D is the number of points $\lambda \in [0, 1]$ for which we compute $Q^*_{M^1_{i,m}}(s)$.[4] This will be worth the cost in the same situations as mentioned at the end of Section 2.

Figure 2 compares the blinkered policy to several other policies from the literature, using a Bernoulli sampling problem with $k = 25$ and a wide range of values for the step cost c. Performance is measured by expected *regret*, where the regret includes the cost of sampling: $R = (\max_i U_i) - U_j + c\,n$ where n is the number of computations and j is the action actually selected. The blinkered policy significantly outperforms all others. The myopic policy plateaus as it quickly reaches a position where no single computation can change the final action choice. ESPb performs quite well given that is making a normal approximation to the Beta posterior. The curves for UCB1-B and UCB1-b show that even given a good stopping rule, UCB1's choice of actions to sample is not ideal.

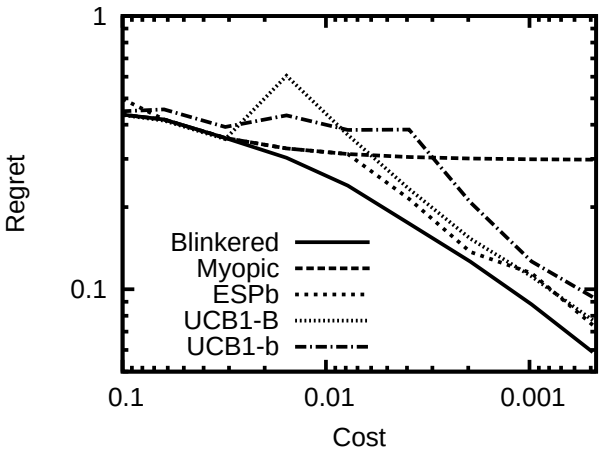

Figure 2: Average regret of various policies as a function of the cost in a 25-action Bernoulli sampling problem, over 1000 trials. Error bars omitted as they are negligible (the relative error is at most 0.03).

5 Upper bounds on Value of Information

In many practical applications of the selection problem, such as search in the game of Go, prior distributions are unavailable.[5] In such cases, one can still bound the value of information of myopic policies using *concentration inequalities* to derive distribution-independent bounds on the VOI. We obtain such bounds under the following assumptions:

[4] In our experiments below, $D = 129$ points are equally spaced, using linear interpolation between points.

[5] The analysis is also applicable to some Bayesian settings, using "fake" samples to simulate prior distributions.

1. Samples are iid given the value of the arms (variables), as in the Bayesian schemes such as Bernoulli sampling.

2. The expectation of a selection in a belief state is equal to the sample mean (and therefore, after sampling terminates, the arm with the greatest sample mean will be selected).

When considering possible samples in the blinkered semi-myopic setting, two cases are possible: either the arm α with the highest sample mean $\overline{X}_\alpha$ is tested, and $\overline{X}_\alpha$ becomes lower than $\overline{X}_\beta$ of the second-best arm β; or, another arm i is tested, and $\overline{X}_i$ becomes higher than $\overline{X}_\alpha$.

Our bounds below are applicable to any bounded distribution (without loss of generality bounded in $[0,1]$). Similar bounds can be derived for certain unbounded distributions, such as the normally distributed prior value with normally distributed sampling. We derive a VOI bound for testing an arm a fixed N times, where N can be the remaining budget of available samples or any other integer quantity. Denote by Λ_i^b the intrinsic VOI of testing the ith arm N times, and the number of samples already taken from the ith arm by n_i.

Theorem 17. *Λ_i^b is bounded from above as*

$$\Lambda_\alpha^b \leq \frac{N\overline{X}_\beta^{n_\beta}}{n_\alpha} \Pr(\overline{X}_\alpha^{n_\alpha+N} \leq \overline{X}_\beta^{n_\beta})$$
$$\Lambda_{i|i\neq\alpha}^b \leq \frac{N(1-\overline{X}_\alpha^{n_\alpha})}{n_i} \Pr(\overline{X}_i^{n_i+N} \geq \overline{X}_\alpha^{n_\alpha}) \quad (7)$$

The probabilities can be bounded from above using the Hoeffding inequality (Hoeffding, 1963):

Theorem 18. *The probabilities in Equation (7) are bounded from above as*

$$\Pr(\overline{X}_\alpha^{n_\alpha+N} \leq \overline{X}_\beta^{n_\beta}) \leq 2\exp\left(-\varphi(\overline{X}_\alpha^{n_\alpha} - \overline{X}_\beta^{n_\beta})^2 n_\alpha\right)$$
$$\Pr(\overline{X}_{i|i\neq\alpha}^{n_\alpha+N} \geq \overline{X}_\beta^{n_\beta}) \leq 2\exp\left(-\varphi(\overline{X}_\alpha^{n_\alpha} - \overline{X}_i^{n_i})^2 n_i\right) \quad (8)$$

where $\varphi = \min\left(2(\frac{1+n/N}{1+\sqrt{n/N}})^2\right) = 8(\sqrt{2}-1)^2 > 1.37.$

Corollary 19. *An upper bound on the VOI estimate Λ_i^b is obtained by substituting Equation (8) into (7).*

$$\Lambda_\alpha^b \leq \hat{\Lambda}_\alpha^b = \frac{2N\overline{X}_\beta^{n_\beta}}{n_\alpha} \exp\left(-\varphi(\overline{X}_\alpha^{n_\alpha} - \overline{X}_\beta^{n_\beta})^2 n_\alpha\right) \quad (9)$$
$$\Lambda_{i|i\neq\alpha}^b \leq \hat{\Lambda}_i^b = \frac{2N(1-\overline{X}_\alpha^{n_\alpha})}{n_i} \exp\left(-\varphi(\overline{X}_\alpha^{n_\alpha} - \overline{X}_i^{n_i})^2 n_i\right)$$

More refined bounds can be obtained through tighter estimates on the probabilities in Equation (7), for example, based on the empirical Bernstein inequality (Maurer and Pontil, 2009), or through a more careful application of the Hoeffding inequality, resulting in:

$$\Lambda_i^b \leq \frac{N\sqrt{\pi}}{n_i\sqrt{n_i}} \left[\mathrm{erf}\left((1-\overline{X}_i^{n_i})\sqrt{n_i}\right) - \mathrm{erf}\left((\overline{X}_\alpha^{n_\alpha} - \overline{X}_i^{n_i})\sqrt{n_i}\right)\right]$$
$$\Lambda_\alpha^b \leq \frac{N\sqrt{\pi}}{n_\alpha\sqrt{n_\alpha}} \left[\mathrm{erf}\left(\overline{X}_\alpha^{n_\alpha}\sqrt{n_\alpha}\right) - \mathrm{erf}\left((\overline{X}_\alpha^{n_\alpha} - \overline{X}_\beta^{n_\beta})\sqrt{n_\alpha}\right)\right] \quad (10)$$

Selection problems usually separate out the decision of *whether* to sample or to stop (called the stopping policy), and *what* to sample. We'll examine the first issue here, along with the empirical evaluation of the above approximate algorithms, and the second in the following section.

Assuming that the sample costs are constant, a semi-myopic policy will decide to test the arm that has the best current VOI estimate. When the distributions are unknown, it makes sense to use the upper bounds established in Theorem 17, as we do in the following. This evaluation assumes a fixed budget of samples, which is completely used up by each of the candidate schemes, making a stopping criterion irrelevant.

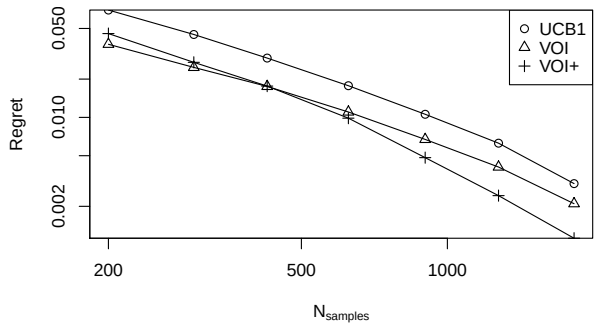

Figure 3: Average regret of various policies as a function of the fixed number of samples in a 25-action Bernoulli sampling problem, over 10000 trials.

The sampling policies are compared on random Bernoulli selection problem instances. Figure 3 shows results for randomly-generated selection problems with 25 Bernoulli arms, where the mean rewards of the arms are distributed uniformly in $[0,1]$, for a range of sample budgets 200..2000, with multiplicative step of 2, averaging over 10000 trials. We compare UCB1 with the policies based on the bounds in Equation (9) (VOI) and Equation (10) (VOI+). UCB1 is always considerably worse than the VOI-aware sampling policies.

6 Sampling in trees

The previous section addressed the selection problem in the flat case. Selection in trees is more complicated. The goal of Monte-Carlo tree search (Chaslot

et al., 2008) at the root node is usually to select an action that appears to be the best based on outcomes of *search rollouts*. But the goal of rollouts at non-root nodes is different than at the root: here it is important to better approximate the value of the node, so that selection at the root can be more informed. The exact analysis of sampling at internal nodes is outside the scope of this paper. At present we have no better proposal for internal nodes than to use UCT there.

We thus propose the following hybrid sampling scheme (Tolpin and Shimony, 2012a): at the *root node*, sample based on the VOI estimate; at *non-root nodes*, sample using UCT.

Strictly speaking, even at the root node the stationarity assumptions[6] underlying our belief-state MDP for selection do not hold exactly. UCT is an adaptive scheme, and therefore the values generated by sampling at non-root nodes will typically cause values observed at children of the root node to be non-stationary. Nevertheless, sampling based on VOI estimates computed as for stationary distributions works well in practice. As illustrated by the empirical evaluation (Section 6), estimates based on upper bounds on the VOI result in good sampling policies, which exhibit performance comparable to the performance of some state-of-the-art heuristic algorithms.

6.1 Stopping criterion

When a sample has a known cost commensurable with the value of information of a measurement, an upper bound on the intrinsic VOI can also be used to stop the sampling if the intrinsic VOI of any arm is less than the total cost of sampling C: $\max_i \Lambda_i \leq C$.

The VOI estimates of Equations (7) and (9) include the remaining sample budget N as a factor, but given the cost of a single sample c, the cost of the remaining samples accounted for in estimating the intrinsic VOI is $C = cN$. N can be dropped on both sides of the inequality, giving a reasonable stopping criterion:

$$\begin{aligned} \frac{1}{N}\Lambda^b_\alpha \leq & \frac{\overline{X}^{n_\beta}_\beta}{n_\alpha} \Pr(\overline{X}^{n_\alpha+N}_\alpha \leq \overline{X}^{n_\alpha}_\beta) \leq c \\ \frac{1}{N}\max_i \Lambda^b_i \leq & \max_i \frac{(1-\overline{X}^{n_\alpha}_\alpha)}{n_i} \Pr(\overline{X}^{n_i+N}_i \geq \overline{X}^{n_\alpha}_\alpha) \leq c \\ & \forall i : i \neq \alpha \end{aligned} \tag{11}$$

The empirical evaluation (Section 6) confirms the viability of this stopping criterion and illustrates the influence of the sample cost c on the performance of the sampling policy. When the sample cost c is unknown, one can perform initial calibration experiments to determine a reasonable value, as done in the following.

6.2 Sample redistribution in trees

The above hybrid approach assumes that the information obtained from rollouts in the current state is discarded after an real-world action is selected. In practice, many successful Monte-Carlo tree search algorithms reuse rollouts generated at earlier search states, if the sample traverses the current search state during the rollout; thus, the value of information of a rollout is determined not just by the influence on the choice of the action at the current state, but also by its potential influence on the choice at future search states.

One way to account for this reuse would be to incorporate the 'future' value of information into a VOI estimate. However, this approach requires a nontrivial extension of the theory of metareasoning for search. Alternately, one can behave myopically with respect to the search tree depth:

1. Estimate VOI as though the information is discarded after each step,
2. Stop early if the VOI is below a certain threshold (see Section 6.1), and
3. Save the unused sample budget for search in future states, such that if the nominal budget is N, and the unused budget in the last state is N_u, the search budget in the next state will be $N + N_u$.

In this approach, the cost c of a sample in the current state is the VOI of increasing the budget of a future state by one sample. It is unclear whether this cost can be accurately estimated, but supposing a fixed value for a given problem type and algorithm implementation would work. Indeed, the empirical evaluation (Section 6.3) confirms that stopping and sample redistribution based on a learned fixed cost substantially improve the performance of the VOI-based sampling policy in game tree search.

6.3 Playing Go against UCT

The hybrid policies were compared on the game Go, a search domain in which UCT-based MCTS has been particularly successful (Gelly and Wang, 2006). A modified version of Pachi (Braudiš and Loup Gailly, 2011), a state of the art Go program, was used for the experiments:

- The UCT engine of Pachi was extended with VOI-aware sampling policies at the first step.

[6] This is not a restriction, however, of the general formalism in Section 2.

- The stopping criterion for the VOI-aware policy was modified and based solely on the sample cost, specified as a constant parameter. The heuristic stopping criterion for the original UCT policy was left unchanged.
- The time-allocation model based on the fixed number of samples was modified for *both the original UCT policy and the VOI-aware policies* such that
  - Initially, the same number of samples is available to the agent at each step, independently of the number of pre-simulated games;
  - If samples were unused at the current step, they become available at the next step.

While the UCT engine is not the most powerful engine of Pachi, it is still a strong player. On the other hand, additional features of more advanced engines would obstruct the MCTS phenomena which are the subject of the experiment. The engines were compared on the 9x9 board, for 5000, 7000, 1000, and 15000 samples (game simulations) per ply, each experiment repeated 1000 times. Figure 4 depicts a calibration experiment, showing the winning rate of the VOI-aware policy against UCT as a function of the stopping threshold c (if the maximum VOI of a sample is below the threshold, the simulation is stopped, and a move is chosen). Each curve in the figure corresponds to a certain number of samples per ply. For the stopping threshold of 10^{-6}, the VOI-aware policy is almost always better than UCT, and reaches the winning rate of 64% for 10000 samples per ply.

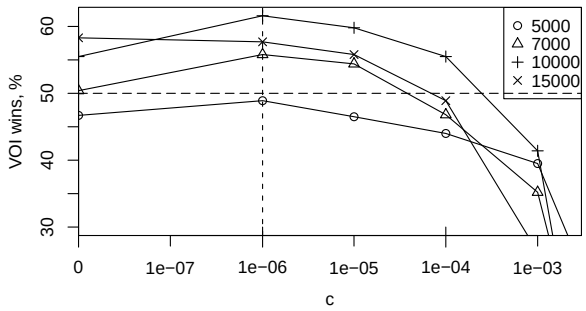

Figure 4: Winning rate of the VOI-aware policy in Go as a function of the cost c, for varying numbers of samples per ply.

Figure 5 shows the winning rate of VOI against UCT $c = 10^{-6}$. In agreement with the intuition (Figure 6.2), VOI-based stopping and sample redistribution is most influential for intermediate numbers of samples per ply. When the maximum number of samples is too low, early stopping would result in poorly selected moves. On the other hand, when the maximum number of samples is sufficiently high, the VOI of increasing the maximum number of samples in a future state is low.

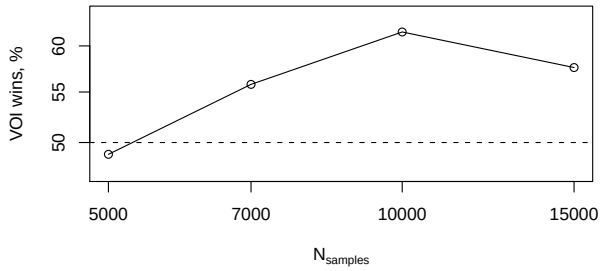

Figure 5: Winning rate of the VOI-aware policy in Go as a function of the number of samples, fixing cost $c = 10^{-6}$.

Note that if we disallowed reuse of samples in both Pachi and in our VOI-based scheme, the VOI based-scheme win rate is even higher than shown in Figure 5. This is as expected, as this setting (which is somewhat unfair to Pachi) is closer to meeting the assumptions underlying the selection MDP.

7 Conclusion

The selection problem has numerous applications. This paper formalized the problem as a belief-state MDP and proved some important properties of the resulting formalism. An application of the selection problem to control of sampling was examined, and the insights provided by properties of the MDP led to approximate solutions that improve the state of the art. This was shown in empirical evaluation both in "flat" selection and when extending the methods to game-tree search for the game of Go.

The methods proposed in the paper open up several new research directions. The first is a better approximate solution of the MDP, that should lead to even better flat sampling algorithms for selection. A more ambitious goal is extending the formalism to trees—in particular, achieving better sampling at non-root nodes, for which the purpose of sampling differs from that at the root.

Abstract

In this paper we present a new approach for tightening upper bounds on the partition function. Our upper bounds are based on fractional covering bounds on the entropy function, and result in a concave program to compute these bounds and a convex program to tighten them. To solve these programs effectively for general region graphs we utilize the entropy barrier method, thus decomposing the original programs by their dual programs and solve them with dual block optimization scheme. The entropy barrier method provides an elegant framework to generalize the message-passing scheme to high-order region graph, as well as to solve the block dual steps in closed-form. This is a key for computational relevancy for large problems with thousands of regions.

1 Introduction

A large set of reasoning problems can be framed as a set of dependency relations among possible structures. These dependencies, usually expressed by a graph, define a joint probability function which drives an inference engine over those structures [18]. Such graphical models, also known as Markov Random Fields (MRFs), are found in a wide variety of fields and applications, including object detection [5], stereo vision [30], parsing [19], or protein design [29], as well as other broad disciplines which include artificial intelligence, signal processing and statistical physics.

The inference problem in MRFs involves assessing the likelihood of possible structures, whether objects, parsers, or molecular structures. The structures are specified by assignments of random variables, whose scores are described in a concise manner by interactions over small subsets of variables. In a fully probabilistic treatment, all possible alternative assignments are considered. However, this requires summing over the assignments with their respective weights – evaluating the partition function. The partition function has a special role which goes beyond that of assigning a probability to the alternative assignments. In addition it plays a fundamental role in various contexts including approximate inference [26], maximum-likelihood parameter estimation [20] and large deviation bounds [4]. Computing the partition function requires summing over the assignments with their respective weights, thus it is a #P hard problem (i.e., efficient weighted counting is unlikely achievable) [31]. Instead there is much focus on finding approximate solutions and bounds [34].

In this paper we propose an iteration of concave and convex programs, each using a primal-dual iterative scheme, to compute increasingly tight upper bounds on the partition function that are based on fractional covering bounds on the entropy [6, 23]. Our work is distinct on a couple of fronts: we handle general region graphical models, unlike previous attempts that focus on particular graphs like bipartite forms (outer and inner regions) or on limited size factors (like pairwise). Secondly, our method is based on achieving a message-passing constellation between nodes of the region graph thereby utilizing the local structure of the problem. A message-passing framework, or more generally the dual decomposition framework, is key for computational relevancy for large problems which contain scores of thousands of regions where the factors are defined on a relatively small number of variables (e.g., when variables correspond to a large grid of points).

We begin by introducing the notation and the fractional covering upper bounds of interest. We subsequently present a message-passing algorithm to compute the upper bound, using dual decomposition. We also introduce a new approach to tighten the fractional covering upper bounds based on the entropy barrier

function and dual block optimization, and demonstrate the effectiveness of the approach.

2 Notations, Problem Setup and Background

Let $x = (x_1, ..., x_n)$ be the realizations of n discrete random variables where the range of the $i'th$ random variable is $\{1, ..., n_i\}$, i.e., $x_i \in \{1, ..., n_i\}$. We consider a joint distribution $p(x_1, ..., x_n)$ and assume that it factors into a product of non-negative functions $\psi_r(x_r)$, known as *potentials*. Usually, the potentials are defined over a small subset of indexes $r \subset \{1, ..., n\}$, called *regions*:

$$p(x_1, ..., x_n) = \frac{1}{Z} \prod_{r \in \mathcal{R}} \psi_r(x_r)$$

where for singletons, i.e. $|r| = 1$, the functions $\psi_r(x_r)$ represent "local evidence" or prior data on the states of x_i, and for $|r| > 1$ the potential functions describe the interactions of their variables $x_r \subset \{x_1, ..., x_n\}$, and Z is the normalization constant, also called the *partition function*. For convenience, we adopt the additive form by setting $\phi_r(x_r) = \ln \psi_r(x_r)$ thereby having the joint probability take the form of a Gibbs distribution:

$$p(x_1, , x_n) = e^{\sum_{r \in \mathcal{R}} \phi_r(x_r) - \ln Z}$$

For example, $p(x_1, x_2, x_3) \propto \exp(\phi_2(x_2) + \phi_{123}(x_1, x_2, x_3) + \phi_{23}(x_2, x_3))$ has three factors with regions $\mathcal{R} = \{2\}, \{1, 2, 3\}, \{2, 3\}$. The factorization structure above defines a hypergraph whose nodes represent the n random variables, and the regions $r \in \mathcal{R}$ correspond to its hyperedges. A convenient way to represent this hypergraph is by a *region graph*. A region graph is a directed graph whose nodes represent the regions and its direct edges correspond to the inclusion relation, i.e., a directed edge from node r to s is possible only if $s \subset r$. We adopt the terminology where $P(r)$ and $C(r)$ stand for all nodes that are parents and children of the node r, respectively. Also, we define R_i to be the set of regions which contains the variable i.

Inference is closely coupled with the ability to evaluate the logarithm of the partition function $\ln Z$. From a variational perspective, there is a relationship between the (minus) Gibbs-Helmholtz free-energy and $\ln Z$:

$$\ln Z = \max_{\substack{p(x) \geq 0, \\ \sum_x p(x) = 1}} \Big\{ \sum_{r \in \mathcal{R}} \sum_{x_r} p(x_r) \phi_r(x_r) + H(p) \Big\} \quad (1)$$

where $p(x_r) = \sum_{x \setminus x_r} p(x)$ is the marginal probability and $H(p) = -\sum_x p(x) \ln p(x)$ is the entropy of the distribution. However, the complexity of the variational representation is unwieldy because both the entropy and the simplex constraint require an evaluation over all possible states of the system $x = (x_1, ..., x_n)$, which is exponential in n. Instead one looks for an approximation or bounds. An upper bound is designed with a tractable approximation of the free-energy by (i) upper bounding the entropy term $H(p)$ by a combination of local entropies over marginal probabilities $p(x_r)$, and (ii) by outer bounding the probability simplex constraints by the so called "local consistency" constraints.

An upper bound on the entropy function $H(p)$ proceeds by replacing the entropy by the fractional covering entropy bounds [6, 23]. These upper bounds are defined as sum of local entropies over the marginal probabilities $H(p(x_r)) = -\sum_{x_r} p(x_r) \ln p(x_r)$:

$$H(p) \leq \sum_{r \in \mathcal{R}} c_r H(p(x_r))$$

These upper bounds hold whenever $c_r \geq 0$ and for every $i = 1, ..., n$ there holds $\sum_{r \in R_i} c_r = 1$, where R_i is the set of all regions that contain i. The second step in obtaining an efficient upper bound is replacing the marginal distributions $p(x_r)$ by "beliefs" $b_r(x_r)$. The beliefs form "pseudo distributions" in the sense that the beliefs might not necessarily arise as marginal probabilities of some distribution $p(x_1, ..., x_n)$. To maintain local consistency between beliefs which share the same variables, we define the *local consistency polytope* $L(G)$ for the region graph G, as follows:

$$L(G) = \left\{ \{b_r\}_{r \in \mathcal{R}} : \begin{array}{ll} \sum\limits_{x_s \setminus x_r} b_s(x_s) = b_r(x_r) & \forall r, s \in P(r) \\ b_r \geq 0, \ \sum_{x_r} b_r(x_r) = 1 & \forall r \in \mathcal{R} \end{array} \right.$$

For example, assume $\mathcal{R}$ consists of the three factors $\{1\}, \{1, 2\}, \{1, 3\}$ then the consistency constraints on the beliefs $b_1(x_1), b_{1,2}(x_1, x_2), b_{1,3}(x_1, x_3)$ enforce their distribution constraints and marginalization constraints $\sum_{x_3} b_{1,3}(x_1, x_3) = b_1(x_1)$ and $\sum_{x_2} b_{1,2}(x_1, x_2) = b_1(x_1)$.

Taken together, the upper bound on the log-partition is defined as follows:

$$\ln Z \leq \max_{b_r(x_r) \in L(G)} \Big\{ \sum_{r, x_r} b_r(x_r) \phi_r(x_r) + \sum_r c_r H(b_r) \Big\} \quad (2)$$

Thus we introduce a family of upper bounds for the partition function, for the set of fractional covering numbers c_r. The computational complexity of these upper bounds is no longer exponential in n, but linear in the number of the regions and the number of assignments in each region.

Computing the fractional covering upper bound: Given potential functions $\phi_r(x_r)$, and nonnegative covering numbers c_r. Set $c_{p,r} = c_p/(c_r + \sum_{p' \in P(r)} c_{p'})$. for every initial values of messages $\lambda_{c \to p}(x_c)$:

1. For $t = 1, 2, ...$

   (a) For $r \in \mathcal{R}$ do:

$$\forall x_r, \forall p \in P(r) \quad \mu_{p \to r}(x_r) = c_p \log \Big(\sum_{x_p \setminus x_r} \exp \Big((\phi_p(x_p) + \sum_{c \in C(p) \setminus r} \lambda_{c \to p}(x_c) - \sum_{p' \in P(p)} \lambda_{p \to p'}(x_p)) \Big/ c_p \Big) \Big)$$

$$\forall x_r, \forall p \in P(r) \quad \lambda_{r \to p}(x_r) = c_{p,r} \Big(\phi_r(x_r) + \sum_{c \in C(r)} \lambda_{c \to r}(x_c) + \sum_{p' \in P(r)} \mu_{p' \to r}(x_r) \Big) - \mu_{p \to r}(x_r)$$

2. Output:

$$\text{(beliefs)} \quad \forall r \in \mathcal{R} \quad c_r \neq 0 : b^*_r(x_r) \propto \exp \Big((\phi_r(x_r) + \sum_{c \in C(r)} \lambda_{c \to r}(x_c) - \sum_{p \in P(r)} \lambda_{r \to p}(x_r)) \Big/ c_r \Big)$$

$$\forall r \in \mathcal{R} \quad c_r = 0 : support(b^*_r) \subset argmax_{x_r} \{ \phi_r(x_r) + \sum_{c \in C(r)} \lambda_{c \to r}(x_c) - \sum_{p \in P(r)} \lambda_{r \to p}(x_r) \}$$

$$\text{(bound)} \quad \sum_{r, x_r} b^*_r(x_r) \phi_r(x_r) + \sum_r c_r H(b^*_r)$$

Figure 1: *The fractional covering upper bound appears in equation (2). The support of the beliefs are their non-zero entries, and when $c_r = 0$ it corresponds to the max-beliefs. When considering bipartite region graphs, this algorithm reduces to many of the previous message-passing algorithms, see Section 6.*

3 Computing High-Order Upper Bounds

In the following we develop an efficient message-passing method to compute the region based upper bounds and their optimal beliefs $b_r(x_r)$, for fixed value of covering numbers c_r, as described in equation (2). These upper bounds depend on the non-negative fractional covering numbers, therefore correspond to maximizing a concave function subject to convex constraints. Such concave programs can be solved by minimizing their dual convex programs. Nevertheless, there are potentially many different convex dual programs, depending on the set of constraints, or Lagrange multipliers, one aims at satisfying. We realize that the probability simplex constraints for $b_r(x_r)$ are easier to satisfy, therefore we derive a dual program which ignores these constraints. For this purpose we use the entropy function as a barrier function over the probability simplex.

Theorem 1. *Define the entropy as a barrier function over the probability simplex,*

$$H(b_r) = \begin{cases} -\sum_{x_r} b_r(x_r) \log b_r(x_r) & if \;\; b_r \in \Delta \\ -\infty & otherwise \end{cases}$$

where $b_r \in \Delta$ if $b_r(x_r) \geq 0$ and $\sum_{x_r} b_r(x_r) = 1$. The fractional covering numbers in equation (2) are non-negative, thus the bound is a concave function and its dual function takes the form

$$D(\lambda) = \sum_r c_r \log \Big(\sum_{x_r} \exp(\hat{\phi}_r(x_r)/c_r) \Big)$$

where

$$\hat{\phi}_r(x_r) = \phi_r(x_r) + \sum_{c \in C(r)} \lambda_{c \to r}(x_c) - \sum_{p \in P(r)} \lambda_{r \to p}(x_r)$$

In particular, strong duality holds and the primal optimal solution can be derived from the dual optimal solution

$$b_r(x_r) \propto \exp \Big(\hat{\phi}_r(x_r) \Big/ c_r \Big)$$

Whenever $c_r = 0$ the corresponding primal optimal solution $b_r(x_r)$ corresponds to the max-beliefs, i.e., probability distributions over the maximal arguments of $\hat{\phi}_r(x_r)$.

Proof: Since we use the entropy as a barrier function over the probability simplex we only need to apply Lagrange multipliers $\lambda_{r \to p}(x_r)$ for the marginalization constraints $b_r(x_r) = \sum_{x_p \setminus x_r} b_p(x_p)$ for every region $r \in \mathcal{R}$, every assignment x_r and every parent $p \in P(r)$. Therefore the Lagrangian takes the form

$$L(b_r, \lambda_{c \to p}) = \sum_{r, x_r} b_r(x_r) \phi_r(x_r) + \sum_r c_r H(b_r)$$
$$+ \sum_{r,\, x_r,\, p \in P(r)} \lambda_{r \to p}(x_r) \Big(\sum_{x_p \setminus x_r} b_p(x_p) - b_r(x_r) \Big)$$

The dual function is recovered by maximizing the beliefs $b_r(x_r)$ in the Lagrangian. Thus

$$\begin{aligned} D(\lambda) &= \sum_r \max_{b_r} \{\sum_{x_r} b_r(x_r)\hat{\phi}_r(x_r) + c_r H(b_r)\} \\ &= \sum_r c_r \max_{b_r} \{\sum_{x_r} b_r(x_r)(\hat{\phi}_r(x_r)/c_r) + H(b_r)\} \end{aligned}$$

The maximization over the beliefs in the Lagrangian is done while satisfying the probability simplex constraint as they are encoded in the domain of the entropy function. The result follows from the duality between the entropy barrier function over the probability simplex and the log-partition function, c.f. equation (1). Strong duality holds using Theorem 6.2.5 in [1]. The primal optimal solution is derived from the dual optimal solution as the primal arguments that maximize the Lagrangian. □

The theorem above uses the conjugate duality between the entropy barrier function, weighted by the non-negative number c_r, and the weighted extension of the log-partition. The weighted log-partition is called the soft-max function and it is used as a smooth approximation for the max function whenever $c_r \to 0$. In particular, when $c_r = 0$ the soft-max function reduces to the max-function, and Theorem 1 demonstrates the known conjugate duality between the indicator function over the probability simplex and the max-function.

One of the most important properties of the dual function is that it decomposes the constraints set, a feature that is typically called dual decomposition. In Theorem 1 every dual variable $\lambda_{c\to p}(x_c)$ represents a marginalization constraint $\sum_{x_p \setminus x_c} b_p(x_p) = b_c(x_c)$ in the primal. Therefore optimizing a single dual variable amounts to solving the primal problem with a single constraint. Therefore, the dual coordinate descent algorithm decomposes the primal problem complexity to smaller sub-problems, while the dual function encodes the consistency between the sub-problems solutions. Moreover, since the marginalization constraints encode the graphical model, performing block coordinate descent results in sending messages along the edges of the region graph, thus we are able to cope with large-scale and high-order graphical models.

Theorem 2. *Block coordinate descent on the dual in Theorem 1 takes the form: For every region $r \in \mathcal{R}$*

$$\forall x_r, \forall p \in P(r)$$

$$\mu_{p\to r}(x_r) = c_p \log\Big(\sum_{x_p \setminus x_r} \exp(\phi_{p,r}(x_p)/c_p)\Big)$$

$$\lambda_{r\to p}(x_r) = c_{p,r}\Big(\phi_r(x_r) + \sum_{c\in C(r)} \lambda_{c\to r}(x_c) + \sum_{p'\in P(r)} \mu_{p'\to r}(x_r)\Big) - \mu_{p\to r}(x_r)$$

where $c_{p,r} = c_p/(c_r + \sum_{p'\in P(r)} c_{p'})$ and $\phi_{p,r}(x_p) = \phi_p(x_p) + \sum_{c\in C(p)\setminus r} \lambda_{c\to p}(x_c) - \sum_{p'\in P(p)} \lambda_{p\to p'}(x_p)$. If a region covering number in the dual objective equals zero, i.e., $c_r = 0$, then the block coordinate descent update rules for this region hold for every non-negative c_r.

Proof: The gradient equals to

$$\frac{\partial D}{\partial \lambda_{r\to p}(x_r)} = \sum_{x_p \setminus x_r} b_p(x_p) - b_r(x_r)$$

where the probability distributions $b_r(x_r), b_p(x_p)$ are proportional to $\exp(\hat{\phi}(x_r)/c_r)$ and $\exp(\hat{\phi}(x_p)/c_p)$ respectively while $\hat{\phi}$ is defined in Theorem 1. Whenever c_r or c_p are zero, their respective (sub)gradients are their max-beliefs or equivalently probability distributions over their maximal arguments of $\hat{\phi}$, c.f., Danskin theorem [1].

The optimal dual variables are those for which $\partial D/\partial \lambda_{r\to p}(x_r) = 0$, i.e., the corresponding beliefs agree on their marginal probabilities. When setting $\mu_{p\to r}(x_r)$ as above, the marginalization of $b_p(x_p)$ equals

$$\sum_{x_p \setminus x_r} b_p(x_p) \propto \exp\Big((\mu_{p\to r}(x_r) + \lambda_{r\to p}(x_r))/c_p\Big)$$

Therefore, by taking the logarithm, the gradient vanishes whenever the beliefs numerators agree up to an additive constant

$$\frac{\mu_{p\to r}(x_r) + \lambda_{r\to p}(x_r)}{c_p} = \frac{\phi'_r(x_r) - \sum_{p\in P(r)} \lambda_{r\to p}(x_r)}{c_r} \quad (3)$$

where $\phi'_r(x_r) = \phi_r(x_r) + \sum_{c\in C(r)} \lambda_{c\to r}(x_c)$. Multiplying both sides by $c_r c_p$ and summing both sides with respect to $p' \in P(r)$ we are able to obtain

$$\sum_{p'\in P(r)} \lambda_{r\to p'}(x_r) = c_{p,r}\Big(\phi'_r(x_r) + \sum_{p'\in P(r)} \mu_{p'\to r}(x_r))\Big)$$

Plugin it into equation (3) results in the desired block dual descent update rule, i.e., $\lambda_{r\to p}(x_r)$ for which the partial derivatives vanish. □

For convenience, the explicit update rules also appear in Fig. 1. The above theorem provides a closed-form solution for block coordinate descent on the dual objective. Since the dual values are always lower bounded by the primal values, this algorithm is guaranteed to converge. However, the dual objective is not strictly convex therefore, a-priori, coordinate descent might not converge to the optimal solution [27]. Nevertheless, our proof technique demonstrates the dual-primal relation of dual coordinate descent, as throughout its runtime it generates a sequence of primal variables,

namely the beliefs, which agree on their marginal probabilities. In the following we describe the conditions for which we can recover the primal optimal and dual optimal solutions.

Theorem 3. *The dual block descent algorithm in Theorem 2 is guaranteed to converge whenever c_r are non-negative. Moreover, if $c_r > 0$ the dual block descent algorithm converges to the dual optimal value, and the beliefs $b_r(x_r)$ that are generated throughout the algorithm runtime converge to the primal optimal solution ; whenever its dual sequence is bounded every of its limit points is an optimal dual solution.*

Proof: See supplementary material. □

The above theorem does not constrain the dual variables, namely the messages. Specifically, although the dual value is guaranteed to converge to the optimum, the messages are not guaranteed to be bounded. This may happen since the dual function is not strictly convex, and the messages can be updated along an unbounded plateau that does not reduce the dual objective. The above result can be extended to guarantee optimality even if $c_r > 0$ only for the maximal regions, i.e., regions that are not contained by other regions. However, this result is mathematically involved as it does not correspond anymore to Bregman divergences and it is beyond the scope of this work.

The algorithm in Theorem 2 has an important meaning even when the primal function is not concave. In this case we lose all convergence guarantees, but the algorithm represents the Lagrangian saddle points. Therefore, whenever the algorithm converges it reaches a local maximum of the primal program.

Theorem 4. *Assume the program in equation (2) has mixed numbers $c_r \gtrless 0$. Then this program is not concave and the algorithm in Theorem 2 is not guaranteed to converge, but whenever it converges it reaches a stationary point for this program.*

Proof: See Supplementary material. □

The saddle point theorem does not consider programs for which the covering numbers can be zero, since in these cases we cannot uniquely restrict the beliefs. Nevertheless, this theorem applies to many important cases, such as the Bethe entropy and the tree reweighed entropies. In these cases, the negative coefficients for variables $c_i = 1 - \sum_{\alpha \supset i} c_\alpha$, where α are the non-singleton regions, play an important role. Specifically, the Bethe entropy provides an exact characterization for the entropy function over tree models, and the tree-reweighted entropy provides tighter bounds than the fractional covering bounds when restricting the fractional coverings to pairwise entropies. Unfortunately, the message-passing algorithm is not guaranteed to converge in these cases but the theorem above proves that when it converges it reaches a (local) maximum of the model.

4 Tightening High-Order Upper Bounds

Up to this point, the fractional covering numbers c_r were held fixed, while we computed the upper bound for the partition function that is described in equation (2). We now consider how to find the optimal covering numbers which minimize the upper bound, while assuming we are able to compute the upper bound and its optimal arguments efficiently as described in Fig. 1. First we state some of the properties of these upper bounds as a function of their fractional covering numbers:

Theorem 5. (Danskin Theorem) *Denote the log-partition upper bound by*

$$U(c) = \max_{b_r(x_r) \in L(G)} \Big\{ \sum_{r,x_r} b_r(x_r)\phi_r(x_r) + \sum_r c_r H(b_r) \Big\}$$

Assume $c_r \geq 0$ and that the maximal regions covering numbers are positive. Then $U(c)$ is a convex and differentiable function, and its partial derivatives are

$$\frac{\partial U}{\partial c_r} = H(b_r^*)$$

where

$$b_r^*(x_r) = \underset{b_r(x_r) \in L(G)}{argmax} \Big\{ \sum_{r,x_r} b_r(x_r)\phi_r(x_r) + \sum_r c_r H(b_r) \Big\}$$

Proof: This is a special case of Danskin theorem, since $L(G)$ is a compact set. [1] □

To find the minimal upper bound on the partition function we need to minimize a convex and differentiable function over the convex set of fractional covering.

$$\min_{c_r \geq 0, \sum_{r \in R_i} c_r = 1} U(c)$$

Minimizing a convex function over a convex set is typically done using the conditional gradient method, for which one finds a direction of descent while respecting the fractional covering constraints [2]. Finding the direction of descent amounts to solving the linear program

$$d = \underset{c_r \geq 0, \sum_{r \in R_i} c_r = 1}{argmin} \sum_r c_r H(b_r^*) \tag{4}$$

The direction of descent is always attained, since it is the minimal argument of a continuous function over a compact set. However, when considering

Tightening the fractional covering upper bound: Given functions $\phi_i(r_i)$. For every initial values of $\lambda_i(r)$:

1. For $t = 1, 2, ...$
   (a) For $r \in \mathcal{R}$ do:

$$\forall i \in r \quad \lambda_i(r) = \epsilon \log \Big(\sum_{r_i \neq r} \exp \Big((\phi_i(r_i) + \lambda_i(r_i) \Big/ \epsilon \Big) \Big) - \phi_i(r)$$

$$\text{additively normalize } \lambda_i(r) \text{ such that } \quad \sum_{i \in r} \lambda_i(r) = 0$$

2. Output: $\forall i$, set $q_i(r_i) \propto \exp \Big((\phi_i(r_i) + \lambda_i(r_i)) \Big/ \epsilon \Big)$ and $\forall r$ set $c_r = q_i(r)$, for any of $i \in r$.

Figure 2: *The dual decomposition algorithm for recovering the direction of descent, described in equation (4). This algorithm can be seen as message-passing by reformulating the indexes $\lambda_i(r) \leftrightarrow \lambda_{i \to r}$. This demonstrates the differences between our two algorithms. The similarity between the two algorithms is a consequence of the block dual steps and the use of the entropy barrier method.*

large-scale problems, this linear program cannot be efficiently solved using standard linear programming solvers. For example, the simplex algorithms or interior point methods typically involve inverting the constraints matrix, an operation that cannot be done efficiently when dealing with graphical models that consist of millions of regions.

In this section we develop a new type of efficient linear programming solver for finding the minimal upper bound. Importantly, we cannot use the message-passing solvers in Section 3 to minimize these upper bounds, since the objective as well as the constraint sets in equation (4) are significantly different. However, we are able to construct efficient solvers while using the entropy barrier function in a similar manner. This emphasizes the computational importance of the entropy barrier function, since it results in closed-form update rules which turn to be crucial for large-scale linear programs.

The constraints of the linear program in equation (4) restrict the covering numbers $(c_r)_{r \in R_i}$ to the probability simplex. In order to use dual decomposition effectively, we need to decouple these simplex constraints, such that they restrict *separate* distributions. Therefore we inflate the covering numbers c_r to non-overlapping probability distribution $q_i(r_i)$ for every $i = 1, ..., n$, while enforcing these distributions to agree, namely $q_i(r) = q_r$ for every $i \in r$. One can verify that these constraints are equivalent to the constraints over c_r in equation (4). Thus we reformulate the linear program in equation (4) as

$$\underset{\substack{\forall i \; q_i \text{ is probability} \\ \forall i \in r \quad q_i(r) = q_r}}{\operatorname{argmin}} \; \sum_{i, r_i} q_i(r_i) \Big(H(b^*_{r_i}) / |r_i| \Big)$$

For computational efficiency we solve the above linear program by dual block ascent. Unfortunately, dual coordinate ascent may be sub-optimal when the dual program is not smooth, or equivalently the primal program is not strictly convex. Therefore we use the entropy barrier method to make the primal program strictly convex, which results in a smooth dual program. The following theorem shows that using the barrier method does not affect the quality of the solution.

Theorem 6. *Let $\phi_i(r_i) = H(b^*_{r_i})/|r_i|$ and consider the linear program for finding the direction of descent*

$$\min_{\substack{\forall i \; q_i \; is \; probability \\ \forall i \in r \quad q_i(r) = q_r}} \; \sum_{i, r_i} q_i(r_i) \phi_i(r_i)$$

Then the primal-dual programs

(*primal*)

$$\min_{\substack{\forall i \; q_i \; is \; probability \\ \forall i \in r \quad q_i(r) = q_r}} \; \sum_{i, r_i} q_i(r_i) \phi_i(r_i) - \epsilon \sum_i H(q_i)$$

(*dual*)

$$\max_{\sum_{i \in r} \lambda_i(r) = 0} \; \epsilon \sum_i \log \Big(\sum_{r_i} \exp \Big((\phi_i(r_i) + \lambda_i(r_i)) \Big/ \epsilon \Big) \Big)$$

are $\delta-$approximations of the original linear program, where $\delta = \sum_i \epsilon \log |r_i|$

Proof: The entropy $H(q_i)$ is a non-negative measure, thus the primal program lower bounds the original linear program. The bound holds since $H(q_i) \leq \log |r_i|$. The dual program is also a $\delta-$approximation since strong duality holds. □

Having a smooth dual program which relates to a strictly convex primal program, we can perform dual

block ascent to reach their optimum. Using the entropy barrier function enables us to derive a closed-form update rules.

Theorem 7. *Consider the primal and dual programs in Theorem 6. Then the block dual ascent takes the form*

$$\forall r,\ \ \forall i \in r$$
$$\lambda_i(r) = \epsilon \log\Big(\sum_{r_i \neq r} \exp\Big(\big(\phi_i(r_i) + \lambda_i(r_i)\big/\epsilon\Big)\Big) - \phi_i(r)$$

additively normalize $\lambda_i(r)$ *such that* $\sum_{i \in r} \lambda_i(r) = 0$

Also, block dual ascent is guaranteed to converge to the dual optimum, the probabilities $q_i(r_i)$ *that are generated throughout the algorithm runtime converge to the primal optimal point and whenever the dual sequence is bounded it is guaranteed to converge to an optimal dual solution.*

Proof: See supplementary material. □

For convenience, the algorithm appears in its explicit form in Fig. 2. The above block dual ascent algorithm can be seen as message-passing, where messages are sent between regions and variables, $\lambda_i(r) \leftrightarrow \lambda_{i \to r}$. This demonstrates the differences between our two algorithms, where the first sends two types of real-valued vectors $\lambda_{c \to p}(x_c), \mu_{p \to c}(x_c)$ along the edges of the regions graph, and the second sends a real number $\lambda_{i \to r}$ between variables and regions. The similarity between the two algorithms is a consequence of the block dual steps and the entropy barrier function.

5 Empirical Evaluation

In our experiments we first compared our message-passing algorithm for computing the fractional covering upper bound in equation (2) with the current state-of-the-art solver [12]. We compared these algorithms on the grid shape spin glass model. A spin glass model consists of n spins $x_1, ..., x_n \in \{-1, 1\}$, whose local potentials are $\phi_i(x_i) = \theta_i x_i$ and its pairwise potentials are $\phi_{i,j}(x_i, x_j) = \theta_{i,j} x_i x_j$. The field parameters θ_i were chosen uniformly at random from $[-0.05, 0.05]$ and the coupling parameters $\theta_{i,j}$ were chosen uniformly at random from $[-1, 1]$. We used the same covering numbers for all edges and squares in the grid, setting $c_{i,j} = c_{i,j,k,l} = 1/9$ and $c_i = 1 - \sum_{r \in R_i \setminus i} c_r$. Therefore we satisfy the covering number constraints, $c_r \geq 0$ and $\sum_{r \in R_i} c_r = 1$. Our algorithm described in Fig. 1 used a region graph which connects squares to pairs and pairs to singletons, namely the Hesse diagram. [12] use a bipartite inner-outer region graph, for which all outer regions, i.e., squares, are connected to all inner regions, i.e., pairs and singletons. We used the same Matlab code, on a single core of Intel I5 with 8GB RAM, for both algorithm as our algorithm can be applied to bipartite region graphs as well. We compared both methods on 5×5 ,..., 100×100 grids and the stopping criteria was a primal-dual gap of 10^{-4}. Fig. 3 shows that passing messages over the Hesse-diagram is better than working over the bipartite inner-outer region graph, and the gap between these methods is significant for large graphical models. We attribute this behavior to the fact that on the Hesse diagram we can pass many messages between pairs and singletons, while using time consuming square messages only when they are needed. In contrast [12] use square messages in every message-passing iteration.

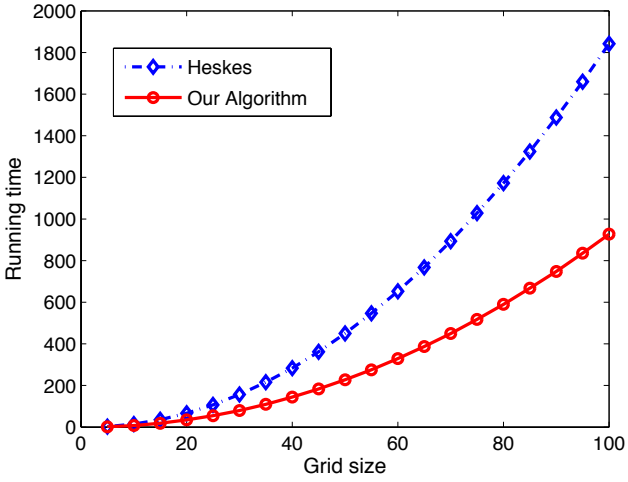

Figure 3: *Comparing our message-passing algorithm for computing the fractional covering upper bound in Section 3 with [12]. Comparison is for* 5×5*,...,* 100×100 *grid shape spin glass models, with singletons, pairs and squares regions. Our approach can utilize intermediate size message, between pairs and singletons, while [12] use the inner-outer region graph, thus sending square based messages in every iteration.*

In our experiments we also compared our dual decomposition algorithm for recovering the direction of descent over the fractional covering numbers in the tightening procedure, as described in Fig. 2. In this experiment we used the singletons, pairs and squares regions that correspond to the grid shape graphs. We used $\phi_i(r_i) = H(b_r^*)/|r|$, where $b_r^*(x_r)$ were the optimal beliefs in our previous experiments. The results in Fig. 4 show that the state-of-the-art off-the-shelf solver, the CPLEX, is good for small scale problems but significantly worse when applied to large scale graphical models. We note that our implementation is in Matlab, which has a significant overhead when applied to small scale problems.

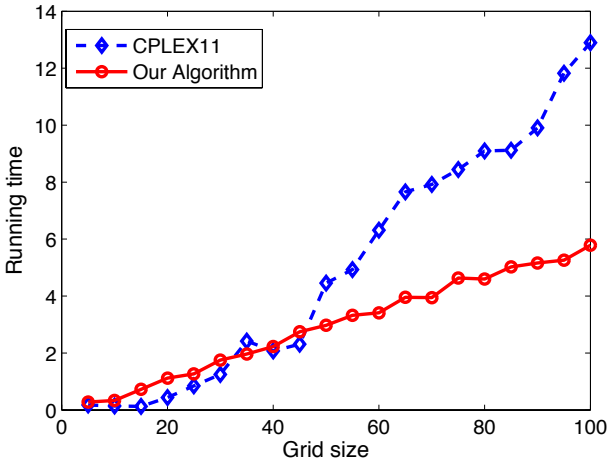

Figure 4: *Comparing our dual decomposition algorithm for recovering the direction of descent over fractional covering numbers in Section 4 with the CPLEX algorithm. Comparison is for singletons, pairs and squares regions that correspond to* 5×5*,...,* 100×100 *grid shape graphs.*

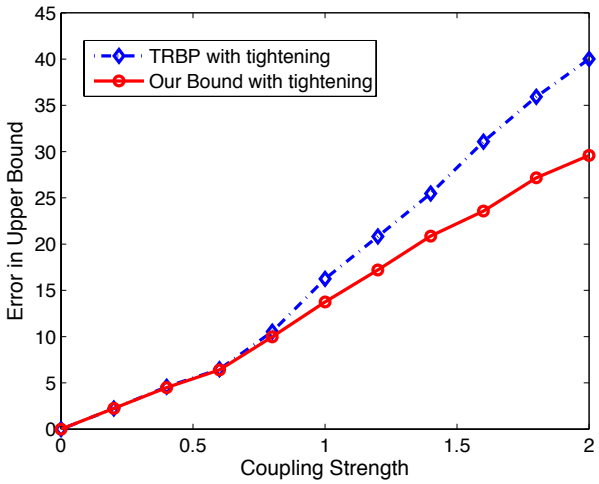

Figure 5: *Comparing tightening tree-reweighted bounds with fractional covering bounds over grid shaped graphs. Our approach can use covering numbers of high-order regions therefore achieves better bounds.*

Tightening the fractional covering upper bounds can be applied to general region graphs. However, we cannot compare our approach on high-order region graph, as all previous approaches are efficient only when the regions consist of at most pairs of indexes. Therefore we compared our approach to tightening tree reweighed upper bounds [32] implemented by [14]. In our experiments we used the grid shaped spin glass model with local field parameters $\theta_i \in [-0.05, 0.05]$ and mixed coupling potentials $\theta_{i,j} \in [-c, c]$ that ranges over $c = 0, ..., 2$. Our tightening algorithm used singletons, pairs and squares regions. The results appear in Fig. 5 showing that going to high-order regions graphs provides tighter upper bounds.

6 Related Work

In this work we investigate upper bounds on the partition function over regions graphs. For this purpose we use the known fractional covering upper bounds for the entropy function [6, 23]. We applied these bound to the partition function through conjugate duality.

Tightening upper bounds for the partition function results in two programs: A concave program for computing the upper bounds and a convex program which tightens these bounds. The field of convex (or concave) optimization is large and contains many different solvers. However, most of these solvers cannot be applied efficiently to our problems, since they ignore their structures [3, 1]. Our work differs from these works in an important respect, as we exploit the structure of the problem, decomposing the constraints through the dual program and then performing efficient closed-form steps in every iteration. This block coordinate steps in the dual enable us to efficiently deal with large-scale problems.

Upper bounds on the partition function were extensively studied in the last decade. [32] presents upper bounds for graphical models that are based on spanning trees, as well as a method to tighten these bounds using conditional gradient descent. The conditional gradient is recovered by looking for a maximal spanning tree in the graphical model. The upper bound for the graphical model is computed by a message-passing algorithm called sum-TRBP, a method that extends to region graphs [35]. This work differs from ours in important respects: First, the spanning tree method best fits graph and encounters computational difficulties when dealing with hypergraphs, or equivalently region graphs. Working with region graphs, their conditional gradient method looks for a spanning hypertree, which is a NP-hard problem [17]. This problem was already pointed out in [32] and motivates this work. Thus in our work we suggest to use the known fractional covering upper bounds over regions graphs [6, 23], and we compute the conditional gradient through dual decomposition and the entropy barrier method. Second, the sum-TRBP and its high-order extension compute a bound that has covering numbers with mixed signs. Thus the sum-TRBP is not guaranteed to converge. In contrast our work considers bounds that have only positive covering numbers, thus our bound computation is guaranteed to converge to the optimum. We

note that there are other algorithms that fix the convergence of sum-TRBP, but these algorithms cannot be applied to high-order regions graphs [9, 11].

Convexity provides a well established framework to extend the spanning trees upper bounds to other combinatorial objects. [8] describe upper bounds based on planar decomposition. Since planarity is a property of pairwise regions this work does not extend to general region graphs. In contrast, our work presents efficient bounds and tightening for high-order region graphs. [7] provide a family of upper bounds that are based on conditional entropy decompositions. These upper bounds can be applied to high-order region graphs. However, this work differs from ours in important respects: First, to compute the bound they directly solved the primal program. Since the primal program consists of conditional entropies, which are not strictly concave, they used a conditional gradient solver which is suboptimal when addressing large scale region graphs. A subsequent work presented the corresponding message-passing solver, but it was restricted to pairwise regions [9]. In contrast, our work introduces the fractional covering entropy bounds which are strictly concave, thus providing an efficient dual decomposition solver through message-passing over the region graph. Second, their tightening approach considers all conditional entropies sequences, thus they are restricted to a small number of sequences. In contrast, our work provides an efficient dual decomposition algorithm to tighten the bound over all fractional covering numbers. [21] introduce a new approach for conditional entropy decomposition, which allows to use more sequences through a mini-bucket elimination method. However, this approach suffers from similar drawbacks as [7] when applied to region graphs.

In Fig. 1 we present a message-passing algorithm to compute upper bounds on the partition function in high-order graphical models. This algorithm can be applied to general programs, consisting of sums of linear terms and entropy terms. In the last decade many different message-passing algorithms were devised for similar programs. Assuming all regions intersect on at most one variable, our algorithm has two types of messages, $\lambda_{i\to\alpha}(x_i)$ and $\mu_{\alpha\to i}(x_i)$, and it reduces to the norm-product belief propagation, which includes as special cases both sum-product and max-product, tree-reweighted belief propagation, NMPLP and the asynchronous splitting algorithm for different values of c_i, c_α [26, 32, 33, 10, 28]. However, the main purpose of our algorithm is high-order region graphs. In this perspective, when the region graph is a bipartite graph that contains outer-inner regions, our algorithm reduces the parent-to-child generalized belief propagation algorithm [36, 16, 13], and its convex forms [12, 24]. These works differ from ours in an important respect, as they consider a bipartite region graph which is computationally demanding since it uses the maximal regions in every iterations. In contrast, our algorithm considers a general region graph, thus enables to pass messages between intermediate size regions to gain computational efficiency.

7 Conclusions and Discussion

In our work we describe methods to tighten upper bounds on the partition function over general region graphs. These upper bounds use the fractional covering bounds on the entropy function. We introduced two dual decomposition algorithms, for computing the upper bound and to minimize the upper bound. Both algorithms use the entropy barrier function to obtain a closed-form block dual steps that optimize their respective dual programs.

To compute the upper bound we solve a concave program, consisting of linear terms and entropy terms. Our solver passes messages along the edges of the region graph that describe these terms. The computational complexity of this solver depends on the structure of the region graph. It turns out that there are many different region graphs, such as the inner-outer graph or the Hesse diagram that describe the same program [12, 36]. Although some works reasoned about the optimal graph, this problem is largely open [25].

Interestingly, the message-passing algorithm for computing the upper bound sends partial log-partition functions $\mu_{p\to c}(x_c)$ weighted by the covering number c_r. In particular, when $c_r = 1$ it sends a sum-product based message and when $c_r = 0$ is sends a max-product based messages. The form of these messages is determined by the covering number, and their primal interpretation relates to the weight c_r of the corresponding entropy function. For example, whenever no entropy terms are used, i.e., we use the algorithm for solving linear program relaxations, we only use max-product based operations and our algorithm contains the max-product, max-TRBP, NMPLP and convex max-product as special cases. In this perspective we could have used this algorithm to tighten linear program relaxations, but this problem was solved by [29]. Surprisingly, using fractional covering upper bounds while some of the covering numbers equal zero, we get a mixture of sum-product and max-product rules. This is a result of having sum of entropy and non-entropy terms in the primal. This goes against the common practice that mixing max-product and sum-product rules relates to the marginal-MAP solution [18, 22, 15]. The relations and differences between these two problems are subject to further research.

Abstract

In typical real-time strategy (RTS) games, enemy units are visible only when they are within sight range of a friendly unit. Knowledge of an opponent's disposition is limited to what can be observed through scouting. Information is costly, since units dedicated to scouting are unavailable for other purposes, and the enemy will resist scouting attempts. It is important to infer as much as possible about the opponent's current and future strategy from the available observations. We present a dynamic Bayes net model of strategies in the RTS game *Starcraft* that combines a generative model of how strategies relate to observable quantities with a principled framework for incorporating evidence gained via scouting. We demonstrate the model's ability to infer unobserved aspects of the game from realistic observations.

1 INTRODUCTION

Real-time strategy (RTS) games, which are video game simulations of both the economic and military aspects of warfare, present a rich variety of reasoning challenges. Players must manage resources, plan at multiple time scales, coordinate heterogeneous armies composed of as many as 100 individual units, and respond to the actions of adversaries, all with incomplete information about the game state and under real-time constraints. We are particularly interested in the problem of decision-making with incomplete information. Specifically, how can an agent predict the intentions of its opponent from a limited number of observations?

This work addresses the problem of *unit count inference* during the early stages of the game. In the opening minutes, players make choices about what kinds of units to build and what technologies to pursue. These choices dictate the overall "feel" of the game: aggressive versus defensive, economy versus technology, etc. The players' plans are reflected in their opening *build orders*. Because resources are limited in the early game, players must commit to a particular path through the technology tree, culminating in a certain composition of the initial army. The primary concern early in the game is to choose an opening strategy that will gain an advantage against the opponent's opening.

This task is complicated by the limited information available to the players. Enemy units are visible only if a friendly unit is nearby. A player's knowledge of her opponent's strategy is thus limited to what has been observed through reconnaissance. It is impractical to observe all important actions of the enemy, because attempting to do so would divert many units from other tasks, and the enemy will attempt to destroy the scouts before they learn anything useful. Instead, players must gain whatever information they can with reasonable effort, and then evaluate their limited knowledge to infer the likely disposition of the enemy. An effective model of opening strategy must be able to make useful inferences from realistic evidence.

We present a dynamic Bayesian network model of opening strategy and apply it to the RTS game *Starcraft*. We combine a latent variable model of the true game state with an observation model that describes how the latent state generates the observed state. The true state, which we call the *battle space*, can be described by the true counts of each type of unit controlled by the enemy. The evolving counts of the various unit types are represented as Markov processes that are conditionally independent given the history of a hidden *strategy* process. The strategy determines which units are produced in a given time step, and the produced units accumulate to form the true counts. The observation model then determines the likelihood of observations given the true state and a measure of observation "effort." Although the hidden state space is potentially very large due to the number and car-

dinality of the "count" variables, the structure of the model admits an efficient particle filtering algorithm for inference, taking advantage of the conditional independence of the unit counts.

1.1 REAL-TIME STRATEGY GAMES

We now briefly describe the mechanics of a typical RTS game. RTS games are simulations of total warfare. Players claim *bases*, which contain *resources*, by building *city centers*. They then use *workers* to harvest the resources, which they spend to construct *buildings* and *mobile units*. We will use the generic term *units* to refer both to buildings and to mobile units. *Production buildings* produce mobile units, including both workers and military units. In contrast, constructing *tech buildings* enables access to more powerful fighting units, and to further tech buildings. The game ends when one player controls no buildings, though players will typically resign a lost position much earlier.

Most RTS games contain a mechanism called the "fog of war". A metaphor for the limited intelligence available to military commanders, the fog of war makes enemy units invisible unless they are within visual range of a friendly unit. Players who lack accurate information about their opponents' activities are at risk of being surprised by attacks for which they are not prepared. Skilled players thus make scouting a high priority, and they are adept at inferring their opponents' intentions on the basis of that scouting. It is this inference process that we seek to model.

1.2 RELATED WORK

A complete description of a player's opening would specify how many units of each type existed at any moment. To our knowledge, no one has yet attempted to create a model of openings at this level of granularity. Existing work simplifies the task by adopting less-detailed descriptions of opening strategies.

A common simplification is to assume a small number of opening categories, such as "rush attack" or "strong economy." Weber and Mateas (2009) created a set of labels for *Starcraft* openings based on player-community vocabulary, and tried a variety of supervised classifiers for predicting the labels. Schadd et al. (2007) designed a two-level hierarchy of labels for the free RTS game *Spring*.

An alternative to categorical strategies is to model the dynamics of the game state itself. One can then represent an opening strategy as a path through the state space. Ponsen et al. (2007) used a finite state machine (FSM) model of building construction in *Wargus*. States represent which buildings have been built, and transitions are triggered by the construction of novel building types. Hsieh and Sun (2008) took a similar approach in *Starcraft* but used a stochastic FSM, with transition probabilities learned from gameplay data. Dereszynski et al. (2011) used a hidden Markov model (HMM). Transitions between hidden states occur at fixed time intervals, and the observations are Bernoulli random variables specifying the probability of building units of each type in the current state.

Except for Schadd et al. (2007), the work discussed so far assumes that the agent has access to information, such as the times at which particular units were constructed, that would be difficult to observe during actual gameplay. Another exception is Synnaeve and Bessière (2011), who used a directed graphical model to describe a joint distribution over strategy categories, game states, and observations in *Starcraft*. Their game states are Boolean vectors indicating whether each type of unit has been built, and game states are conditionally independent given strategy categories. Observations are incorporated by assigning 0 posterior probability to states that are inconsistent with observations.

The idea of an observation model (also known as a detection model) has been applied in many settings. Observation models are needed when we do not observe the true state of a system, but rather the results of some process parameterized by the latent true state. For example, in ecological modeling, we are often interested in the true number of individuals of a certain species present in the environment, but have access only to counts provided by field observers, who may not detect the species even if it is present (MacKenzie et al., 2002). The observation model describes how the hidden state determines the observed state, possibly as a function of covariates such as observer effort. One can then find the MAP estimate of the hidden state, accounting for the evidence. Our model is quite similar in spirit to the "occupancy-detection" models discussed by Hutchinson et al. (2011).

1.3 OUR CONTRIBUTIONS

This work improves upon existing models of RTS game opening strategy in several ways. First, we model the game state at the level of individual unit counts over time, enabling inference at the level of detail necessary for making gameplay decisions. Second, because individual unit counts are directly observable during gameplay, our model does not require evidence that is impossible to acquire in order to make inferences. Third, because our observation model includes predictors of scouting success, we can extract maximum value from limited observations, particularly from *failure* to observe a unit despite significant effort.

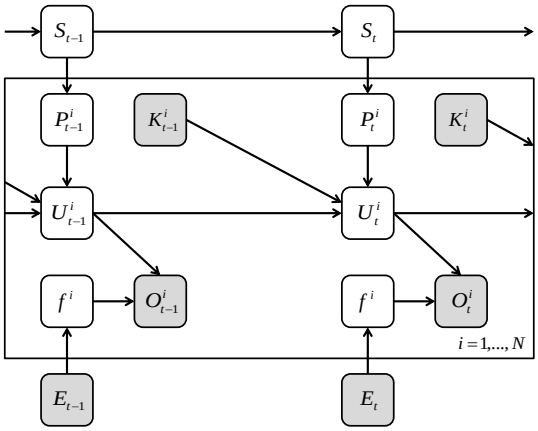

Figure 1: Two-slice representation of the reconnaissance model. We use plate notation to show that separate P, K, U, f, and O variables exist for each unit type i (but note that the variables are not exchangeable). There is a direct link from U^i_{t-1} to U^i_t for each unit type. Shaded rectangles denote variables that we can directly observe.

2 THE MODEL

The overall model (Figure 1) is a discrete-time dynamic Bayes net (Dean and Kanazawa, 1988), combining two distinct components, the *state model* and the *observation model*, which we describe separately.

2.1 STATE MODEL

The state model describes the process that generates the true state of the battle space. Each game corresponds to a path through a discrete state space beginning at a designated start state. Let S_t denote the state at time t. Time is discretized into 30-second intervals, and the player makes a state transition once every 30 seconds. We will say "epoch k" or "time $t = k$" to denote the time step begun by the kth transition. When the player visits state s, he or she decides how many units of each type to produce. Let P^i_t be the number of units of type i produced at time t. We model the decision to produce k units of type i as occurring in two steps. First, a decision is made about whether to produce any units of type i at all. Then, if the first decision is to produce one or more units, a decision is made about how many units to produce. This is modeled by the zero-inflated Poisson distribution

$$P(P^i_t = k | S_t = s) = \begin{cases} 1 - \nu^i_s & k = 0 \\ \nu^i_s \cdot Pois(k-1; \lambda^i_s) & k > 0 \end{cases}$$

Here, ν^i_s is the probability of producing one or more units of type i in state s, and hence, $1 - \nu^i_s$ is the probability of producing zero units. The number of units produced (beyond the first) is then determined by the Poisson rate parameter λ^i_s.

We model production as a two-step decision to make it easier to capture the decision not to produce any units of a particular type. This is important for modeling the production of *tech buildings*. In most cases, only one tech building of a given type is needed—it just serves as a prerequisite for producing higher-tech units. Decisions to produce tech buildings reflect strategic choices, so it is important to capture these 0/1 decisions. The alternative of just using a Poisson distribution does not handle this well, because there is no way to control the probability of producing 0 units without also changing the shape of the distribution. Similarly, modeling the unit production as Bernoulli random variables is not appropriate, because there do exist cases where two such buildings will be produced.

Let $\mathbf{P}_t = (P^i_t)_{i=1}^N$ denote the vector of unit production for all N unit types at time t. In our model, the P^i_t variables are independent conditioned on the current state S_t. Of course, there are important constraints among production rates of multiple unit types, since producing units of one type consumes resources that cannot be spent to produce other types. In principle, these constraints can be incorporated by using a sufficiently large number of states. However, that may conflict with the goal of capturing the player's overall strategy via the sequence of state transitions. Thus, the number of states must be selected appropriately to balance these objectives.

When scouting, we cannot directly observe the production of units; rather, a scout only observes (a subset of) the units that exist at a given time. To connect the individual unit production decisions to the scouting observations, we need to model the total number of units U^i_t of type i that exist at time t. This is equal to the number of units produced by time t minus the number that have died. Each U^i_t takes values in $\{0, 1, \ldots, U_{\max}\}$, where $U_{\max}$ is the maximum number of units that can exist. Because the production variable P^i_t has infinite support, the assignment $U^i_t = U_{\max}$ represents the situation where there are $U_{\max}$ *or more* units of type i.

Unit deaths can occur in two ways. Most deaths involve our units killing their units, and these deaths, $\mathbf{K}_t = (K^i_t)_{i=1}^N$, are observed. Each unit of type i also has a small probability ℓ^i of suffering an unobserved loss in each time step. For example, a building that was scouted while under construction may subsequently be canceled. Starting from initial unit counts c^i, the total count of unit type i at time t is defined recursively as

$$\begin{aligned} U^i_0 &= c^i \\ U^i_t &\sim Binomial(U^i_{t-1} - K^i_{t-1}, 1 - \ell^i) + P^i_t \end{aligned}$$

When calculating U^i_t in the case where $U^i_{t-1} = U_{\max}$,

we do not know the exact value represented by U^i_{t-1}, so we assume that it is *exactly* $U_{\max}$. Very rarely, this will lead us to underestimate U^i_t, but we set $U_{\max}$ to be large enough to avoid this problem in most cases.

Let $\mathbf{U}_t = (U^i_t)_{i=1}^N$ be the vector collecting the numbers of units of each type that exist at time t. We refer to $\mathbf{U}_t$ as the "battle space" at time t.

2.2 OBSERVATION MODEL

The *observation model* specifies the likelihood of an observation given a particular assignment to $\mathbf{U}_t$. We define an *observation* as the number of units of each type that we saw during a time interval, $\mathbf{O}_t = (O^i_t)_{i=1}^N$. We assume that we can distinguish between individual enemy units within an epoch, but not between epochs. That is, if we make two observations of a unit of a certain type during the same epoch, we know whether we have seen the same unit twice, or two different units. We can therefore model these observations as sampling without replacement from $\mathbf{U}_t$ within an epoch. For observations in different epochs, we assume that we cannot tell whether a unit observed in one epoch is the same as a unit observed in a previous epoch.

If we observe an enemy unit, we know that the unit exists. If, on the other hand, we do not observe a unit, there are two possible explanations. Either the unit does not exist, or it does exist but we did not look hard enough for it. Hence our observation model needs to incorporate some measure of scouting "effort". If we put little effort into scouting, failure to observe a unit does not tell us much about whether it exists. If we scout extensively and still do not see the unit, it probably does not exist.

We can exploit domain knowledge to come up with a measure of effort. In *Starcraft*, players construct most of their buildings in either their *main base* or their *natural expansion*. The main base is the area of the map where the player's starting units appear at the beginning of the game, while the natural expansion is the location where it is most "natural" to construct a second base. Because buildings must be defended, it is tactically advantageous to keep them close together. In the early game, the main base and the natural expansion are thus the most important areas to scout, since that is where the buildings will be located. A natural measure of scouting effort, then, is the proportion of these two areas that have been seen. We denote this proportion for slice t as E_t.

We must now decide how our scouting effort influences the number of units we observe. Our initial approach was to treat each observable unit as an independent Bernoulli trial, with probability of success E_t. An observation would then be a vector of Binomial random variables, $O^i_t \sim Binomial(U^i_t, E_t)$.

The Binomial model assumes that the locations of units are distributed uniformly and independently in space. However, this assumption is wrong. Units tend to cluster together. For example, the primary task of "worker" units is to gather resources, which they do by traveling back and forth between the city center and the resource. Thus, almost all worker units will be found in the area between the city center and the resources. If we see one worker, it is probably because we have seen part of this area, and we would expect to have seen most of the other workers, too. There is thus more variance in the observations than the Binomial model would predict; the data are *overdispersed* with respect to the Binomial distribution.

We account for overdispersion by placing a Beta prior on the success probability parameter of the Binomial, forming a Beta-Binomial model (Haseman and Kupper, 1979):

$$\begin{aligned} O^i_t &\sim BetaBinomial(U^i_t, \mu^i_t, \rho^i) \\ &= \binom{U^i_t}{O^i_t} \frac{B(O^i_t + \alpha^i_t, U^i_t - O^i_t + \beta^i_t)}{B(\alpha^i_t, \beta^i_t)} \end{aligned}$$

where $B(x, y)$ is the beta function, and

$$\alpha^i_t = \mu^i_t \frac{1-\rho^i}{\rho^i}, \quad \beta^i_t = (1-\mu^i_t)\frac{1-\rho^i}{\rho^i}.$$

We adopt the (μ, ρ) parameterization of the Beta distribution, where $\mu \in [0, 1]$ is the mean of the Beta and $\rho \in [0, 1]$ is the dispersion parameter, which can be thought of as the correlation between individual successes. The Beta distribution is a conjugate prior of the Binomial. When $\rho \to 0$, the Beta-Binomial approaches the Binomial, while as ρ increases, the density spreads out and eventually becomes bimodal. The bi-modality captures the "clumpiness" of the units: depending on whether the part of the area of interest we saw contains the units, the success probability is either high or low, but probably not in the middle.

For each unit type i, we learn a mapping $f^i(E_t)$ from the observation effort to the mean and dispersion of a Beta-Binomial distribution:

$$\begin{aligned} logit(\hat{\mu}^i_t) &= a^i_0 + a^i_1 E_t \\ logit(\hat{\rho}^i) &= b^i. \end{aligned}$$

This is then plugged into the Beta-Binomial to compute the likelihood of observing O^i_t given that U^i_t units exist. We learn a different mapping for each unit type, to allow for differences in dispersion and ease of observability between unit types. The regression coefficients are assumed constant in time, but $\hat{\mu}^i_t$ varies in time due to its dependence on E_t.

2.3 TRAINING

All model variables except $\mathbf{S}$ are observed during training. Because all other variables are conditionally independent of $\mathbf{S}$ given $\mathbf{P}$ and $\mathbf{P}$ is observed, we can factor the full model into a latent variable model composed of $\mathbf{S}$ and $\mathbf{P}$, and a fully observed model containing the rest of the parameters. We can learn the parameters of $\mathbf{S}$ and $\mathbf{P}$ separately from the rest, simplifying training.

The production process is a hidden Markov model (HMM) (Rabiner, 1990), where S_t is the latent state and $P_t^1, ..., P_t^N$ are the emissions. The parameters of the HMM are the initial state probabilities $P(S_0) = Multinomial(\eta_1, ..., \eta_M)$, the state transition probabilities $P(S_t|S_{t-1} = s) = Multinomial(\pi_1^s, ..., \pi_M^s)$, and the inflated Poisson parameters $P(P_t^i = k > 0|S_t = s) = \nu_s^i \cdot Pois(k - 1; \lambda_s^i)$. We denote the parameter set of the HMM $\Phi = (\eta_1, ..., \eta_M, \pi_1^1, ..., \pi_M^M, \lambda_1^1, ..., \lambda_M^N, \nu_1^1, ..., \nu_M^N)$.

At training time, we observe $\mathbf{P}_t$. We can then estimate Φ in the usual way using the Expectation Maximization (EM) algorithm. We initialized the EM algorithm as follows: the η and π parameters are set to $1/M$, values of ν are drawn from a Uniform$(0, 1)$, and λ parameters are drawn from a Uniform$(0, 10)$.

The "unobserved loss" probabilities ℓ^i are estimated as the number of unobserved losses of units of type i divided by the number of unit-epochs (analogous to human-years) during which a unit of that type existed. For unit types that were present in at least 100 unit-epochs, ℓ^i was estimated using additive smoothing as $\hat{\ell}^i = \frac{d^i+1}{D^i+2}$ where d^i is the number of unobserved losses of unit type i and D^i is the number of unit-epochs for type i. The smoothing ensures that all unit types have non-zero ℓ^i even if there were no unobserved losses in the training data. For types that were not present in at least 100 unit-epochs, the median estimate was used.

The functions f^i giving the parameters of the distributions of O_t^i are learned via logistic regression with a maximum likelihood objective using the R package `aod` (Lesnoff et al., 2010). We fit a $\hat{\mu}^i$ parameter for unit type i only if a unit of that type was observed on at least 100 occasions in the dataset. We fit a $\hat{\rho}^i$ parameter only if the unit type met the condition for $\hat{\mu}^i$ and there were at least two of the unit type present (but not necessarily observed) on at least 100 occasions. The reason for the condition on $\hat{\rho}$ is that if it is rare for more than one instance of the unit to exist, then there is little dispersion in the data, and the estimate of $\hat{\rho}^i$ will be near 0. In this case, $\hat{\rho}^i$ would merely be modeling the tendency not to build more than one unit, which is properly the job of $\mathbf{P}_t$. For types that did not have enough data for $\hat{\mu}$ or $\hat{\rho}$, the median of the estimated regression coefficients are used.

2.4 INFERENCE

We denote the subset of latent variables for a slice t as $X_t = \{S_t, P_t^1, \ldots, P_t^N, U_t^1, \ldots, U_t^N\}$, and the observed variables as $Y_t = \{E_t, K_t^1, \ldots, K_t^N, O_t^1, \ldots, O_t^N\}$. We use the lowercase y_t and x_t to denote instantiations of these variables (i.e, y_t refers to the evidence at time t). Because each U_t^i is conditioned on S_t, and S_t and U_t^i are Markovian, an exact filtering pass would require representing the forward message $\alpha_t = P(S_t, U_t^1, ..., U_t^N)$. This is intractable for even a modest number of types, since the size of the joint distribution is $MU_{\max}^N$. However, a key observation is that, given the history of the strategy state, $S_{0:t} = (S_0, \ldots, S_t)$, the model up to time t decomposes into N independent HMMs, each tracking the count of a single type. We leverage this structure by employing a Rao-Blackwellized particle filter (RBPF) for approximate inference (Doucet et al., 2000; Murphy, 2000).

In our application of RBPF, we draw particles of $S_{0:t}$, and compute $P(U_t^i|s_{0:t})$ analytically via standard HMM filtering. Following an importance sampling framework, particles are generated at each time step from a proposal distribution $Q(S_t)$. We use the state transition model for our proposal, $Q(S_t) = P(S_t|s_{t-1})$. While this choice ignores recent evidence at time t, it is computationally efficient to sample, and there are often periods of no evidence, anyway.

At $t = 0$ we draw R particles from the initial state prior $s_0^1, \ldots, s_0^R \sim P(S_0)$. Each particle has an importance weight $w_t^r = \phi(s_t^r)/Q(s_t^r)$, where $\phi(s_t^r)$ is the probability of the particle's value s_t^r given by the full model (up to normalization). At $t = 0$, $w_0^r = (P(y_0|s_r)P(s_r))/Q(s_r)$. For $t > 0$, each particle generates its next value of the state $s_t^i \sim Q(S_t) = P(S_t|s_{t-1}^i)$. We then update its weight using the ratio:

$$w_t^{r'} = \frac{P(Y_t = y_t|y_{0:t-1}, s_{0:t}^r)P(S_t = s_t^r|S_{t-1} = s_{t-1}^r)}{P(S_t = s_t^r|S_{t-1} = s_{t-1}^r)}.$$

The new weight for particle r is then $w_t^r = w_{t-1}^r w_t^{r'}$.

Because our proposal distribution is identical to $P(S_t|S_{t-1})$ (canceling out the denominator), we are only interested in the likelihood term of the numerator, $P(Y_t = y_t|y_{0:t-1}, s_{0:t}^r)$, which factors as

$$\prod_{i=1}^{N} \Big[P(U_t^i|U_{t-1}^i, P_t^i, K_{t-1}^i)P(U_{t-1}^{i,r}) \cdot P(P_t^i|S_t = s_t^r)P(O_t^i|U_t^i, E_t^i) \Big].$$

$P(U_{t-1}^{i,r})$ is a forward-pass message that captures the posterior marginal distribution over the counts of unit type i at time $t - 1$. After we weight a sample, we

compute $P(U_t^{i,r}|s_{0:t}^r, y_t)$ to update its belief about the unit count and to pass to slice $t+1$. Each particle computes N such messages, one for each unit type.

Particle filters often include a resampling step in which a new set of particles is sampled in proportion to the weights of the current set and given uniform weights. We do not include a resampling step because we expect that there will often be periods of no observations, particularly in the opening several epochs. Resampling would reduce the diversity of the particle population, with the result that if observations later come in that suggest *a priori* unlikely strategies, there may be no particles left that can represent them well.

3 EXPERIMENTS

We evaluated our model on its ability to infer the correct hidden unit counts, given the observations available to players during real games. We used two different metrics. For unit types that are usually present in numbers greater than 1, such as army units, we measured the model's ability to infer the correct *number* of units. For unit types that are either not built or built once, such as tech buildings, we measured accuracy in determining whether or not the unit is present. We also specifically tested the model's ability to infer the *absence* of units, a task that requires the observation model and the state model to work together.

Our experiments were conducted using gameplay data[1] from the RTS game *Starcraft*. We collected replays of 509 Protoss versus Terran games from the archives of the "Gosu Gamers" website.[2] *Starcraft* features three playable "races," Protoss, Terran, and Zerg, each with different units and abilities. We focused on a single match-up in this work. In our experiments, we take the perspective of the Terran player, and try to predict what the Protoss player is doing.

Data about unit counts and observations was extracted from the replays using the BWAPI library (BWAPI, 2012). We used the BWTA terrain analysis library (Perkins, 2010) to divide the maps into regions, and manually identified the regions corresponding to the Protoss player's main base and natural expansion.

The dataset was divided into 5 folds for cross-validation. To select M (number of strategy states) in the production model, we compared the average likelihood $P(\mathbf{P}|\Phi)$ on the held-out data for $M = 20, 25, 30, 35$, and 40. The likelihoods for $M = 25, 30$, and 35 were statistically identical, and we selected $M = 30$ based on examination of the learned parameters and our knowledge of *Starcraft*. After selecting M, we estimated the observation model parameters for each of the 5 folds using their respective training sets.

[1]Our dataset is available at `http://web.engr.oregonstate.edu/~tgd/rts/scouting/`

[2]`http://www.gosugamers.net/starcraft/replays/`

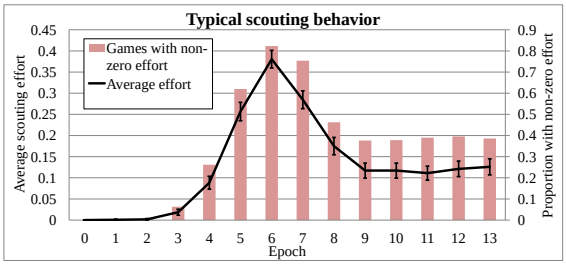

Figure 2: Average scouting effort, and proportion of games with non-zero effort, by epoch.

3.1 BASELINE METHOD

We implemented a simple baseline consisting of two sets of averages: the average number of units of each type at the end of each epoch for 1) all games, and 2) only games in which the unit was present in at least one epoch. At time t, if no units of type i have been scouted so far, the baseline predicts the average for type i at time t across all games. If at least one unit of type i has been scouted, the baseline predicts the average across games in which that unit type was present. The baseline should perform fairly well in the opening, since many openings are similar and thus unit counts often have low variance.

3.2 TYPICAL SCOUTING BEHAVIOR

Since our model uses observations obtained through scouting as its evidence, it is important to know what typical scouting behavior looks like. There is a pronounced peak in scouting effort from $t = 5$ to $t = 8$, after which effort falls back to a steady "background" level (Figure 2). The first significant scouting appears to begin at $t = 4$. Based on this pattern of scouting, we should expect our model to perform best during the peak scouting period, $t = 5, 6, 7, 8$.

3.3 MODEL ANALYSIS

The (logistic-transformed) regression coefficients of the observation model reveal varying levels of dispersion for different types of units. Typical values of $\hat{\rho}^i$ for mobile units were around 0.3, suggesting that mobile units often travel in groups. Values for buildings varied more widely. For Gateways (which produce military units), $\hat{\rho}^i$ was equal to 0.71, indicating that Gateways are very likely to be close to one another. At the other extreme, the value of $\hat{\rho}^i$ for the Nexus (the "city center" where resources are deposited by workers) was 10^{-8}, since Nexi are never built near one another. The regression coefficients of the scouting effort were al-

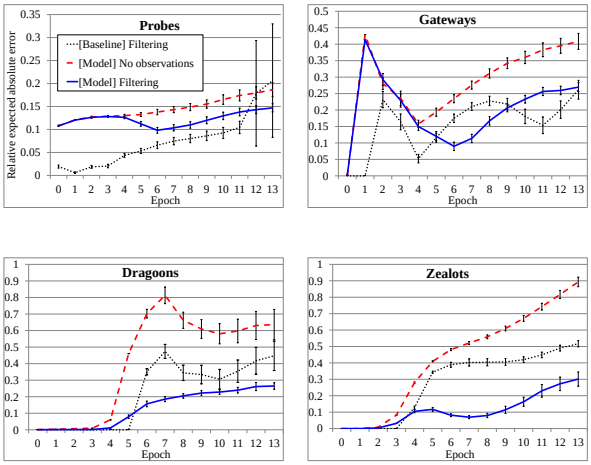

Figure 3: Relative expected absolute error for filtering predictions of common unit types, versus baseline. The error bars are 95% confidence intervals.

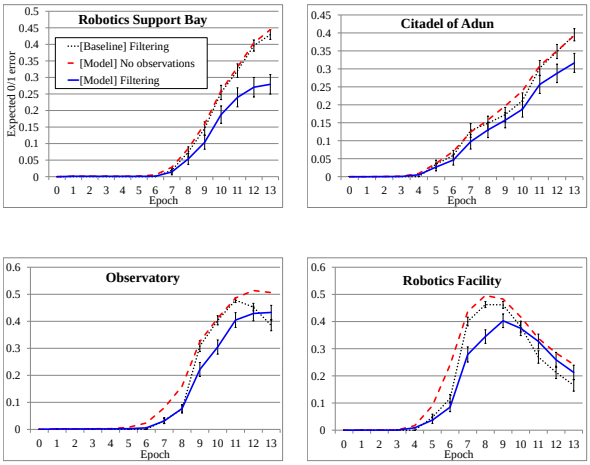

Figure 4: Expected 0/1 error for filtering predictions of tech buildings, versus baseline. The error bars are 95% confidence intervals. Error bars have been omitted for the model with no observations, for clarity.

most all near 1.0, indicating that our scouting effort measure is a good predictor of scouting success. The two effort coefficients that were substantially less than 1 corresponded to units with the *Cloak* ability, which can only be seen by particular kinds of units. For one of these units, the Observer, the model learned that greater scouting effort *decreases* the probability of detection. This seems incorrect; we believe it occurs because in addition to being hard to detect, Observers usually are not fielded until after the period of peak scouting, so effort is negatively correlated with Observer presence.

3.4 INFERRING UNIT QUANTITIES

For common units that are built in large numbers, we would like to be able to infer the true counts. In *Starcraft*, the most common units in the early game are the Probe (the Protoss worker), the Dragoon and Zealot (basic military units), and the Gateway (a building that produces Dragoons and Zealots). Figure 3 compares our model's performance to that of the baseline for the filtering task over these four unit types. The dotted lines show the baseline method, the solid lines show our model's accuracy at filtering, and the dashed lines show our model's accuracy with no observations. The error measure is relative expected absolute error. That is, for a true count u_t^i and the model's marginal distribution U_t^i, the error is given by

$$\varepsilon_t^i = E[|U_t^i - u_t^i|]/(u_t^i + 1).$$

We outperform the baseline from the onset of scouting for both Dragoons and Zealots. For Probes, we do worse for most of the opening, although both models have low error. We can attribute the good performance of the baseline to the low variance in Probe counts. Players almost always build Probes as quickly as possible in order to increase resource income, up to a "saturation" point that depends on the number of bases the player has secured. The large increase in the baseline's error at the end of the opening suggests that this is a point where some players have reached saturation while others have not. Our model does not experience a notable increase in error because it can represent multi-modal distributions. For Gateways, the baseline is notably better from $t = 10$ to $t = 12$. This is explained by the typical timing of Gateway construction. The first dip at $t = 4$ is a time when nearly everyone has built their first Gateway. Players will then build a second "batch" of Gateways, with the exact timing and number depending on their strategy. The second dip in baseline error around $t = 11$ is the end of the second period of Gateway production. Our model has trouble capturing this structure because it is stationary.

The shapes of the error curves for our model in the case of no observations are very similar to the baseline, although the baseline generally has better accuracy. Our model tracks the average-case behavior, but over-predicts production due to the Markov assumption on strategy states. For example, our model will give some probability of transitioning to a Dragoon-producing state earlier than a Dragoon could possibly have been produced.

3.5 INFERRING TECH BUILDINGS

While counts are important for units that are produced in numbers, for tech buildings we are primarily concerned with whether or not they exist. Thus, we compared our model to an appropriately modified baseline

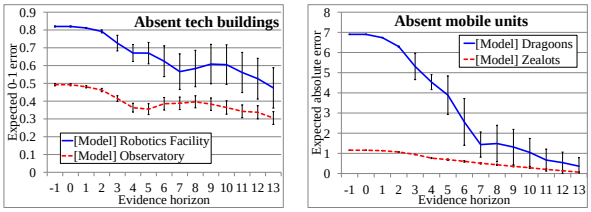

Figure 5: Error in predictions for $t = 13$ given evidence up to various horizons, on games where the target unit is *not* present. Error bars are 95% confidence intervals.

using expected 0/1 error for four tech buildings.

There are two qualitatively different shapes in the baseline error curves (Figure 4). For the Robotics Facility and the Observatory, baseline error peaked and then decreased, while for the Citadel of Adun ("Citadel") and Robotics Support Bay ("Support Bay"), it continued to increase for the entire opening. Our model with no observations tracks the baseline error closely, until the baseline error begins to drop.

We again seem to outperform the baseline from the onset of scouting, though the baseline sometimes makes a comeback at the end of the opening. As with the Gateway results in Section 3.4, the drop in error for the Robotics Facility at the end of the opening is explained by typical strategy. The great majority of openings involve building a single Robotics Facility before epoch 13. In constrast to the Gateway results, our model was able to capture this temporal structure for the Robotics Facility, perhaps because a Robotics Facility is built only once, whereas multiple Gateways are built over a period of time. On the other hand, a Support Bay will only be built in some openings, and will be skipped entirely in others. We would expect error to stabilize after the time period during which the Support Bay would be constructed passes, and we do see some evidence of this for our model with observations. It is also worth noting that the probability of scouting a Robotics Facility given that it exists is 0.37, while the probability of scouting a Support Bay is only 0.18.

3.6 INFERRING ABSENCE OF UNITS

Because we model the probability of observation success as a function of effort put into observing, we can make maximum use of *negative* observations to infer that units are *not* present. In Figure 5, we show our model's error for predictions of the *final* epoch, given evidence up to varying *horizons*, in games where the target unit was *not* present. For example, at horizon 6, the model is making predictions for $t = 13$ given evidence through $t = 6$. The true count is equal to 0, so all of the error comes from over-predicting. We see that as more negative observations arrive, the

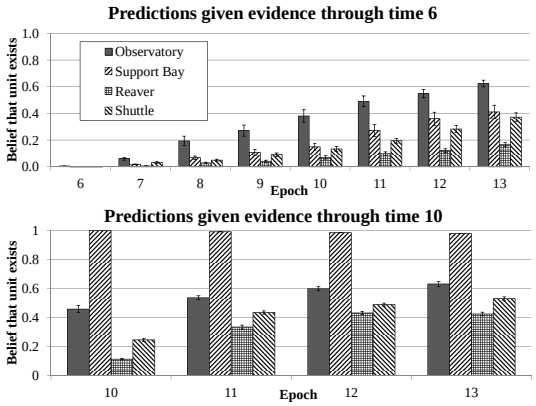

Figure 6: Belief that a unit of each of four different types will exist in future epochs in our Reaver drop case study game, given evidence up to $t = 6$ and $t = 10$. The Shuttle and Support Bay were actually built at $t = 9$, and the Reaver was built at $t = 11$. No Observatory was built. Error bars are 95% confidence intervals over 30 runs.

model revises its predictions downwards. The observation model uses the negative observations to infer that there are currently no units, and the rates of production given by the state model limit the number of units that could be built in the remaining time. The effect is strongest for units that are normally easy to scout. For example, Dragoons are present in all but 11 games, and they are easy to observe because they will be trying to attack the scout. Similarly, Robotics Facilities are both more common and more frequently scouted than Observatories. The baseline (not shown) would have a large, flat error on this task.

3.7 CASE STUDY

To demonstrate how our model would be applied in a game-playing agent, we examined a single game in detail. In this game, the Protoss player follows the *Reaver drop* strategy, which involves using a transport aircraft to carry a powerful unit called a Reaver behind enemy lines to attack the workers. This attack is potentially devastating, but easy to stop unless we are caught by surprise. We must note that one of the reasons that we chose this particular game is that the Terran player's scouting was particularly effective, giving our model a chance to make interesting inferences.

The key units in this strategy are the *Robotics Support Bay*, which is the tech building required for the Reaver; the *Shuttle*, which is the aircraft that transports the Reaver; and of course the Reaver itself. We can also contrast the Reaver drop opening to the "standard" opening, which involves building an *Observatory*.

This game features two distinct periods of scouting.

The Terran player scouts the Protoss at $t = 6$, leaves for a while, then returns to scout again at $t = 10$. Figure 6 shows, for each of the key units, the model's belief that at least one such unit will exist at each future time step, given evidence up to $t = 6$ and $t = 10$.

We first examine our model's predictions with evidence up to $t = 6$. The Terran player has just scouted the Robotics Facility, but the Support Bay and Reaver have not been built yet. Belief that an Observatory or a Support Bay exists begins to increase at $t = 8$. The Observatory is the "standard" continuation, so it receives more belief. Belief that a Shuttle exists increases in step with belief in the Support Bay because the Support Bay is strongly associated with the Reaver drop strategy, which always features a Shuttle. Belief that a Reaver exists increases more slowly than belief in the Support Bay because a Support Bay must be completed before a Reaver can be built. In the game, the Support Bay and Shuttle were actually built at $t = 9$, and the Reaver was built at $t = 11$.

We now examine how the model's predictions change when more evidence arrives. At $t = 10$, the Terran player scouts the Support Bay. This should unambiguously signal that a Reaver is going to be built, since there is no other reason to build a Support Bay. As expected, belief that a Reaver is coming increases considerably compared to the prediction with evidence through time 6. Belief that a Shuttle exists has also increased.

4 DISCUSSION

Our model generally performed well in comparison to the baseline for both count predictions and 0/1 predictions. The fact that our model is stationary while the baseline is non-stationary appears to account for most of the cases where the baseline was equal to or better than our model. Whereas the baseline can exploit the fact that certain patterns of production events are associated with particular time periods, in our model the Markov property of the hidden state erases information about how much time has elapsed. In the early game, our model begins predicting production events too early because it models the first several epochs, which all look the same, with a single state that has a high self-transition probability. Later in the game, uncertainty about the time means it has trouble capturing time-dependent "pauses" in production. On the other hand, our model can in principle be extended to full-length games, while our baseline method is too coarse to be useful much beyond the opening.

Another weakness of our model is that it incorporates no explicit prior knowledge about configurations of unit counts. For example, there will almost never be two Observatories, but our model can only account for this by designing the state transition matrix to visit the Observatory-producing state only once. Accuracy could be improved by making production of a unit at time t (P_t^i) dependent on the count of that unit at time $t-1$ (U_{t-1}^i), with a corresponding increase in the complexity of the latent variable portion of the model. The situation worsens if we want to incorporate prerequisite relationships, as these cause the counting processes for *different* unit types to become coupled, destroying the conditional independences that we leveraged for efficient inference.

5 FUTURE WORK

A significant future challenge is to devise a model that can perform well in a full-length game. The space of possible strategies expands greatly as the game runs longer and the actions of the opponent begin to influence one's own decisions. Naively extending the current model by adding states is likely to prove intractable. One possibility is to try to exploit hierarchical structure in strategies to reduce the strategy space. We suspect that strategic decisions take place on multiple time scales—broad objectives at the top level, and smaller steps necessary to achieve them at the bottom. A model of a full game will need to incorporate a model of resource flow in order to reason effectively about production rates. It will also need to account for changes in the opponent's strategy in response to our actions.

We are also interested in applying opponent models to optimize scouting policies. As we saw in Figure 2, human players have converged on at least one time period in which the tradeoff between probability of scouting success and expected information gain is at an optimum. An agent could use our model to determine *when* important information is likely to be available. Modeling the probability that a scouting action will succeed in acquiring information, assuming that the information is there, is a challenging problem in itself.

Optimally-Weighted Herding is Bayesian Quadrature

Abstract

Herding and kernel herding are deterministic methods of choosing samples which summarise a probability distribution. A related task is choosing samples for estimating integrals using Bayesian quadrature. We show that the criterion minimised when selecting samples in kernel herding is equivalent to the posterior variance in Bayesian quadrature. We then show that sequential Bayesian quadrature can be viewed as a weighted version of kernel herding which achieves performance superior to any other weighted herding method. We demonstrate empirically a rate of convergence faster than $\mathcal{O}(1/N)$. Our results also imply an upper bound on the empirical error of the Bayesian quadrature estimate.

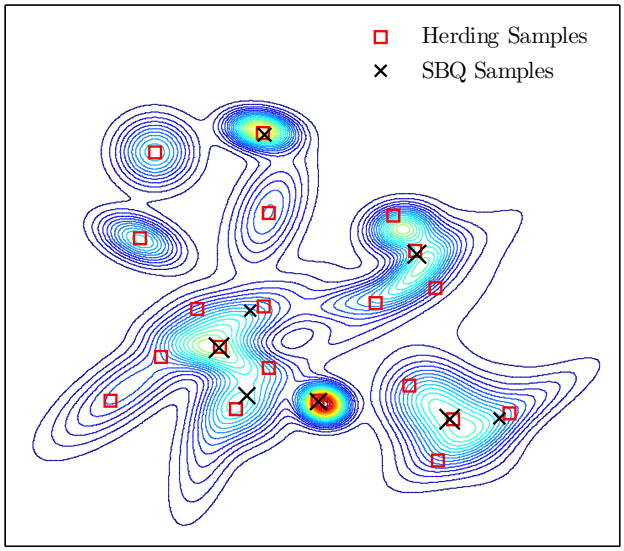

Figure 1: The first 8 samples from sequential Bayesian quadrature, versus the first 20 samples from herding. Only 8 weighted SBQ samples are needed to give an estimator with the same maximum mean discrepancy as using 20 herding samples with uniform weights. Relative sizes of samples indicate their relative weights.

1 INTRODUCTION

The problem: Integrals A common problem in statistical machine learning is to compute expectations of functions over probability distributions of the form:

$$Z_{f,p} = \int f(x)p(x)dx \tag{1}$$

Examples include computing marginal distributions, making predictions marginalizing over parameters, or computing the Bayes risk in a decision problem. In this paper we assume that the distribution $p(x)$ is known in analytic form, and $f(x)$ can be evaluated at arbitrary locations.

Monte Carlo methods produce random samples from the distribution p and then approximate the integral by taking the empirical mean $\hat{Z} = \frac{1}{N}\sum_{n=1}^{N} f_{x_n}$ of the function evaluated at those points. This non-deterministic estimate converges at a rate $\mathcal{O}(\frac{1}{\sqrt{N}})$.

When exact sampling from p is impossible or impractical, Markov chain Monte Carlo (MCMC) methods are often used. MCMC methods can be applied to almost any problem but convergence of the estimate depends on several factors and is hard to estimate (Cowles & Carlin, 1996). The focus of this paper is on quasi-Monte Carlo methods that – instead of sampling randomly – produce a set of pseudo-samples in a deterministic fashion. These methods operate by directly minimising some sort of discrepancy between the empirical distribution of pseudo-samples and the target distribution. Whenever these methods are applicable, they achieve convergence rates superior to the $\mathcal{O}(\frac{1}{\sqrt{N}})$ rate typical of random sampling.

In this paper we highlight and explore the connections between two deterministic sampling and integration methods: Bayesian quadrature (BQ) (O'Hagan, 1991; Rasmussen & Ghahramani, 2003) (also known as Bayesian Monte Carlo) and kernel herding (Chen et al., 2010). Bayesian quadrature estimates integral (1) by inferring a posterior distribution over f conditioned on the observed evaluations f_{x_n}, and then computing the posterior expectation of $Z_{f,p}$. The points where the function should be evaluated can be found via Bayesian experimental design, providing a deterministic procedure for selecting sample locations.

Herding, proposed recently by Chen et al. (2010), produces pseudosamples by minimising the discrepancy of moments between the sample set and the target distribution. Similarly to traditional Monte Carlo, an estimate is formed by taking the empirical mean over samples $\hat{Z} = \frac{1}{N}\sum_{n=1}^{N} f_{x_n}$. Under certain assumptions, herding has provably fast, $\mathcal{O}(\frac{1}{N})$ convergence rates in the parametric case, and has demonstrated strong empirical performance in a variety of tasks.

Summary of contributions In this paper, we make two main contributions. First, we show that the Maximum Mean Discrepancy (MMD) criterion used to choose samples in kernel herding is identical to the expected error in the estimate of the integral $Z_{f,p}$ under a Gaussian process prior for f. This expected error is the criterion being minimized when choosing samples for Bayesian quadrature. Because Bayesian quadrature assigns different weights to each of the observed function values $f(x)$, we can view Bayesian quadrature as a weighted version of kernel herding. We show that these weights are optimal in a minimax sense over all functions in the Hilbert space defined by our kernel. This implies that Bayesian quadrature dominates uniformly-weighted kernel herding and other non-optimally weighted herding in rate of convergence.

Second, we show that minimising the MMD, when using BQ weights is closely related to the sparse dictionary selection problem studied in (Krause & Cevher, 2010), and therefore is approximately submodular with respect to the samples chosen. This allows us to reason about the performance of greedy forward selection algorithms for Bayesian Quadrature. We call this greedy method Sequential Bayesian Quadrature (SBQ).

We then demonstrate empirically the relative performance of herding, i.i.d random sampling, and SBQ, and demonstrate that SBQ attains a rate of convergence faster than $\mathcal{O}(1/N)$.

2 HERDING

Herding was introduced by Welling (2009) as a method for generating pseudo-samples from a distribution in such a way that certain nonlinear moments of the sample set closely match those of the target distribution. The empirical mean $\frac{1}{N}\sum_{n=1}^{N} f_{x_n}$ over these pseudosamples is then used to estimate integral (1).

2.1 Maximum Mean Discrepancy

For selecting pseudosamples, herding relies on an objective based on the maximum mean discrepancy (MMD; Sriperumbudur et al., 2010). MMD measures the divergence between two distributions, p and q with respect to a class of integrand functions $\mathcal{F}$ as follows:

$$\mathrm{MMD}_{\mathcal{F}}(p,q) = \sup_{f\in\mathcal{F}} \left| \int f_x p(x)dx - \int f_x q(x)dx \right| \quad (2)$$

Intuitively, if two distributions are close in the MMD sense, then no matter which function f we choose from $\mathcal{F}$, the difference in its integral over p or q should be small. A particularly interesting case is when the function class $\mathcal{F}$ is functions of unit norm from a reproducing kernel Hilbert space (RKHS) $\mathcal{H}$. In this case, the MMD between two distributions can be conveniently expressed using expectations of the associated kernel $k(x,x')$ only (Sriperumbudur et al., 2010):

$$MMD^2_{\mathcal{H}}(p,q) = \sup_{\substack{f\in\mathcal{H}\\ \|f\|_{\mathcal{H}}=1}} \left| \int f_x p(x)dx - \int f_x q(x)dx \right|^2 \quad (3)$$

$$= \|\mu_p - \mu_q\|^2_{\mathcal{H}} \quad (4)$$

$$= \iint k(x,y)p(x)p(y)dxdy - 2\iint k(x,y)p(x)q(y)dxdy + \iint k(x,y)q(x)q(y)dxdy, \quad (5)$$

where in the above formula $\mu_p = \int \phi(x)p(x)dx \in \mathcal{H}$ denotes the *mean element* associated with the distribution p. For characteristic kernels, such as the Gaussian kernel, the mapping between a distribution and its mean element is bijective. As a consequence $\mathrm{MMD}_{\mathcal{H}}(p,q) = 0$ if and only if $p = q$, making it a powerful measure of divergence.

Herding uses maximum mean discrepancy to evaluate of how well the sample set $\{x_1,\ldots,x_N\}$ represents the target distribution p:

$$\epsilon_{herding}\left(\{x_1,\ldots,x_N\}\right) = \mathrm{MMD}_{\mathcal{H}}\left(p, \frac{1}{N}\sum_{n=1}^{N}\delta_{x_n}\right) \tag{6}$$

$$= \iint k(x,y)p(x)p(y)dxdy$$
$$-2\frac{1}{N}\sum_{n=1}^{N}\int k(x,x_n)p(x)dx + \frac{1}{N^2}\sum_{n,m=1}^{N}k(x_n,x_m) \tag{7}$$

The herding procedure greedily minimizes its objective $\epsilon_{herding}\left(\{x_1,\ldots,x_N\}\right)$, adding pseudosamples x_n one at a time. When selecting the $n+1$-st pseudosample:

$$x_{n+1} \leftarrow \operatorname*{argmin}_{x\in\mathcal{X}} \epsilon_{herding}\left(\{x_1,\ldots,x_n,x\}\right) \tag{8}$$
$$= \operatorname*{argmax}_{x\in\mathcal{X}} 2\mathbb{E}_{x'\sim p}\left[k(x,x')\right] - \frac{1}{n+1}\sum_{m=1}^{n}k(x,x_m),$$

assuming $k(x,x) = \text{const}$. The formula (8) admits an intuitive interpretation: the first term encourages sampling in areas with high mass under the target distribution $p(x)$. The second term discourages sampling at points close to existing samples.

Evaluating (8) requires us to compute $\mathbb{E}_{x'\sim p}\left[k(x,x')\right]$, that is to integrate the kernel against the target distribution. Throughout the paper we will assume that these integrals can be computed in closed form. Whilst the integration can indeed be carried out analytically in several cases (Song et al., 2008; Chen et al., 2010), this requirement is the most pertinent limitation on applications of kernel herding, Bayesian quadrature and related algorithms.

2.2 Complexity and Convergence Rates

Criterion (8) can be evaluated in only $\mathcal{O}(n)$ time. Adding these up for all subsequent samples, and assuming that optimisation in each step has $\mathcal{O}(1)$ complexity, producing N pseudosamples via kernel herding costs $\mathcal{O}(N^2)$ operations in total.

In finite dimensional Hilbert spaces, the herding algorithm has been shown to reduce MMD at a rate $\mathcal{O}(\frac{1}{N})$, which compares favourably with the $\mathcal{O}(\frac{1}{\sqrt{N}})$ rate obtained by non-deterministic Monte Carlo samplers. However, as pointed out by Bach et al. (2012), this fast convergence is not guaranteed in infinite dimensional Hilbert spaces, such as the RKHS corresponding to the Gaussian kernel.

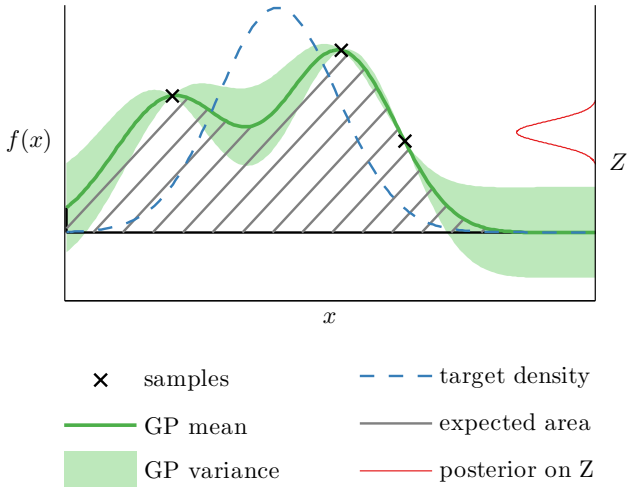

Figure 2: An illustration of Bayesian Quadrature. The function $f(x)$ is sampled at a set of input locations. This induces a Gaussian process posterior distribution on f, which is integrated in closed form against the target density, $p(x)$. Since the amount of volume under f is uncertain, this gives rise to a (Gaussian) posterior distribution over $Z_{f,p}$.

3 BAYESIAN QUADRATURE

So far, we have only considered integration methods in which the integral (1) is approximated by the empirical mean of the function evaluated at some set of samples, or pseudo-samples. Equivalently, we can say that Monte Carlo and herding both assign an equal $\frac{1}{N}$ weight to each of the samples.

In (Rasmussen & Ghahramani, 2003), an alternate method is proposed: Bayesian Monte Carlo, or Bayesian quadrature (BQ). BQ puts a prior distribution on f, then estimates integral (1) by inferring a posterior distribution over the function f, conditioned on the observations $f(x_n)$ at some query points x_n. The posterior distribution over f then implies a distribution over $Z_{f,p}$. This method allows us to choose sample locations x_n in any desired manner. See Figure 2 for an illustration of Bayesian Quadrature.

3.1 BQ Estimator

Here we derive the BQ estimate of (1), after conditioning on function evaluations $f(x_1)\ldots f(x_N)$, denoted as $f(X)$. The Bayesian solution implies a distribution over $Z_{f,p}$. The mean of this distribution, $\mathbb{E}\left[Z\right]$ is the optimal Bayesian estimator for a squared loss.

For simplicity, f is assigned a Gaussian process prior with kernel function k and mean 0. This assumption is very similar to the one made by kernel herding in Eqn. (7).

After conditioning on f_x, we obtain a closed-form posterior over f:

$$p(f(x_\star)|f(X)) = \mathcal{N}\big(f_{x_\star}|\bar{f}(x_\star), \mathrm{cov}(x_\star, x'_\star)\big) \quad (9)$$

where

$$\bar{f}(x_\star) = k(x_\star, X)K^{-1}f(X) \quad (10)$$

$$\mathrm{cov}(x_\star, x'_\star) = k(x_\star, x_\star) - k(x_\star, X)K^{-1}k(X, x_\star) \quad (11)$$

and $K = k(X, X)$. Conveniently, the GP posterior allows us to compute the expectation of (1) in closed form:

$$\mathbb{E}_{\mathrm{GP}}[Z] = \mathbb{E}_{\mathrm{GP}}\left[\int f(x)p(x)dx\right] \quad (12)$$

$$= \iint f(x)p(f(x)|f(X))p(x)dxdf \quad (13)$$

$$= \int \bar{f}(x)p(x)dx \quad (14)$$

$$= \left[\int k(x, X)p(x)dx\right] K^{-1}f(X) \quad (15)$$

$$= \mathbf{z}^T K^{-1} f(X) \quad (16)$$

where

$$z_n = \int k(x, x_n)p(x)dx = \mathbb{E}_{x'\sim p}[k(x_n, x')]. \quad (17)$$

Conveniently, as in kernel herding, the desired expectation of $Z_{f,p}$ is simply a linear combination of observed function values $f(x)$:

$$\mathbb{E}_{\mathrm{GP}}[Z] = \mathbf{z}^T K^{-1} f(X) \quad (18)$$

$$= \sum_n w_{\mathrm{BQ}}^{(n)} f_{x_n}) \quad (19)$$

where

$$w_{\mathrm{BQ}}^{(n)} = \sum_m \mathbf{z}_j^T K_{nm}^{-1} \quad (20)$$

Thus, we can view the BQ estimate as a weighted version of the herding estimate. Interestingly, the weights w_{BQ} do not need to sum to 1, and are not even necessarily positive.

3.1.1 Non-normalized and Negative Weights

When weighting samples, it is often assumed, or enforced (as in Bach et al., 2012; Song et al., 2008), that the weights w form a probability distribution. However, there is no technical reason for this requirement, and in fact, the optimal weights do not have this property. Figure 3 shows a representative set of 100 BQ weights chosen on samples representing the distribution in figure 1. There are several negative weights, and the sum of all weights is 0.93.

Figure 4 demonstrates that, in general, the sum of the Bayesian weights exhibits shrinkage when the number of samples is small.

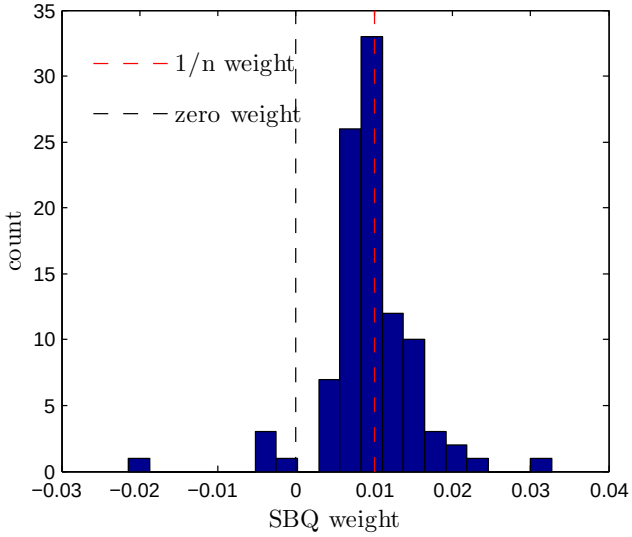

Figure 3: A set of optimal weights given by BQ, after 100 SBQ samples were selected on the distribution shown in Figure 1. Note that the optimal weights are spread away from the uniform weight ($\frac{1}{N}$), and that some weights are even negative. The sum of these weights is 0.93.

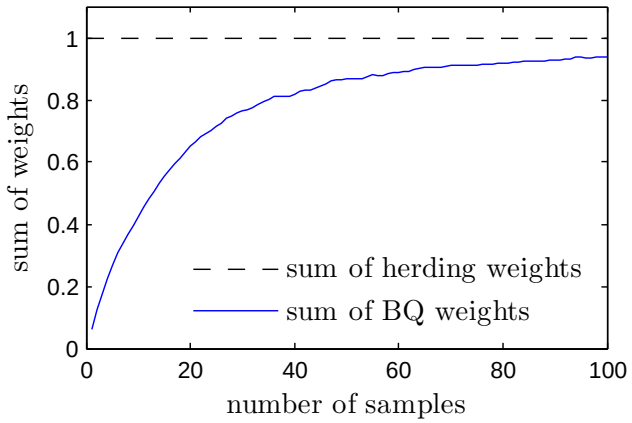

Figure 4: An example of Bayesian shrinkage in the sample weights. In this example, the kernel width is approximately 1/20 the width of the distribution being considered. Because the prior over functions is zero mean, in the small sample case the weights are shrunk towards zero. The weights given by simple Monte Carlo and herding do not exhibit shrinkage.

3.2 Optimal sampling for BQ

Bayesian quadrature provides not only a mean estimate of $Z_{f,p}$, but a full Gaussian posterior distribution. The variance of this distribution $\mathbb{V}\left[Z_{f,p}|f_{x_1},\ldots,f_{x_N}\right]$ quantifies our uncertainty in the estimate. When selecting locations to evaluate the function f, minimising the posterior variance is a sensible strategy. Below, we give a closed form formula for the posterior variance of $Z_{f,p}$, conditioned on the observations $f_{x_1}\ldots f_{x_N}$, which we will denote by ϵ^2_{BQ}. For a longer derivation, see Rasmussen & Ghahramani (2003).

$$\epsilon^2_{\text{BQ}}(x_1,\ldots,x_N) = \mathbb{V}\left[Z_{f,p}|f_{x_1},\ldots,f_{x_N}\right] \tag{21}$$
$$= \mathbb{E}_{x,x'\sim p}\left[k(x,x')\right] - \mathbf{z}^T K^{-1}\mathbf{z}, \tag{22}$$

where $\mathbf{z}_n = \mathbb{E}_{x'\sim p}\left[k(x_n,x')\right]$ as before. Perhaps surprisingly, the posterior variance of $Z_{f,p}$ does not depend on the observed function values, only on the location x_n of samples. A similar independence is observed in other optimal experimental design problems involving Gaussian processes (Krause et al., 2006). This allows the optimal samples to be computed ahead of time, before observing any values of f at all (Minka, 2000).

We can contrast the BQ objective ϵ^2_{BQ} in (22) to the objective being minimized in herding, $\epsilon^2_{herding}$ of equation (7). Just like $\epsilon^2_{herding}$, ϵ^2_{BQ} expresses a trade-off between accuracy and diversity of samples. On the one hand, as samples get close to high density regions under p, the values in $\mathbf{z}$ increase, which results in decreasing variance. On the other hand, as samples get closer to each other, eigenvalues of K increase, resulting in an increase in variance.

In a similar fashion to herding, we may use a greedy method to minimise ϵ^2_{BQ}, adding one sample at a time. We will call this algorithm *Sequential Bayesian Quadrature* (SBQ):

$$x_{n+1} \leftarrow \operatorname*{argmin}_{x\in\mathcal{X}} \epsilon_{\text{BQ}}\left(\{x_1,\ldots,x_n,x\}\right) \tag{23}$$

Using incremental updates to the Cholesky factor, the criterion can be evaluated in $\mathcal{O}(n^2)$ time. Iteratively selecting N samples thus takes $\mathcal{O}(N^3)$ time, assuming optimisation can be done on $\mathcal{O}(1)$ time.

4 RELATING $\mathbb{V}\left[Z_{f,p}\right]$ TO MMD

The similarity in the behaviour of $\epsilon^2_{herding}$ and ϵ^2_{BQ} is not a coincidence, the two quantities are closely related to each other, and to MMD.

Proposition 1. *The expected variance in the Bayesian quadrature ϵ^2_{BQ} is the maximum mean discrepancy between the target distribution p and $q_{\text{BQ}}(x) = \sum_{n=1}^N w^{(n)}_{\text{BQ}}\delta_{x_n}(x)$*

Proof. The proof involves invoking the representer theorem, using bilinearity of scalar products and the fact that if f is a standard Gaussian process then $\forall g\in\mathcal{H}: \langle f,g\rangle \sim \mathcal{N}(0,\|g\|_{\mathcal{H}})$:

$$\mathbb{V}\left[Z_{f,p}|f_{x_1},\ldots,f_{x_N}\right] = \tag{24}$$
$$= \mathbb{E}_{f\sim GP}\left(\int f(x)p(x)dx - \sum_{n=1}^N w^{(n)}_{\text{BQ}} f(x_n)\right)^2 \tag{25}$$
$$= \mathbb{E}_{f\sim GP}\left(\int \langle f,\phi(x)\rangle\, p(x)dx - \sum_{n=1}^N w^{(n)}_{\text{BQ}}\,\langle f,\phi(x_n)\rangle\right)^2 \tag{26}$$
$$= \mathbb{E}_{f\sim GP}\left\langle f, \int \phi(x)p(x)dx - \sum_{n=1}^N w^{(n)}_{\text{BQ}}\phi(x_n)\right\rangle^2 \tag{27}$$
$$= \left\|\mu_p - \mu_{q_{\text{BQ}}}\right\|^2_{\mathcal{H}} \tag{28}$$
$$= \text{MMD}^2(p,q_{\text{BQ}}) \tag{29}$$

□

We know that the the posterior mean $\mathbb{E}_{\text{GP}}\left[Z_{f,p}|f_1,\ldots,f_N\right]$ is a Bayes estimator and has therefore the minimal expected squared error amongst all estimators. This allows us to further rewrite ϵ^2_{BQ} into the following minimax forms:

$$\epsilon^2_{\text{BQ}} = \sup_{\substack{f\in\mathcal{H}\\ \|f\|_{\mathcal{H}}\mathcal{H}=1}} \left|\int f_x p(x)dx - \sum_{n=1}^N w^{(n)}_{\text{BQ}} f_{x_n}\right|^2 \tag{30}$$
$$= \inf_{\hat{Z}:\mathcal{X}^N\mapsto\mathbb{R}} \sup_{\substack{f\in\mathcal{H}\\ \|f\|_{\mathcal{H}}\mathcal{H}=1}} \left|Z - \hat{Z}\left(f_{x_1},\ldots,f_{x_N}\right)\right|^2 \tag{31}$$
$$= \inf_{\boldsymbol{w}\in\mathbb{R}^N} \sup_{\substack{f\in\mathcal{H}\\ \|f\|_{\mathcal{H}}\mathcal{H}=1}} \left|\int f_x p(x)dx - \sum_{n=1}^N w_n f_{x_n}\right|^2 \tag{32}$$

Looking at ϵ^2_{BQ} this way, we may discover the deep similarity to the criterion $\epsilon^2_{herding}$ that kernel herding minimises. Optimal sampling for Bayesian quadrature minimises the same objective as kernel herding, but with the uniform $\frac{1}{N}$ weights replaced by the optimal weights. As a corollary

$$\epsilon^2_{\text{BQ}}(x_1,\ldots,x_N) \le \epsilon^2_{KH}(x_1,\ldots,x_N) \tag{33}$$

It is interesting that ϵ^2_{BQ} has both a Bayesian interpretation as posterior variance under a Gaussian process prior, and a frequentist interpretation as a minimax bound on estimation error with respect to an RKHS.

5 SUBMODULARITY

In this section, we use the concept of approximate submodularity (Krause & Cevher, 2010), in order to study convergence properties of SBQ.

A set function $s : 2^{\mathcal{X}} \mapsto \mathbb{R}$ is *submodular* if, for all $A \subseteq B \subseteq \mathcal{X}$ and $\forall x \in \mathcal{X}$

$$s(A \cup \{x\}) - s(A) \geq s(B \cup \{x\}) - s(B) \tag{34}$$

Intuitively, submodularity is a diminishing returns property: adding an element to a smaller set has larger relative effect than adding it to a larger set. A key result (see e. g. Krause & Cevher, 2010, and references therein) is that greedily maximising a submodular function is guaranteed not to differ from the optimal strategy by more than a constant factor of $(1 - \frac{1}{e})$.

Herding and SBQ are examples of greedy algorithms optimising set functions: they add each pseudosamples in such a way as to minimize the instantaneous reduction in MMD. So it is intuitive to check whether the objective functions these methods minimise are submodular. Unfortunately, neither $\epsilon_{herding}$, nor ϵ_{BQ} satisfies all conditions necessary for submodularity. However, noting that SBQ is identical to the sparse dictionary selection problem studied in detail by Krause & Cevher (2010), we can conclude that SBQ satisfies a weaker condition called *approximate submodularity*.

A set function $s : 2^{\mathcal{X}} \mapsto \mathbb{R}$ is *approximately submodular* with constant $\epsilon > 0$, if for all $A \subseteq B \subseteq \mathcal{X}$ and $\forall x \in \mathcal{X}$

$$s(A \cup \{x\}) - s(A) \geq s(B \cup \{x\}) - s(B) - \epsilon \tag{35}$$

Proposition 2. *$\epsilon^2_{\text{BQ}}(\emptyset) - \epsilon^2_{\text{BQ}}(\cdot)$ is weakly a weakly submodular set function with constant $\epsilon < 4r$, where r is the incoherency*

$$r = \max_{x, x' \in \mathcal{P} \subseteq \mathcal{X}} \frac{k(x, x')}{\sqrt{k(x, x) k(x', x')}} \tag{36}$$

Proof. By the definition of MMD we can see that $-\epsilon^2_{\text{BQ}} = \inf_{w \in \mathbb{R}^N} \left\| \mu_p - \sum_{n=1}^N w^{(n)}_{\text{BQ}} k(\cdot, x_n) \right\|^2_{\mathcal{H}}$ is the negative squared distance between the mean element μ_p and its projection onto the subspace spanned by the elements $k(\cdot, x_n)$. Substituting $k = 1$ into Theorem 1 of Krause & Cevher (2010) concludes the proof. □

Unfortunately, weak submodularity does not provide the strong near-optimality guarantees as submodularity does . If $s : 2^{\mathcal{X}} \mapsto \mathbb{R}$ is a weakly submodular function with constant ϵ, and $|\mathcal{A}_n| = n$ is the result of greedy optimisation of s, then

$$s(\mathcal{A}_n) \geq \left(1 - \frac{1}{e}\right) \max_{|\mathcal{A}| \leq n} s(\mathcal{A}) - n\epsilon \tag{37}$$

As pointed out by Krause & Cevher (2010), this guarantee is very weak, as in our case the objective function $\epsilon^2_{\text{BQ}}(\emptyset) - \epsilon^2_{\text{BQ}}(\cdot)$ is upper bounded by a constant. However, establishing a connection between SBQ and sparse dictionary selection problem opens up interesting directions for future research, and it may be possible to apply algorithms and theory developed for sparse dictionary selection to kernel-based quasi-Monte Carlo methods.

6 EXPERIMENTS

In this section, we examine empirically the rates of convergence of sequential Bayesian quadrature and herding. We examine both the expected error rates, and the empirical error rates.

In all experiments, the target distribution p is chosen a 2D mixture of 20 Gaussians, whose equiprobability contours are shown in Figure 1. To ensure a comparison fair to herding, the target distribution, and the kernel used by both methods, correspond exactly to the one used in (Chen et al., 2010, Fig. 1). For experimental simplicity, each of the sequential sampling algorithms minimizes the next sample location from a pool of 10000 locations randomly drawn from the base distribution. In practice, one would run a local optimizer from each of these candidate locations, however in our experiments we found that this did not make a significant difference in the sample locations chosen.

6.1 Matching a distribution

We first extend an experiment from (Chen et al., 2010) designed to illustrate the mode-seeking behavior of herding in comparison to random samples. In that experiment, it is shown that a small number of i. i. d. samples drawn from a multimodal distribution will tend to, by chance, assign too many samples to some modes, and too few to some other modes. In contrast, herding places 'super-samples' in such a way as to avoid regions already well-represented, and seeks modes that are under-represented.

We demonstrate that although herding improves upon i. i. d. sampling, the uniform weighting of super-samples leads to sub-optimal performance. Figure 1 shows the first 20 samples chosen by kernel herding, in comparison with the first 8 samples chosen by SBQ. By weighting the 8 SBQ samples by the quadrature weights in (20), we can obtain the same expected loss as by using the 20 uniformly-weighted herding samples. Figure 5 shows MMD versus the number of samples added, on the distribution shown in Figure 1. We can see that in all cases, SBQ dominates herding. It appears that SBQ converges at a faster rate than $\mathcal{O}(1/N)$, although the

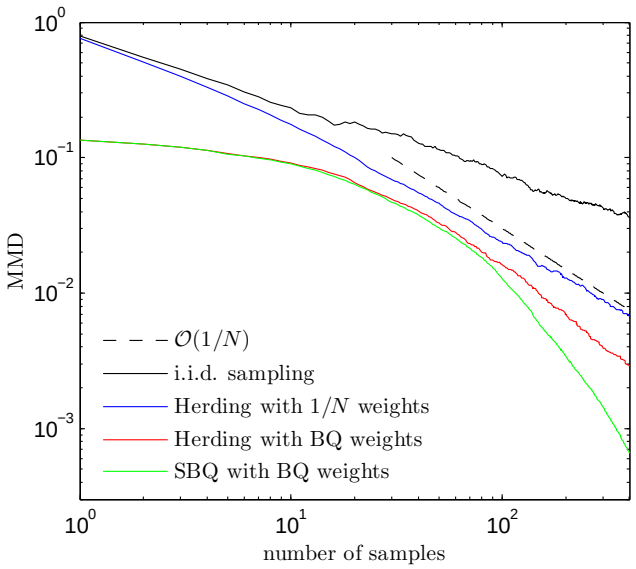

Figure 5: The maximum mean discrepancy, or expected error of several different quadrature methods. Herding appears to approach a rate close to $\mathcal{O}(1/N)$. SBQ appears to attain a faster, but unknown rate.

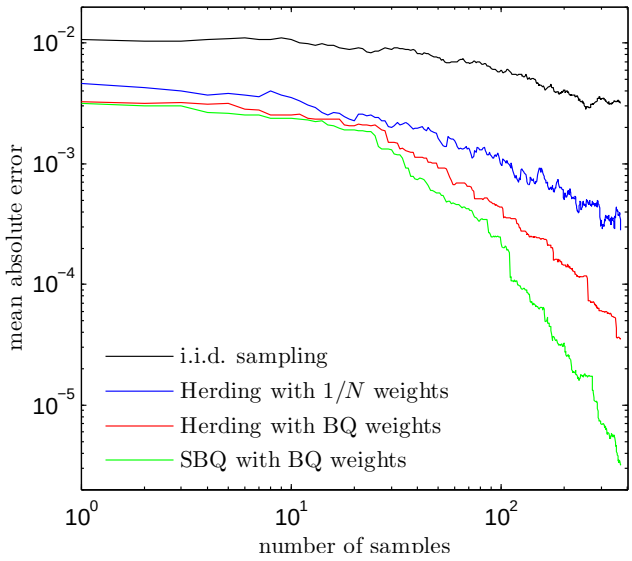

Figure 6: Within-model error: The empirical error rate in estimating $Z_{f,p}$, for several different sampling methods, averaged over 250 functions randomly drawn from the RKHS corresponding to the kernel used.

form of this rate is unknown.

There are two differences between herding and SBQ: SBQ chooses samples according to a different criterion, and also weights those samples differently. We may ask whether the sample locations or the weights are contributing more to the faster convergence of SBQ. Indeed, in Figure 1 we observe that the samples selected by SBQ are quite similar to the samples selected by kernel herding. To answer this question, we also plot in Figure 5 the performance of a fourth method, which selects samples using herding, but later re-weights the herding samples with BQ weights. Initially, this method attains similar performance to SBQ, but as the number of samples increases, SBQ attains a better rate of convergence. This result indicates that the different sample locations chosen by SBQ, and not only the optimal weights, are responsible for the increased convergence rate of SBQ.

6.2 Estimating Integrals

We then examined the empirical performance of the different estimators at estimating integrals of real functions. To begin with, we looked at performance on 100 randomly drawn functions, of the form:

$$f(x) = \sum_{i=1}^{10} \alpha_i k(x, c_i) \tag{38}$$

where

$$\|f\|_{\mathcal{H}}^2 = \sum_{i=1}^{10}\sum_{j=1}^{10} \alpha_i \alpha_j k(c_i, c_j) = 1 \tag{39}$$

That is, these functions belonged exactly to the unit ball of the RKHS defined by the kernel $k(x, x')$ used to model them. Figure 6 shows the empirical error versus the number of samples, on the distribution shown in Figure 1. The empirical rates attained by the method appear to be similar to the MMD rates in Figure 5.

By definition, MMD provides a upper bound on the estimation error in the integral of any function in the unit ball of the RKHS (Eqn. (3)), including the Bayesian estimator, SBQ. Figure 7 demonstrates this quickly decreasing bound on the SBQ empirical error.

6.3 Out-of-model performance

A central assumption underlying SBQ is that the integrand function belongs to the RKHS specified by the kernel. To see how performance is effected if this assumption is violated, we performed empirical tests with functions chosen from outside the RKHS. We drew 100 functions of the form:

$$f(x) = \sum_{i=1}^{10} \alpha_i \exp(-\frac{1}{2}(x - c_i)^T \Sigma_i^{-1}(x - c_i) \tag{40}$$

where each α_i c_i Σ_i were drawn from broad distributions. This ensured that the drawn functions had features such as narrow bumps and ridges which would

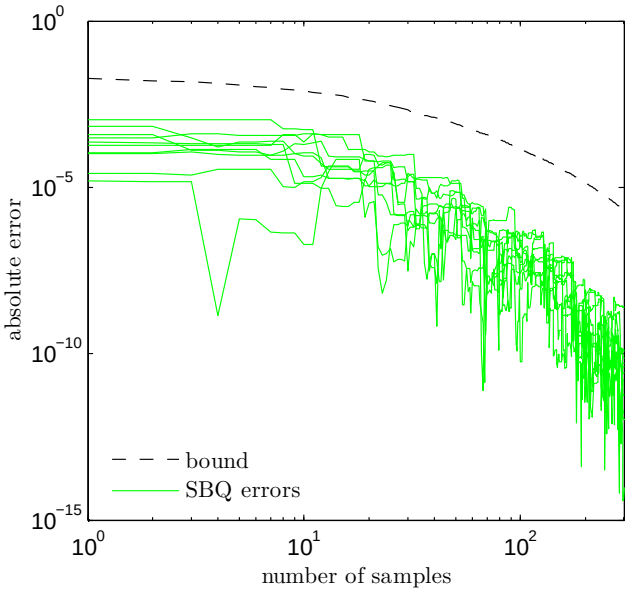

Figure 7: The empirical error rate in estimating $Z_{f,p}$, for the SBQ estimator, on 10 random functions drawn from the RKHS corresponding to the kernel used. Also shown is the upper bound on the error rate implied by the MMD.

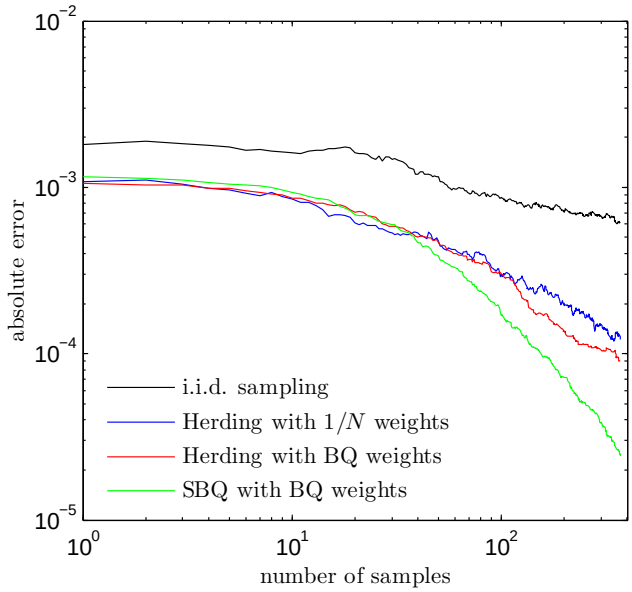

Figure 8: Out-of-model error: The empirical error rates in estimating $Z_{f,p}$, for several different sampling methods, averaged over 250 functions drawn from outside the RKHS corresponding to the kernels used.

not be well modelled by functions belonging to the isotropic kernel defined by k. Figure 8 shows that, on functions drawn from outside the assumed RKHS, relative performance of all methods remains similar.

Code to reproduce all results is available at `http://mlg.eng.cam.ac.uk/duvenaud/`

7 DISCUSSION

7.1 Choice of Kernel

Using herding techniques, we are able to achieve fast convergence on a Hilbert space of *well-behaved* functions, but this fast convergence is at the expense of the estimate not necessarily converging for functions outside this space. If we use a characteristic kernel (Sriperumbudur et al., 2010), such as the exponentiated-quadratic or Laplacian kernels, then convergence in MMD implies weak convergence of q_N to the target distribution. This means that the estimate converges for any bounded measurable function f. The speed of convergence, however, may not be as fast.

Therefore it is crucial that the kernel we choose is representative of the function or functions f we will integrate. For example, in our experiments, the convergence of herding was sensitive to the width of the Gaussian kernel. One of the major weaknesses of kernel methods in general is the difficulty of setting kernel parameters. A key benefit of the Bayesian interpretation of herding and MMD presented in this paper is that it provides a recipe for adapting the Hilbert space to the observations $f(x_n)$. To be precise, we can fit the kernel parameters by maximizing the marginal likelihood of Gaussian process conditioned on the observations. Details can be found in (Rasmussen & Williams, 2006).

7.2 Computational Complexity

While we have shown that Bayesian Quadrature provides the optimal re-weighting of samples, computing the optimal weights comes at an increased computational cost relative to herding. The computational complexity of computing Bayesian quadrature weights for N samples is $\mathcal{O}(N^3)$, due to the necessity of inverting the Gram matrix $K(x, x)$. Using the Woodbury identity, the cost of adding a new sample to an existing set is $\mathcal{O}(N^2)$. For herding, the computational complexity of evaluating a new sample is only $\mathcal{O}(N)$, making the cost of choosing N herding samples $\mathcal{O}(N^2)$. For Monte Carlo sampling, the cost of adding an i.i.d. sample from the target distribution is only $\mathcal{O}(1)$.

The relative computational cost of computing samples and weights using BQ, herding, and sampling must be weighed against the cost of evaluating f at the sample locations. Depending on this trade-off, the three sampling methods form a Pareto frontier over computational speed and estimator accuracy. When computing

method	complexity	rate	guarantee
MCMC	$\mathcal{O}(N)$	variable	ergodic theorem
i.i.d. MC	$\mathcal{O}(N)$	$\frac{1}{\sqrt{N}}$	law of large numbers
herding	$\mathcal{O}(N^2)$	$\frac{1}{\sqrt{N}} \geq \cdot \geq \frac{1}{N}$	(Chen et al., 2010; Bach et al., 2012)
SBQ	$\mathcal{O}(N^3)$	unknown	approximate submodularity

Table 1: A comparison of the rates of convergence and computational complexity of several integration methods.

f is cheap, we may wish to use Monte Carlo methods. In cases where f is computationally costly, we would expect to choose the SBQ method. When f is relatively expensive, but a very large number of samples are required, we may choose to use kernel herding instead. However, because the rate of convergence of SBQ is faster, there may be situations in which the $\mathcal{O}(N^3)$ cost is relatively inexpensive, due to the smaller N required by SBQ to achieve the same accuracy as compared to using other methods.

There also exists the possibility to switch to a less costly sampling algorithm as the number of samples increases. Table 1 summarizes the rates of convergence of all the methods considered here.

8 CONCLUSIONS

In this paper, we have shown three main results: First, we proved that the loss minimized by kernel herding is closely related to the loss minimized by Bayesian quadrature, when selecting sample locations. This implies that sequential Bayesian quadrature can viewed as an optimally-weighted version of kernel herding.

Second, we showed that the loss minimized by the Bayesian method is approximately submodular with respect to the samples chosen, and established connections to the submodular dictionary selection problem studied in (Krause & Cevher, 2010).

Finally, we empirically demonstrated a superior rate of convergence of SBQ over herding, and demonstrated a bound on the empirical error of the Bayesian quadrature estimate.

8.1 Future Work

In section 5, we showed that SBQ is approximately submodular, which provides only weak sub-optimality guarantees of its performance. It would be of interest to further explore the connection between Bayesian Quadrature and the dictionary selection problem to see if algorithms developed for dictionary selection can provide further practical or theoretical developments. The results in section 6, specifically Figure 5, suggest that the convergence rate of SBQ is faster than $\mathcal{O}(1/N)$. However, we are not aware of any work showing what the theoretically optimal rate is. It would be of great interest to determine this optimal rate of convergence for particular classes of kernels.

Abstract

Much of scientific data is collected as randomized experiments intervening on some and observing other variables of interest. Quite often, a given phenomenon is investigated in several studies, and different sets of variables are involved in each study. In this article we consider the problem of integrating such knowledge, inferring as much as possible concerning the underlying causal structure with respect to the union of observed variables from such experimental or passive observational overlapping data sets. We do not assume acyclicity or joint causal sufficiency of the underlying data generating model, but we do restrict the causal relationships to be linear and use only second order statistics of the data. We derive conditions for full model identifiability in the most generic case, and provide novel techniques for incorporating an assumption of faithfulness to aid in inference. In each case we seek to establish what is and what is not determined by the data at hand.

1 INTRODUCTION

For many scientific domains different research groups study the same or closely related phenomena. In general the resulting data sets may contain different sets of variables with only partial overlap, and some of the data sets may be passive observational, while others have resulted from experiments intervening on a subset of the variables. In the context of discovering causal pathways, it would be desirable to be able to integrate all the findings of these 'overlapping' experimental and observational data sets, not only to gain an overall view, but, where possible, to also detect causal relations that were not identified in any individual study.

In the literature on causal discovery methods this problem has been addressed in two complementary, yet so far, independent ways. On the one hand a variety of algorithms have been developed that integrate data from *overlapping* but purely *passive observational* data sets (Tillman et al., 2009; Triantafillou et al., 2010; Tillman and Spirtes, 2011). On the other hand there are several procedures that combine multiple *experimental* studies on the *same* set of variables (Cooper and Yoo, 1999; Tong and Koller, 2001; Murphy, 2001; Eaton and Murphy, 2007; He and Geng, 2008; Schmidt and Murphy, 2009; Eberhardt et al., 2010; Hyttinen et al., 2010).

In this article we present methods that combine the two approaches: we consider data sets that contain passive observational or experimental measures of overlapping sets of variables. We do *not* assume that the set of variables is jointly causally sufficient; in other words we allow for the possible existence of common causes of the measured variables that are not measured in *any* of the available data sets. Moreover, unlike any of the previous work on overlapping data sets, we do *not* assume that the underlying causal structure is acyclic. To ensure that we have a well-defined representation of the *cyclic* relations, we assume that the causal relations are *linear* (see Section 2). The assumption of linearity also enables the use of quantitative constraints that can lead to the identifiability of the underlying causal structure in cases which are non-identifiable without such a parametric assumption (Hyttinen et al., 2011). We provide necessary and sufficient conditions under which the true causal model can be identified, but given the weak set of background assumptions, these are inevitably very demanding. In general there may only be a very limited number of experimental data sets, and so the remaining underdetermination can still be quite substantial. We then provide a novel approach for incorporating the assumption of *faithfulness* (Spirtes et al., 1993) to aid in model search for this family of linear models. We show that, for sparse graphs, a significant amount of structure can be inferred using this framework.

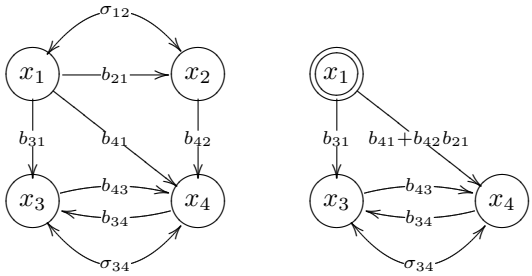

Figure 1: An example of a linear cyclic model with latent variables (left) and the corresponding manipulated model in an experiment where x_1 is intervened, x_3, x_4 are observed and x_2 is hidden (right). Single-headed arrows denote non-zero direct effects while double-headed arrows represent the existence of latent confounders. The disturbance variables are omitted to improve readability.

This paper is structured as follows. We formalize the problem in Section 2, by defining the model family we are considering, specifying the representation used for overlapping data sets, and formulating the inference problem. Then, in Section 3, we derive necessary and sufficient conditions for the identifiability of the model, in the absence of extra assumptions. In Section 4, we consider an approach to integrate simple faithfulness constraints, which we then extend to a more general and powerful method in Sections 5-6. Simulations are provided in Section 7, and some conclusions in Section 8.

2 MODEL AND PROBLEM DEFINITION

We use the following formal representation of the setting with overlapping data sets: Given data sets $\mathcal{D}_1, \ldots, \mathcal{D}_K$ with measurements on the sets of variables $\mathcal{V}_1, \ldots, \mathcal{V}_K$, respectively, let the joint set of variables be $\mathcal{V} = \{x_1, \ldots, x_n\} = \bigcup_{k=1,\ldots,K} \mathcal{V}_k$. Obviously, the individual sets $\mathcal{V}_k$ of variables in $\mathcal{D}_k$ will generally not be causally sufficient, but we also allow the *joint* set of variables $\mathcal{V}$ to be causally insufficient, i.e. there can be confounders that are not measured in any of the available data sets. Each data set $\mathcal{D}_k$ is considered to be the result of an experiment $\mathcal{E}_k$ that partitions the variables $\mathcal{V}$ into $\mathcal{J}_k$ (intervened), $\mathcal{U}_k$ (observed), and $\mathcal{L}_k$ (hidden) variables. We assume that all variables in $\mathcal{V}$ are measured in at least one of the experiments, i.e. for any $x \in \mathcal{V}$ there exists some experiment $\mathcal{E}_k$ with $1 \leq k \leq K$ such that $x \in \mathcal{J}_k \cup \mathcal{U}_k$. Passive observational studies are trivially represented by 'null'-experiments where $\mathcal{J}_k = \emptyset$.

We assume that there is a single generating model over the variables in $\mathcal{V}$ that, suitably manipulated for each experiment, gives rise to all the data sets. We consider the model class of linear cyclic models with latent variables (linear non-recursive SEMs with correlated disturbances) (Bollen, 1989). The model can be described by the equation

$$\mathbf{x} := \mathbf{B}\mathbf{x} + \mathbf{e} \tag{1}$$

where $\mathbf{x}$ is a vector that denotes the variables in $\mathcal{V}$ while $\mathbf{e}$ represents the corresponding exogenous disturbances. The model is parameterized by a direct effects matrix $\mathbf{B}$ and a covariance matrix of the disturbances $\mathrm{cov}(\mathbf{e}) = \mathbf{\Sigma_e}$. Confounding due to variables *external* to the joint set of variables $\mathcal{V}$ is modeled implicitly by non-zero off-diagonal entries in $\mathbf{\Sigma_e}$ that correlate the disturbances. Figure 1 shows how the structure of such a model can be described by a mixed graph. Note that we assume throughout that the diagonal of $\mathbf{B}$ is zero; this is not a substantial assumption.[1]

We use the standard notion of "surgical" interventions (Pearl, 2000), where an intervention makes the intervened variable independent of its normal causes. Formally, the intervened model $(\tilde{\mathbf{B}}, \tilde{\mathbf{\Sigma}}_\mathbf{e})$ is the same as the unintervened model $(\mathbf{B}, \mathbf{\Sigma_e})$ except that each row in $\tilde{\mathbf{B}}$ corresponding to edges incident on some $x_i \in \mathcal{J}$ is set to zero (thereby breaking the edges into any such variables); similarly, for the ith row and column of $\tilde{\mathbf{\Sigma}}_\mathbf{e}$. An intervention vector $\mathbf{c}$ is added to the model Equation (1) that determines the values of (only) the intervened variables according to an intervention distribution with $\boldsymbol{\mu_c}$ and $\mathbf{\Sigma_c}$. For notational simplicity we assume that the intervened variables are randomized independently with zero mean and unit variance. This does not seriously limit the applicability of the methods.[2] For any individual (experimental) data set $\mathcal{D}_k$ we then assume that only the values of $\mathbf{x}$ corresponding to variables in $\mathcal{J}_k \cup \mathcal{U}_k$ are revealed (see Figure 1, right).

To ensure that the cyclic model has a well-defined equilibrium distribution, Hyttinen et al. (2012) examined models that are *weakly stable*, that is, models for which the $\mathbf{I} - \mathbf{B}$ matrix of the model (where $\mathbf{I}$ is the identity matrix) and all corresponding manipulated versions are invertible. Weak stability implies that the observed distribution follows a covariance matrix $\mathrm{cov}(\mathbf{x}) = (\mathbf{I}-\mathbf{B})^{-1}\mathbf{\Sigma_e}(\mathbf{I}-\mathbf{B})^{-T}$. However, in the

[1] There is inherent underdetermination of the diagonal elements of $\mathbf{B}$, related to self-loops (edges from a node to itself) in the model. These do not affect the equilibrium distribution in linear cyclic models, and can be handled by a suitable normalization (Hyttinen et al., 2012).

[2] A detailed formal account of the intervened model is given by Hyttinen et al. (2012), see their Equation 7 and Lemma 5.

case of overlapping data sets we have to make a slightly stronger assumption to obtain the desired identifiability results:

Assumption 1 (No unit cycles) *The sum-product of edge-coefficients on any subset of paths from a variable back to itself cannot sum up to exactly 1.*

Weak stability follows from this assumption. The proof of this claim, and all subsequent results in this paper, can be found in the Appendix in the Supplementary Material.

We can now state our learning problem formally: Given data sets $\mathcal{D}_1, \ldots, \mathcal{D}_K$ containing measurements of the marginalized distribution of a (experimentally manipulated) linear cyclic model with latent variables $(\mathbf{B}, \mathbf{\Sigma_e})$ that satisfies Assumption 1, identify as many causal relations among the joint set of variables, i.e. entries in $\mathbf{B}$, as possible.

3 IDENTIFIABILITY

One of the advantages of linear cyclic models is that the correlation measured between an intervened variable x_i and a non-intervened variable x_j corresponds to the sum-product of all the directed paths from x_i to x_j in a graph where all arcs into the intervened variables in $\mathcal{J}_k$ are cut. Eberhardt et al. (2010) refer to these terms as *experimental effects* and use the notation $\text{cov}_k(x_i, x_j) = t(x_i \rightsquigarrow x_j || \mathcal{J}_k)$. When the intervention set of an experimental effect contains all but one variable, then it corresponds to the *direct effect*: $t(x_i \rightsquigarrow x_j || \mathcal{V} \setminus \{x_j\}) = b(x_i \rightarrow x_j) = \mathbf{B}[j, i]$. Similarly, when only one variable is subject to intervention, we have the *total effect*: $t(x_i \rightsquigarrow x_j || \{x_i\}) = t(x_i \rightsquigarrow x_j)$.

Eberhardt et al. (2010) describe a learning algorithm which uses experimental effects estimated from the data to form linear equations on the unknown total effects. In particular, for an experiment with a variable $x_i \in \mathcal{J}_k$ and a variable $x_u \in \mathcal{U}_k$, one can obtain the constraint

$$t(x_i \rightsquigarrow x_u) = \sum_{x_j \in \mathcal{J}_k \setminus \{x_i\}} t(x_i \rightsquigarrow x_j) t(x_j \rightsquigarrow x_u || \mathcal{J}_k) + t(x_i \rightsquigarrow x_u || \mathcal{J}_k). \quad (2)$$

Note that for all $x_j \in \mathcal{J}_k$ the experimental effects $t(x_j \rightsquigarrow x_u || \mathcal{J}_k)$ are directly given by the relevant covariances (see above) in the data from this experiment, so the equation is linear in the unknown total effects. The intuition behind the equation is that the set of all directed paths from x_i to x_u in the original (unmanipulated) model can be separated into those going through each of the other intervened variables (the ones in $\mathcal{J}_k \setminus \{x_i\}$) and the remaining ones. Collecting a sufficient number of such linear constraints makes it possible to identify all total effects, from which it is straightforward to obtain the direct effects, as described in their paper.

While their learning procedure was constructed for the fully observed case, we note that it is directly applicable to our overlapping data sets case, since for any $x_i \in \mathcal{J}_k$ and any $x_u \in \mathcal{U}_k$, all required experimental effects are covariances between observed variables (and do not involve any variables in $\mathcal{L}_k$). Moreover, the identifiability results described in Eberhardt et al. (2010) and Hyttinen et al. (2012) can be generalized to the current setting once it is clarified how their conditions apply when the set of variables $\mathcal{V}$ is split into three sets $\mathcal{J}_k, \mathcal{U}_k$ and $\mathcal{L}_k$, rather than just $\mathcal{J}_k$ and $\mathcal{U}_k$. For this purpose, we say that a given set of experiments $\mathcal{E}_1, \ldots, \mathcal{E}_K$ satisfies the *pair condition* for the ordered pair of variables (x_j, x_u) if there is an experiment $\mathcal{E}_k$, with $1 \leq k \leq K$, such that $x_j \in \mathcal{J}_k$ and $x_u \in \mathcal{U}_k$. Note that an experiment with $x_j \in \mathcal{J}_k$ and $x_l \in \mathcal{L}_k$ does not satisfy the pair condition for the pair (x_j, x_l) even though x_l is not subject to intervention. The identifiability conditions for overlapping data sets are then as follows:

Theorem 1 (Sufficiency) *Given some set of experiments, a linear cyclic model with latent variables satisfying Assumption 1 is fully identified if the pair condition is satisfied for all ordered pairs* $(x_i, x_j) \in \mathcal{V} \times \mathcal{V},\ x_i \neq x_j$.

Note that unlike in Eberhardt et al. (2010), our sufficiency result here requires the slightly stronger Assumption 1. We further show that the sufficient condition is also in the worst case necessary.

Theorem 2 (Worst Case Necessity) *Given any set of experiments that does* not *satisfy the pair condition for all ordered pairs of variables* $(x_i, x_j) \in \mathcal{V} \times \mathcal{V},\ x_i \neq x_j$, *there exist two distinct linear cyclic models with latent variables satisfying Assumption 1 that are indistinguishable given those experiments.*

So with minor adjustments to the conditions and assumptions, we obtain for the overlapping data sets case very similar identifiability results as were given for the case when all data sets shared the same set of variables. In fact, as indicated in Appendix C, the learning algorithm of Eberhardt et al. (2010) is also *complete* given the background assumptions we have been considering here, in the sense that the information gained from the experimental effects fully exhausts what can be inferred about the underlying causal model. That is, correlations between non-intervened variables in this case provide no extra benefit. In Section 7 we use this algorithm ('EHS') as a baseline comparison of what a

complete procedure can infer without making stronger search space assumptions. Together, Theorems 1 and 2 provide *a priori* guidelines to identify which experimental results are needed to complement any available ones. Note that K specifically chosen experiments are enough to the satisfy the identifiability condition for models with up to $\binom{K}{\lfloor K/2 \rfloor}$ variables (Spencer, 1970).

4 FAITHFULNESS & BILINEARITY

In most realistic contexts the set of available overlapping data sets will not contain a sufficient variety of experimental interventions to satisfy the demanding identifiability condition given in the previous section. Hence, the full model will typically not be fully identified by the 'EHS' procedure. Furthermore, in most cases the overwhelming majority of the direct effects will remain underdetermined, as is evident from the simulations in Section 7.

Thus, a useful approach might be to strengthen the assumptions regarding the underlying model. The natural assumption, prevalent throughout causal discovery research, is the assumption of *faithfulness* (Spirtes et al., 1993), which can be seen as a simplicity or minimality assumption for causal discovery procedures. Most commonly used for inference in passive observational data, we consider the natural extension of the faithfulness assumption to experimental contexts: A data-generating model is said to be *faithful* if *all independences true in any (manipulated) observed distribution are consequences of the structure of the (manipulated) graph, and not due to the specific parameter values of the model*. In short, faithfulness enables us to infer from a statistical independence that there is an absence of a causal connection between the variables in question, in the particular context under which the statistical independence occurs. It is well known that heavy confounding often results in causal models that are effectively unfaithful given the limited sample size of the data. Nevertheless, if one has reason to believe that models are sparse and confounding limited, then faithfulness may constitute a reasonable assumption that can provide further insights.

Hyttinen et al. (2010) considered a set of simple faithfulness rules by which marginal or conditional independencies in the observed variables were used to derive constraints of the form $b(x_i \to x_j) = \mathbf{B}[j,i] = 0$, i.e. based on statistical independencies in the experimental data, some direct effects were inferred to equal zero. While these constraints are (trivially) linear in the direct effects, they are highly *non-linear* in the total effects, and thus cannot easily be integrated with linear constraints on the total effects of the form of Equation 2. To solve this problem Hyttinen et al. (2010) noted that one could, in fact, use the measured experimental effects to put linear constraints on the *direct effects*, as opposed to the total effects.

$$t(x_i \rightsquigarrow x_u || \mathcal{J}_k) = b(x_i \rightsquigarrow x_u) + \sum_{x_j \in \mathcal{V} \setminus (\mathcal{J} \cup \{x_u\})} t(x_i \rightsquigarrow x_j || \mathcal{J}_k) b(x_j \rightsquigarrow x_u) \quad (3)$$

In this way, the constraints from the experimental effects could be straightforwardly combined with faithfulness constraints, resulting in a fully linear system of equations constraining the direct effects (Hyttinen et al., 2010). The resulting linear system can be analyzed to determine which direct effects are identified and which are underdetermined; this procedure is empirically evaluated in Section 7 under the abbreviation 'HEH'.

Unfortunately, in the overlapping variables scenario, in most cases one cannot obtain many linear constraints on the direct effects. This is because one or more of the non-intervened variables may be latent, and one needs the experimental effects to *all* non-intervened variables in a given experiment to construct the linear constraints on the direct effects. In general, the experimental effects $t(x_i \rightsquigarrow x_j || \mathcal{J}_k)$ are not available when $x_j \in \mathcal{L}_k$, unless they can be inferred from the combination of results from all data sets. On the other hand, as we discussed in Section 3, we *can* obtain linear constraints on the *total* effects, because latents do not form a problem in this case. The remaining problem is thus that, in general, we may have a large set of linear constraints on the elements of the total effects matrix $\mathbf{T} = (\mathbf{I} - \mathbf{B})^{-1}$, where $\mathbf{T}[j,i] = t(x_i \rightsquigarrow x_j)$, combined with the knowledge that certain elements of $\mathbf{B}$ are zero, but finding a solution to this combined set of constraints is no longer trivial.

One approach to solving this problem is to take the *combination* of the direct effects (elements of $\mathbf{B}$) *and* the total effects (elements of $\mathbf{T}$) as the unknown free parameters of the problem. In this way, we now have a *bilinear* system of equations: There are equations linear in the elements of $\mathbf{B}$, equations linear in the elements of $\mathbf{T}$, and the constraint $\mathbf{T}(\mathbf{I} - \mathbf{B}) = \mathbf{I}$ yields equations that are bilinear; they are linear in one parameter vector given the other. To determine the underdetermination of the system under this combined set of constraints thus involves characterizing the solution set for such a bilinear equation system. Unfortunately, no efficient solution methods for large bilinear equation systems are known, except in certain special cases (Cohen and Tomasi, 1997; Johnson and Link, 2009).

Nevertheless, one can attempt to solve the system by

minimizing the objective function

$$C(\mathbf{B}, \mathbf{T}) = \|\mathbf{K}_1 \text{vec}(\mathbf{B}) - \mathbf{k}_1\|^2 + \|\mathbf{K}_2 \text{vec}(\mathbf{T}) - \mathbf{k}_2\|^2 + \|\mathbf{T}(\mathbf{I} - \mathbf{B}) - \mathbf{I}\|^2, \quad (4)$$

where the $\|\cdot\|^2$ denotes squared Euclidean norm (for a vector) and squared Frobenius norm (for a matrix), i.e. in both cases the sum of squares of the elements. In this objective function, the first term (involving $\mathbf{K}_1$ and $\mathbf{k}_1$) represents all linear constraints on the elements of $\mathbf{B}$ that we have been able to construct, the second term (involving $\mathbf{K}_2$ and $\mathbf{k}_2$) similarly represents any available linear constraints on the elements of $\mathbf{T}$, while the last term derives from the constraint $\mathbf{T} = (\mathbf{I} - \mathbf{B})^{-1}$. This objective function is quadratic in $\mathbf{B}$ (for fixed $\mathbf{T}$), and quadratic in $\mathbf{T}$ (for fixed $\mathbf{B}$), so it is easy to set up an alternating variables approach which minimizes with respect to each one at a time, keeping the other fixed. Since the objective is not convex with respect to the joint parameter vector, one cannot be guaranteed to find the global minimum using such a procedure. In our experience, however, this approach is generally quite effective in finding solutions to the underlying system of equations, when such solutions exist. We use this procedure, starting from a sample of random initial points, to generate a sample of solutions to the available constraints. For each of the direct effects (elements of $\mathbf{B}$) we then, on the basis of its variance in the sample, classify it as determined or underdetermined. For determined coefficients we further infer whether the coefficient is zero (edge is absent) or non-zero (edge is present), based on the mean value of the coefficient in the sample. Note that any constraints on the model parameters that follow the above bilinear form can easily be added to this inference procedure. In fact, it turns out that several of the faithfulness constraints derived in the following section can be added. With these additions, we empirically evaluate this method (under the abbreviation 'BILIN') in the simulations in Section 7.

5 FAITHFULNESS CONSTRAINTS ON SETS OF PATHS

While constraints of the form $b(x_i \to x_j) = 0$ are the most obvious consequences of the faithfulness assumption, they by no means exhaust the inferences that are possible in linear models. In this section, we provide a more general framework for deriving and representing faithfulness constraints, and in the following section we make use of these constraints in an inference algorithm for the overlapping data sets setting.

We build on the work of Claassen and Heskes (2011), who developed a logical inference procedure based on *minimal* conditioning sets to derive graphical consequences of the faithfulness assumption. A minimal conditioning set, indicated by the brackets, identifies exactly the set of variables that make a pair of variables (in)dependent. Formally, for variables x and y and disjoint sets of variables C and D not containing x and y, we denote a minimal independence by

$$x \perp\!\!\!\perp y \,|\, D \cup [C] \text{ whenever we have } x \perp\!\!\!\perp y \,|\, D \cup C \text{ and } \forall C' \subsetneq C, x \not\perp\!\!\!\perp y \,|\, D \cup C',$$

and a minimal dependence by

$$x \not\perp\!\!\!\perp y \,|\, D \cup [C] \text{ whenever we have } x \not\perp\!\!\!\perp y \,|\, D \cup C \text{ and } \forall C' \subsetneq C, x \perp\!\!\!\perp y \,|\, D \cup C'.$$

In both cases D and C can be empty, although when C is empty, the statements become trivial. Under the assumption that the generating model is acyclic, Claassen and Heskes (2011) provide causal inference rules based on such minimal dependencies and independencies, that identify all consequences of faithfulness given passive observational data on a set of (potentially) causally insufficient variables. We drop their acyclicity axiom and change and expand their rules to apply to overlapping data sets, experimental data, and cyclic generating models. We use them to derive constraints on the experimental effects of hypothetical experiments, which, in turn, are used to identify additional features of the underlying causal model.

For example, if we find that $x \perp\!\!\!\perp y \,|\, [z]$ in the manipulated distribution where only z is subject to an intervention, then we infer that $t(x \rightsquigarrow y || \{x, z\}) = 0$, i.e. for an experiment in which x and z are subject to intervention, there would be no correlation between x and y, since, by faithfulness, there is no directed path from x to y that does not pass through z. Moreover, we can generalize this constraint to all supersets of the intervention set:

$$t(x \rightsquigarrow y || \mathcal{J}) = 0 \quad \Rightarrow \quad t(x \rightsquigarrow y || \mathcal{J} \cup C) = 0 \quad (5)$$

for all $C \subseteq \mathcal{V} \setminus \{y\}$. Note, in particular, that C may contain variables in $\mathcal{L}$. As a special case of this rule we thus obtain the direct effect constraint $t(x \rightsquigarrow y || \mathcal{V} \setminus \{y\}) = b(x \to y) = 0$. Similarly, x and y can be reversed in all the previous constraints. If we additionally found for some non-intervened w, that $x \not\perp\!\!\!\perp y \,|\, \{z\} \cup [w]$, then w is a so-called "unshielded collider", which implies that $t(w \rightsquigarrow x || \{w, z\}) = t(w \rightsquigarrow y || \{w, z\}) = 0$. Again we can also generate constraints for all the experimental effects with supersets of the intervention sets.

Since faithfulness in general implies the absence of particular causal pathways given a set of discovered independence constraints, it implies for the linear models that we have been considering, that the sum-products

of edge coefficients representing a (set of) path(s) connecting two variables are zero. An independence between x and y in a passive observational data set can thus give rise to a set of polynomial equations representing the fact that there is no directed pathway from x to y or vice versa, and that there is no (latent) common cause of x and y. Quite apart from the large number of equations such a general approach produces, there are no known efficient solution methods for such a set of equations. We thus have to determine which subset of the consequences of faithfulness we can handle.

We found that for consequences of faithfulness that can be represented as bilinear equations on the experimental effects, such as Equation 6, computationally feasible solution methods could still be developed.

$$t(x \rightsquigarrow u || \mathcal{J} \cup \{x\}) \cdot t(u \rightsquigarrow y || \mathcal{J} \cup \{u\}) \quad = \quad 0 \quad (6)$$

The bilinear approach of Section 4 can include such equations as (6) if one of the experimental effects is a total effect and the other is a direct effect. In Section 6 we present a method that handles versions of Equation 6 in its more general form. In Appendix D we describe the full set of faithfulness rules we apply and the equations we use. These include the skeleton rules of the PC-algorithm, as well as many other standard faithfulness inferences. We also note the rules' limitations by giving an example of an inference that we cannot include in the current bilinear representation.

The independence constraints due to faithfulness thus allow us to obtain zero-constraints on a variety of experimental effects and their products without ever having to perform the corresponding experiment or having a data set that includes all the variables present in the constraint. We note that in practice inferences due to faithfulness are very sensitive to the correctness of the independence test judgments. In particular, once the inference depends on more than a simple unconditional independence test, reliability rapidly decreases and the theoretical gains one obtains in the infinite sample limit evaporate (see Section 7 for more discussion and comparisons). So while a complete method for inferences based on faithfulness given the background assumptions here is still of theoretical interest, its practical usefulness may be limited.

6 INFERENCE ALGORITHM

In Section 4 we took an approach that overparameterized the search problem by treating both the total and the direct effects as unknown. The proposed method searched for solutions using the available constraints that could be represented in the bilinear system relating total and direct effects. But in the previous section we showed that the assumption of faithfulness implies zero-constraints on the experimental effects that cannot, in general, be used by such a bilinear method (see Equations 5 & 6). In this section we propose a method that includes these more general constraints on experimental effects that are neither total nor direct effects. We consider *all* experimental effects as unknown parameters of the model. This can be seen as taking the overparametrization one step further, but given that there are now a total of $n(n-1)2^{n-2}$ different experimental effects for a model with n variables in $\mathcal{V}$, the iterative approach of Section 4 becomes unfeasible; something simpler is needed.

Algorithm 1 Linear Inference algorithm: LININF

Record all observed experimental effects.

Record any experimental effects directly identified as zero by the faithfulness rules.

While TRUE,

- Initialize matrix $\mathbf{A}$ and vector $\mathbf{b}$ as empty. Let $\mathbf{x}$ be the vector of the remaining unknown experimental effects.
- For all experimental effects $t(x_i \rightsquigarrow x_u || \mathcal{J}_k)$,
  - For all sets $\mathcal{J}_l$ such that $\mathcal{J}_k \subsetneq \mathcal{J}_l \subsetneq \mathcal{V} \setminus \{x_u\}$,
    - If Equation 7 is *linear* with respect to the unknown experimental effects, add it to the system $\mathbf{Ax} = \mathbf{b}$.
- For all equations induced by the faithfulness rules,
  - If the equation is *linear* with respect to the unknown experimental effects, add it to the system $\mathbf{Ax} = \mathbf{b}$.
- Solve $\mathbf{x}$ from $\mathbf{Ax} = \mathbf{b}$ and determine the uniquely identified elements of $\mathbf{x}$.
- Record all experimental effects corresponding to uniquely identified elements of $\mathbf{x}$, and derive implied experimental effects based on Equation 5.
- Exit if no new experimental effects were recorded.

Output the recorded experimental effects.

Some experimental effects are readily observed in the overlapping experiments. We use these observed experimental effects to determine some of the remaining unknown ones. Hyttinen et al. (2012) generalized Equation 2 to show how some experimental effects can be used to constrain others. If two experiments with intervention sets $\mathcal{J}_k$ and $\mathcal{J}_l$ satisfy $\mathcal{J}_k \subsetneq \mathcal{J}_l \subsetneq \mathcal{V} \setminus \{x_u\}$, then the experimental effects of the two experiments are related by the following equation:

$$t(x_i \rightsquigarrow x_u || \mathcal{J}_k) = t(x_i \rightsquigarrow x_u || \mathcal{J}_l) + \sum_{x_j \in \mathcal{J}_l \setminus \mathcal{J}_k} t(x_i \rightsquigarrow x_j || \mathcal{J}_k) t(x_j \rightsquigarrow x_u || \mathcal{J}_l) \quad (7)$$

Generally such equations are non-linear in the unknown experimental effects. However, the equation is *linear* if for all $x_j \in \mathcal{J}_l \setminus \mathcal{J}_k$ either $t(x_i \rightsquigarrow x_j || \mathcal{J}_k)$ or

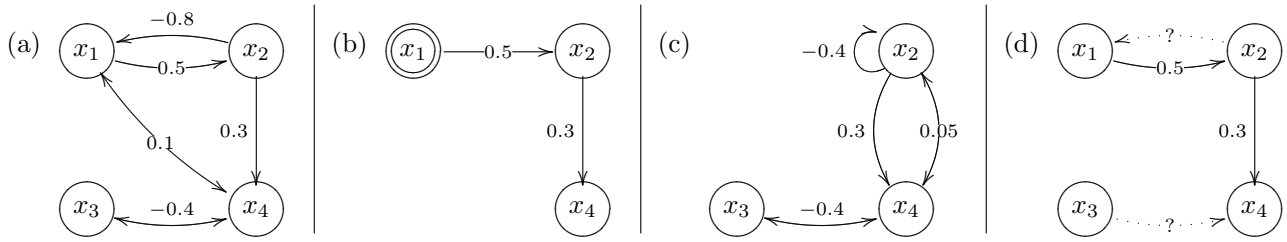

Figure 2: A case study. (a) True data generating model. (b) The manipulated and marginalized model corresponding to an experiment with $\mathcal{J}_1 = \{x_1\}$, $\mathcal{U}_1 = \{x_2, x_4\}$, and $\mathcal{L}_1 = \{x_3\}$. (c) The marginalized model corresponding to a 'null'-experiment with $\mathcal{J}_2 = \emptyset$, $\mathcal{U}_2 = \{x_2, x_3, x_4\}$, and $\mathcal{L}_2 = \{x_1\}$. (d) The causal structure over the union of observed variables learned by LININF (omitting any double-headed arcs). Notice that all causal arcs between x_1 and x_3 are discovered to be absent, although variables x_1 and x_3 are not observed together in either of the observed data sets. Dotted arrows indicate underdetermined parameters.

$t(x_j \rightsquigarrow x_u || \mathcal{J}_l)$ is already known. In addition, the full set of implications from the faithfulness rules of Section 5 (see Appendix D) may require that a particular experimental effect is zero, or – as in Equation 6 – that $t(x_i \rightsquigarrow x_j || \mathcal{J}_k) t(x_j \rightsquigarrow x_u || \mathcal{J}_l)$ is zero. Combining all the available information can render several equations linear. We ignore any equations that remain non-linear in the unknown experimental effects in order to keep the solvability of the system feasible.

There are a total of $n(n-1)\sum_{i=0}^{n-2}\binom{n-2}{i}(2^{n-i-2}-1)$ equations similar to Equation 7 for a model with n variables in $\mathcal{V}$. Thus, if even a small share of these equations are linear with respect to the unknown experimental effects, the model space compatible with the constraints at hand will be substantially restricted. Furthermore, equations that were initially non-linear in the unknown experimental effects, can be rendered linear as we iterate the inference and more experimental effects are determined. Since we are only using linear equations, we can trivially see which of the unknown experimental effects are uniquely determined by the system of equations. Similarly, since the direct effects are just a special case of the experimental effects, we can find which direct effects are underdetermined.

The Linear Inference algorithm using these ideas is outlined in Algorithm 1. A powerful part of the algorithm is the application of the inference in Equation 5 throughout the several rounds of inference. For finite samples this inference depends on judging whether an inferred experimental effect that is not measured in any of the available data sets, is zero. One option is to run the same algorithm in parallel on several resampled data sets, and see whether all estimates for a single experimental effect are effectively zero or not.

Unlike the bilinear procedure of Section 4, this linear inference procedure is consistent. It is incomplete as it does not exploit the available non-linear equations, but it is able to extract more information from the overlapping experiments by benefiting from the vast number of different faithfulness constraints produced by sparse data generating models.

7 SIMULATIONS

In the overlapping data set setting the general idea is that the experiments have already been run, with little regard to how the data sets and interventions may fit together. So it is likely that the identifiability condition of Section 3 is not satisfied and that there still is a large amount of underdetermination. In particular, one might expect substantial underdetermination with regard to the causal relations between variables that are never measured together in one data set. Figure 2 offers a concrete example of how the findings from multiple experimental data sets can be synthesized to yield knowledge not available from any of the individual data sets. Panel (a) shows the true underlying data generating model. This model is subject to one experiment where x_1 is intervened, x_2 and x_4 are observed, while x_3 is latent (b), and one 'null'-experiment where all variables except x_1 are passively observed (c). Note that x_1 and x_3 are never measured together in the same data set. One can think of the two experiments as resulting from two different research groups investigating two overlapping sets of variables. Panel (b) represents the manipulated and marginalized version of the true model corresponding to the first experiment, while (c) represents the marginalized model corresponding to the 'null'-experiment. Panel (d) shows the output of the Linear Inference algorithm described in Section 6 applied to the overlapping data sets of the two experiments. Here, solid edges denote identified edges, absences of edges denotes cases where the algorithm has inferred that there is no edge, and what remains undetermined is shown by dotted edges. Note that faithfulness has been effectively used to detect the absence of several edges in the underlying model. In

particular, x_4 is determined *not* to be a direct cause of any other variable, without there being any experiment intervening on x_4. Also, similarly to the results of Tillman et al. (2009) for passive observational data from acyclic models, we can detect the absence of edges between x_1 and x_3, *even though they were never measured together in any of the data sets.* Only the existence of the arcs $x_2 \to x_1$ and $x_3 \to x_4$ (indicated by dotted arrows) is left underdetermined. Finally, note that we have not discussed the detection of confounding here, so the absence of bi-directed edges in panel (d) is not indicative of any prediction on such edges.

We assessed the performance of our methods more generally in simulations. To test the effect of the faithfulness assumption we ran the method of Eberhardt et al. (2010) (EHS), that was shown in Section 3 to be complete for our circumstances, as a baseline for comparison. It does not assume faithfulness. We compared this baseline with the performance of the new BILINear and LINear-INFerence methods, presented in Sections 4 and 6, respectively, that were specifically designed for the overlapping data set case, and that assume faithfulness. Lastly, we ran the method of Hyttinen et al. (2010) (HEH), that only uses faithfulness constraints on the *direct effects* obtained *within* each data set.

The methods[3] were modified to produce one of three answers: 'present', ' absent', or 'unknown', for each possible edge, i.e. each entry of $\mathbf{B}$. An algorithm could only return 'present' if it had actually identified a specific value for the edge parameter. We compared how much of the true model the algorithms identified, and what percentage of that was correct.

To ensure that assuming faithfulness could actually make a difference, we simulated the methods on sparse models. We generated 100 6-variable models, with around 20% of the possible edges present, and 15% of the possible non-zero covariances, representing exogenous latent confounders. We drew the connection strengths randomly, though we avoided generating coefficients that were very close to zero, in order to make the predictions of absence/presence of edges meaningful. For each model, we constructed 5 overlapping experiments by selecting uniformly among partitions of the set of variables into intervened, observed and hidden variables, with the only constraint that for each experiment, neither $\mathcal{J}$ nor $\mathcal{U}$ were empty.

Figure 3 reports the percentage correct among the edges reported absent (left) and present (right) for

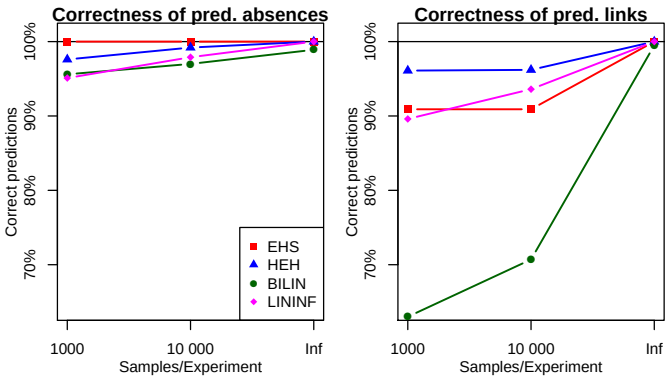

Figure 3: Accuracy of the learning algorithms. Each point on the lines is the average over 100 models.

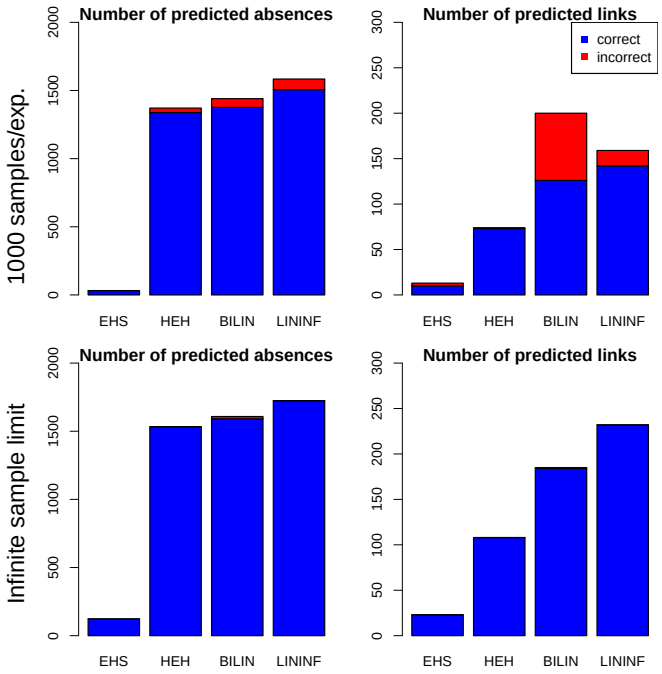

Figure 4: Predictions of the learning algorithms. Each bar represents the predictions over 100 models.

each algorithm at 1,000 and 10,000 samples per experiment, as well as for the infinite sample limit. Note that for the finite sample cases we restricted the maximum size of the conditioning set, in the search for faithfulness rules, to 1; this tends to improve the accuracy of the predictions. Similarly, in the finite sample cases, we restricted the number of inference rounds in the LININF algorithm to 1. With the exception of BILIN, the algorithms have a similar performance across the board. BILIN offers an undesirable trade-off: for finite samples it offers a high correctness of predicted absences, but a poor performance for predicted links. And since it is not consistent, it does not guarantee the absences of errors in the infinite sample limit, as

[3]Code implementing all compared methods and reproducing the simulations is available at `http://www.cs.helsinki.fi/u/ajhyttin/exp/`

can be seen in the presence of errors for the predicted absences.

Figure 4 shows the actual numbers of correct and incorrect predicted absences (left column) and links (right column) for each algorithm at 1,000 samples per experiment (top row) and the infinite sample limit (bottom row). In the 100 true models of the simulation there were a *total* of 624 edges and 2376 absences (confounding is not included in either of these counts). The first thing to notice is the scale of the plots: Substantial underdetermination remains for all algorithms, especially with respect to the identified links: More than half the links remain underdetermined. With respect to the individual algorithms we notice that EHS produces very few predictions, most edges are simply marked as 'unknown', since faithfulness is not assumed. HEH produces a remarkable number of predicted absences with good accuracy, so that the improvement of the methods tailored to the setting of overlapping experiments is limited for finite samples. However, the improvement in the number of predicted links is clearly quite significant (top and bottom right plots).

It would be desirable to have a comparison of how much underdetermination is inevitable given the overlapping data sets. A brute force check is not feasible even for six variable models, and we are not aware of any general results on equivalence classes for (manipulated) linear cyclic models with latent confounders. Developing an extension of LININF that is complete with regard to faithfulness may thus be the more promising route for such a comparison.

8 CONCLUSION

We have presented two new algorithms (BILIN and LININF) designed for causal learning from overlapping experimental or passive observational data sets. The first algorithm relies on a bilinear iterative optimization, while the second is based on solving linear constraints on general experimental effects. Both algorithms assume faithfulness, but apply to the general model class of linear cyclic models with latent confounding. We have also formulated necessary and sufficient conditions for model identifiability when faithfulness is not assumed.

The approach we have taken brings together several different strands of related work: We have connected the results on combining different *experimental* results on the *same* set of variables with the techniques of integrating *overlapping* data sets of *passive observational* data. To do so, we have relied on the inferences based on faithfulness developed for *non-parametric, acyclic* causal models with latent confounding, but adapted them to *linear, cyclic* models with latent confounding.

Abstract

We develop several algorithms taking advantage of two common approaches for bounding MPE queries in graphical models: mini-bucket elimination and message-passing updates for linear programming relaxations. Both methods are quite similar, and offer useful perspectives for the other; our hybrid approaches attempt to balance the advantages of each. We demonstrate the power of our hybrid algorithms through extensive empirical evaluation. Most notably, a Branch and Bound search guided by the heuristic function calculated by one of our new algorithms has recently won first place in the PASCAL2 inference challenge.

1 INTRODUCTION

Combinatorial optimization tasks such as finding the most likely variable assignment of a probability model, the *most probable explanation* (MPE) or maximum *a posteriori* (MAP) problem, arise in many applications. These problems are typically NP-hard; graphical models provide a popular framework for reasoning about such tasks and organizing computations (Pearl, 1988).

Mini-Bucket Elimination (MBE) (Dechter & Rish, 2003) is a popular bounding scheme that generates upper and lower bounds by applying the exact Bucket Elimination (BE) algorithm (Dechter, 1999) to a simplified problem obtained by duplicating variables. The relaxation view of MBE is closely related to a family of iterative approximation techniques based on linear programming (LP). These include "reweighted" max-product (Wainwright *et al.*, 2005), max-product linear programming (MPLP) (Globerson & Jaakkola, 2007), dual decomposition (Komodakis *et al.*, 2007), and soft arc consistency (Schiex, 2000; Bistarelli *et al.*, 2000). These algorithms simplify the graphical model into independent components and tighten the resulting bound via iterative cost-shifting updates. They can be thought of as "re-parameterizing" the original functions without changing the global model. Most of the schemes operate on the original factors of the model, although some works tighten the approximations by introducing larger clusters (Sontag *et al.*, 2008).

In this paper we combine these ideas to define two new hybrid schemes. One algorithm, called mini-buckets with max-marginal matching (MBE-MM), is a non-iterative algorithm that applies a single pass of cost-shifting during the mini-bucket construction. The second approach, Join Graph Linear Programming (JGLP) applies cost-shifting updates to the full mini-bucket join-graph, iteratively. Our empirical evaluation demonstrates the increased power of these hybrid approximations over their individual components.

Finally, one of the primary uses of bounding schemes is in generating heuristics for Best-First and Branch and Bound search (Marinescu & Dechter, 2009a,b). Our hybrid schemes drastically decrease the search space explored by Branch and Bound to significantly increase its power, evidenced by both our empirical evaluation and the results of the current Probabilistic Inference Challenge[1], where our algorithm won first place in all optimization categories.

From an LP perspective, JGLP can be viewed as a specific algorithm within the class of generalized EMPLP (Sontag & Jaakkola, 2009). Its main novelty is in showing how the systematic join-graph structures of mini-bucket can facilitate effective clique choices. JGLP works "top down", creating large clusters immediately, compared to other methods (e.g., Sontag & Jaakkola, 2009; Batra *et al.*, 2011) that work "bottom up" (gradually including triplets, etc.) and may be less effective for large-width problems. Our non-iterative MBE-MM algorithm is an MBE scheme with some cost-shifting done locally in each bucket. From

[1] http://www.cs.huji.ac.il/project/PASCAL/

this perspective it is closely related to (Rollon & Larrosa, 2006); the two methods differ primarily in the form of the cost-shifting update within each bucket. However, our update is motivated by its connection to a globally applicable tightening algorithm.

2 PRELIMINARIES

We consider combinatorial optimization problems expressed as graphical models, including Markov and Bayesian networks (Pearl, 1988) and constraint networks (Dechter, 2003). A *graphical model* is a tuple $\mathcal{M} = (\mathbf{X}, \mathbf{D}, \mathbf{F}, \bigotimes)$, where $\mathbf{X} = \{X_i : i \in V\}$ is a set of variables indexed by set V and $\mathbf{D} = \{D_i : i \in V\}$ is the set of their finite domains of values. $\mathbf{F} = \{f_\alpha : \alpha \in F\}$ is a set of discrete functions, where we use $\alpha \subseteq V$ and $X_\alpha \subseteq \mathbf{X}$ to indicate the scope of function f_α, i.e., $X_\alpha = \text{var}(f_\alpha) = \{X_i : i \in \alpha\}$. The set of function scopes implies a *primal graph* whose vertices are the variables and which includes an edge connecting any two variables that appear in the scope of the same function. The combination operator $\bigotimes \in \{\prod, \sum, \bowtie\}$ defines the complete function represented by the graphical model $\mathcal{M}$ as $C(\mathbf{X}) = \bigotimes_{\alpha \in F} f_\alpha(X_\alpha)$. In this work, we focus on *max-sum problems*, in which we would like to compute the optimal value C^* and/or its optimizing configuration x^*:

$$C^* = C(x^*) = \max_{\mathbf{X}} \sum_{\alpha \in F} f_\alpha(X_\alpha) \tag{1}$$

2.1 MINI-BUCKET ELIMINATION

Bucket elimination (BE) (Dechter, 1999) is a popular algorithm for solving reasoning tasks over graphical models. It is a special case of cluster tree elimination in which the tree-structure upon which messages are passed is determined by the variable elimination order used. In BE terminology, the nodes of the tree-structure are referred to as buckets and each bucket is associated with a variable to be eliminated.

Each bucket is processed by BE in two steps. First, all functions in the bucket are combined (by summation in the case of max-sum problem). Then the variable associated with the bucket is eliminated from the combined function (by maximization in case of max-sum task). The function resulting from the combination and elimination steps can be viewed as a "message" λ_i and is passed to the parent of the current bucket. Processing occurs in this fashion, from the leaves of the tree to the root, one node (bucket) at a time. The time and space complexity of BE are exponential in the graph parameter called the induced width w along the ordering o (Dechter, 1999).

Mini-bucket elimination (MBE) (Dechter & Rish, 2003) is an approximation scheme designed to avoid the space and time complexity of BE. Consider a bucket $\mathbf{B}_i$ and an integer bounding parameter z. MBE creates a z-partition $Q_i = \{q_i^1, \ldots, q_i^p\}$ of $\mathbf{B}_i$, where each set of functions $q_i^j \in Q_i$, called a *mini-bucket*, includes no more than $z + 1$ variables. Then each mini-bucket is processed separately, just as in BE. The scheme generates an upper bound on the exact optimal solution and its time and space complexity of MBE is exponential in z, which is chosen to be less than w, when w is too large. In general, increasing z tightens the upper bound, until $z = w$, in which case MBE finds the exact solution. The form of mini-bucket makes it easy to estimate and control both the computational and storage complexity through a single parameter z.

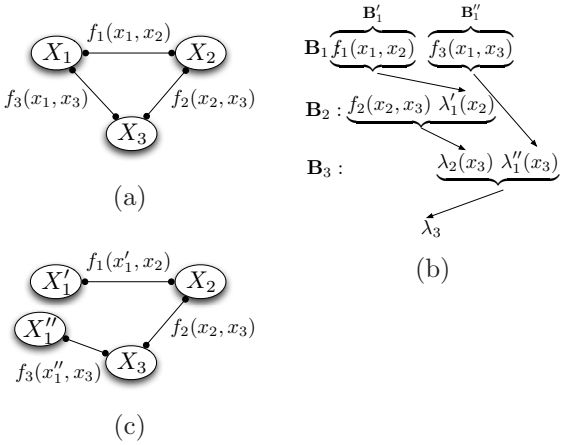

Figure 1: The mini-bucket procedure for a simple graph. (a) Original graph; (b) the buckets and messages computed in MBE; (c) interpreting MBE as variable duplication, and message passing on the resulting junction tree. X_1 is duplicated in each of two mini-buckets $q_1^1 = \{f_1(X_1, X_2)\}$ and $q_1^2 = \{f_3(X_1, X_3)\}$.

MBE's value is not only as a stand-alone bounding scheme, but also as a mechanism for generating powerful heuristic evaluation functions for informed search algorithms. Exploration of its potential as a heuristic generation scheme has yielded some of the most powerful Best-First and Branch and Bound search engines for graphical models, as summarized in (Kask & Dechter, 2001; Marinescu & Dechter, 2009a,b).

Mini-bucket elimination can also be interpreted using a junction tree view. The MBE bound corresponds to a problem relaxation in which a copy X_i^j of variable X_i is made for each mini-bucket $q_i^j \in Q_i$, and the resulting messages λ_i^j correspond to the messages in a junction tree defined on the augmented model over the variable copies; this junction tree is guaranteed to have induced-width z or less. Figure 1 shows a simple example on three variables. The problems are equivalent if all copies of X_i are constrained to be equal;

Algorithm 1 Join-Graph Structuring(z)

Input: Graphical model $\langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \sum \rangle$, parameter z
Output: Join-graph with cluster size $\leq z+1$

1: Order the variables from X_1 to X_n minimizing (heuristically) induced-width
2: Generate an ordered partition of functions $\mathbf{F} = \{f_\alpha\}$ into buckets $\mathbf{B}_1, \ldots, \mathbf{B}_n$, where $\mathbf{B}_i$ is a bucket of variable X_i
3: **for** $i \leftarrow n$ down to 1 (Processing bucket $\mathbf{B}_i$) **do**
4: Partition functions in $\mathbf{B}_i$ into $Q_i = \{q_i^1, \ldots, q_i^p\}$; each q_i^k has no more than $z+1$ variables.
5: For each mini-bucket q_i^k create a new set of variables $S_i^k = \{X | X \in q_i^k\} - \{X_i\}$ and place it in the bucket of its highest variable in the ordering
6: Maintain an arc between q_i^k and the mini-bucket (created later) that includes S_i^k
7: **end for**
8: Associate each resulting mini-bucket with a node in the join-graph
9: **Creating arcs:** keep the arcs created in step 6 and also connect the mini-bucket clusters belonging to the same bucket (for example, in a chain).

otherwise, the additional degrees of freedom lead to a relaxed problem and thus an upper bound.

The mini-bucket tree has several desirable properties (Mateescu *et al.*, 2010), including that it is a join-graph (satisfies the running intersection property) and each cluster has at most $z+1$ variables. The join-graph construction process is given in Algorithm 1.

2.2 LINEAR PROGRAMMING METHODS

Recently various iterative re-parameterization approaches have been introduced that are derived by solving an Linear Programming (LP) relaxation of the graphical model. Wainwright et al. (Wainwright *et al.*, 2005) established the connections between LP relaxations of integer programming problems and (approximate) dynamic programming methods using message-passing in the max-product algebra; subsequent improvements in algorithms such as max-product linear programming (MPLP) include coordinate-descent updates that ensure convergence (Globerson & Jaakkola, 2007; Sontag & Jaakkola, 2009). These methods are closely related to the mini-bucket bounds; since we build upon these approaches we introduce some of the ideas in more detail here.

To match the bulk of the graphical model LP relaxation literature, for this section we assume that the network consists of only pairwise functions $f_{ij}(X_i, X_j)$. A simple bound on the max-sum objective is then given by maxima of the individual functions:

$$C^* = \max_{\mathbf{X}} \sum_{(ij)\in F} f_{ij}(X_i, X_j) \leq \sum_{(ij)\in F} \max_{\mathbf{X}} f_{ij}(X_i, X_j), \tag{2}$$

exchanging the sum and max operators. One can interpret this operation as making an individual copy of each variable for each function, and optimizing over them separately.

However, we can also introduce a collection of functions $\{\lambda_{ij}(X_i), \lambda_{ji}(X_j)\}$ for each edge (ij), and require

$$\lambda \in \Lambda \quad \Leftrightarrow \quad \forall i, \quad \sum_j \lambda_{ij}(X_i) = 0$$

Then, we have

$$\begin{aligned} C^* &= \max_{\mathbf{X}} \sum_{(ij)\in F} f_{ij}(X_i, X_j) \\ &= \max_{\mathbf{X}} \sum_{(ij)\in F} f_{ij}(X_i, X_j) + \sum_i \sum_j \lambda_{ij}(X_i) \\ &\leq \min_{\lambda\in\Lambda} \sum_{(ij)\in F} \max_{\mathbf{X}} \left(f_{ij}(X_i, X_j) + \lambda_{ij}(X_i) + \lambda_{ji}(X_j) \right) \end{aligned} \tag{3}$$

by distributing each λ_{ij} to its associated factor and applying the inequality (2).

The new functions $\tilde{f}_{ij} = f_{ij}(X_i, X_j) + \lambda_{ij}(X_i) + \lambda_{ji}(X_j)$ define a *re-parameterization* of the original distribution, i.e., they change the individual functions without modifying the complete function $C(\mathbf{X})$. Depending on the literature, the λ_{ij} are interpreted as "cost-shifting" operations that transfer cost from one function to another while preserving the overall cost function (Schiex, 2000; Rollon & Larrosa, 2006), or as Lagrange multipliers enforcing consistency among the copies of X_i (Yedidia *et al.*, 2004; Wainwright *et al.*, 2005). In the former interpretation, the updates are called "soft arc-consistency" due to their similarity to arc-consistency for constraint satisfaction (Cooper & Schiex, 2004). Under the latter view, the bound corresponds to a *dual decomposition* solver for a linear programming (LP) relaxation of the original problem (Komodakis & Paragios, 2008; Sontag *et al.*, 2010).

The main distinguishing feature among such dual decomposition approaches is the way in which the bound is tightened by updating[2] the functions λ, generally either sub-gradient or gradient approaches (Komodakis & Paragios, 2008; Jojic *et al.*, 2010) or coordinate descent updates that can be interpreted as "message passing" (Globerson & Jaakkola, 2007; Sontag & Jaakkola, 2009). In practice, coordinate descent updates tend to tighten the bound more quickly, but can become caught in sub-optimal minima caused by

[2]We refer to these iterative bound improvement updates as "LP-tightening" updates, although technically we are tightening the decomposition bound (3) which is the dual of the LP. This is in contrast to literature that uses "tightening" to mean the inclusion of additional constraints (higher-order consistency), e.g., (Sontag *et al.*, 2008).

Algorithm 2 LP-tightening

Input: Graphical model $\langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \sum \rangle$, where f_α is a potential defined on variables X_α.
Output: Upper bound on the optimum value

1: Iterate until convergence:
2: **for** any pair α, β with $X_{\alpha\beta} = X_\alpha \cap X_\beta \neq \emptyset$ **do**
3: Compute max-marginals:
$\gamma_\alpha(X_{\alpha\beta}) = \max_{X_\alpha \setminus X_{\alpha\beta}} f_\alpha(X_\alpha)$
$\gamma_\beta(X_{\alpha\beta}) = \max_{X_\beta \setminus X_{\alpha\beta}} f_\beta(X_\beta)$
Update parameterization:
$f_\alpha(X_\alpha) \leftarrow f_\alpha(X_\alpha) + \frac{1}{2}\big(\gamma_\beta(X_{\alpha\beta}) - \gamma_\alpha(X_{\alpha\beta})\big)$
$f_\beta(X_\beta) \leftarrow f_\beta(X_\beta) + \frac{1}{2}\big(\gamma_\alpha(X_{\alpha\beta}) - \gamma_\beta(X_{\alpha\beta})\big)$
4: **end for**

the limited number of coordinate directions considered. Here we give an extremely simple update, most closely related to the "tree-block" coordinate descent updates derived in (Sontag & Jaakkola, 2009).

The algorithm is initialized with all $\lambda_{ij}(X_i) = 0$. Let us re-arrange the terms on right hand side of inequality 3, grouping together all functions that include a particular variable X_i in their scope. Consider minimizing over a single pair $\lambda_{ij}(X_i), \lambda_{ik}(X_i)$; since all other terms are fixed, we minimize

$$\begin{aligned}
&\big[\max_{\mathbf{X}} f_{ij} + \lambda_{ij}\big] + \big[\max_{\mathbf{X}} f_{ik} + \lambda_{ik}\big] \\
&= \max_{X_i} \big[\gamma_{ij}(X_i) + \lambda_{ij}(X_i)\big] + \max_{X_i} \big[\gamma_{ik}(X_i) + \lambda_{ik}(X_i)\big] \\
&\geq \max_{X_i} \big[\gamma_{ij}(X_i) + \lambda_{ij}(X_i) + \gamma_{ik}(X_i) + \lambda_{ik}(X_i)\big]
\end{aligned}$$

where we have defined the "max-marginals" $\gamma_{ij}(X_i) = \max_{X_j} f_{ij}(X_i, X_j)$, and we require that $\lambda_{ij}(X_i) + \lambda_{ik}(X_i) = 0$ to preserve $\lambda \in \Lambda$. Many choices of λ_{ij} achieve this minimum; a useful one is

$$\lambda_{ij} = \frac{1}{2}\big(\gamma_{ik}(X_i) - \gamma_{ij}(X_i)\big)$$

We can then set $f_{ij} \leftarrow f_{ij} + \lambda_{ij}$ and $\lambda_{ij} = 0$ (preserving $\lambda_{ij}(X_i) = 0$ for all i,j) and repeat, giving a simple coordinate descent update that can be interpreted as a max-marginal or "moment"-matching procedure on the functions f_{ij}. The update is easy to extend to higher-order functions $f_\alpha(X_\alpha)$; see Algorithm 2.

Another useful intuition comes from the alternative choice, $\lambda_{ij} = \gamma_{ik}(X_i) = \max_{X_k} f_{ik}(X_i, X_k)$. In this case, the contribution of edge (ik)'s term to the bound becomes zero. The "message" λ_{ij} is equivalent to the dynamic program computed on the chain j–i–k. It is thus easy to see that dynamic programming (or variable elimination) on a tree can also be interpreted as coordinate descent on the same bound, using the same set of coordinates, and that this procedure will exactly optimize any tree-structured graph (Johnson *et al.*, 2007; Yarkony *et al.*, 2010).

Algorithm 3 Factor graph LP (FGLP)

Input: Graphical model $\langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \sum \rangle$, where f_α is a potential defined on variables X_α.
Output: Upper bound on the optimum value

1: Iterate until convergence:
2: **for** each variable X_i **do**
3: Get factors $F_i = \{\alpha : i \in \alpha\}$ with X_i in their scope
4: $\forall \alpha$, compute max-marginals:
$\gamma_\alpha(X_i) = \max_{X_\alpha \setminus X_i} f_\alpha(X_\alpha)$
5: $\forall \alpha$, update parameterization:
$f_\alpha(X_\alpha) \leftarrow f_\alpha(X_\alpha) - \gamma_\alpha(X_i) + \frac{1}{|F_i|} \sum_{\beta \in F_i} \gamma_\beta(X_i)$
6: **end for**

A well-known LP-tightening algorithm is message-passing linear programming (MPLP) (Globerson & Jaakkola, 2007); its generalized version for higher-order cliques tightens the same bound as Algorithm 2 under descent updates along the same coordinates. The main distinction is that MPLP is formulated as sending messages between variable "beliefs" and the f_{ij}. Message-passing has the advantage that scheduled updates (e.g., Elidan *et al.*, 2006; Sutton & McCallum, 2007) are easily applied. However, for cliques with large separator sets these messages can consume a noticable fraction of available memory. In contrast, reparameterization updates like Algorithm 2 never store the λ, giving a memory advantage for large cliques. Although some scheduling approaches, such as those based on the decoding gap (Tarlow *et al.*, 2011), are still applicable to pure reparameterization updates, our implementation used a fixed update ordering.

The original MPLP, soft-arc consistency, and many other LP algorithms operate directly on the original functions f_α, updating coordinates that consist of single variable functions $\lambda(X_i)$ at each step; this corresponds to message passing on the "factor graph" representation of the model. Algorithm 3 (FGLP) gives a simple extension of the matching update that operates on this factor graph LP and tightens all f_{ij} involved with some X_i simultaneously. FGLP is similar to the "star-shaped" tree block coordinate descent derived in (Sontag & Jaakkola, 2009), but centered on separators (variables) rather than cliques (factors); in practice on our problems we found it faster than other update methods for this LP.

3 JOIN GRAPH LINEAR PROGRAMMING

From the perspective of Section 2.2, mini-bucket can be viewed within the LP-tightening framework. The mini-bucket procedure defines a join graph represented as a collection of maximal cliques and separators. The mini-bucket computations define a downward sweep of dynamic programming on the join graph with du-

plicate variables; it is equivalent to running an LP-tightening procedure to convergence, *only* messages along edges of the mini-bucket spanning tree.

Given this view, it is straightforward to consider iterative updates on the same set of maximal cliques. We can construct a join graph using the mini-bucket relaxation, again assigning the original functions f to their earliest clique and defining for any mini-bucket q_i^k a function associated with its corresponding clique,

$$F_{q_i^k}(X_{q_i^k}) = \sum_{f_\alpha \in q_i^k} f_\alpha(X_\alpha) \tag{4}$$

We then perform re-parameterization updates to the functions F_q as in Algorithm 2. The resulting join-graph linear programming (JGLP) algorithm is shown in Algorithm 4.

Note that once JGLP converges, re-processing these new functions using mini-bucket elimination using the same value of z will not change the choice of cliques (since no two cliques q, q' could be joined without violating the clique size bound, $|X_q| \leq z+1$). Additionally, the MBE pass will not change the bound value, since the MBE dynamic program can be viewed as a sequence of coordinate-descent updates along a subset of the edges, all of which must already be tight if the algorithm has converged. In the sequel, we will use this property of JGLP when developing heuristic evaluation functions for search; see Section 5.

MBE vs. LP perspectives. From the LP perspective, the MBE process can be thought of as a heuristic for selecting the cliques used to define the LP bound. This heuristic has the advantage of being very fast and controlled by a single integer value that is easy to search over, and it is easy to estimate the memory requirements of the approximation. In practice this results in a "top-down" construction, in which z is set to the induced width and reduced until the computational resource constraints are met. Existing heuristics for selecting variable orderings with low induced width (Robertson & Seymour, 1983; Kask *et al.*, 2011; Bodlaender, 2007; Gogate & Dechter, 2004) can be easily applied as well. In contrast, most existing generalized LP solvers work in a "bottom-up" fashion, running the LP to convergence on the original graph, then proposing slightly larger cliques (for example, from among fully connected triplets of variables (Sontag *et al.*, 2008)) based on some greedy heuristic. However, for problems with small variables and reasonable resource constraints, it is easy to represent very large cliques ($z = 15$ to 25), in which case the top-down approach can be far more effective.

From the MBE perspective, the LP tightening updates provide an iterative version of mini-bucket that attempts to compensate for the variable copying relaxation. From this view it is most closely related to non-iterative cost-shifting procedures during the mini-bucket construction phase (Rollon & Larrosa, 2006). Another iterative "relax and compensate" approach was recently proposed in (Choi & Darwiche, 2009), but did not explicitly maintain a re-parameterization or use coordinate descent (thus could fail to converge).

Algorithm 4 Algorithm JGLP

Input: Graphical model $\langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \sum \rangle$; variable order $o = \{X_1, \ldots, X_n\}$; parameter z.
Output: Upper bound on the optimum value

```
Place each function f_α in its latest bucket in o
Build mini-bucket join graph (Algorithm 1)
Find the function of each mini-bucket as in (4)
Iterate to convergence / time-limit:
for all pairs q^i, q^j connected by an edge do
    Find common variables, S = var(q^i) ∩ var(q^j)
    Find the max-marginals of each mini-bucket
    q^k: γ_k = max_{var(q^k)\S}(F_k), k = i, j
    Update functions in both mini-buckets
    q^i: F_i ← F_i − ½(γ_i − γ_j)
    q^j: F_j ← F_j + ½(γ_i − γ_j)
end for
Return: Ĉ* = Σ_i max_{X_i} F_i(X_i)
```

4 MBE-MM

While the iterative nature of JGLP is appealing, it can have significant additional time and space overhead compared to MBE. We would thus also like to consider a single-pass MBE-like algorithm in which LP tightening is performed only within each bucket. We call the resulting algorithm *mini-bucket with max-marginal matching*, or MBE-MM.

MBE-MM proceeds by following the standard mini-bucket downward pass. However, when each mini-bucket $q_i^j \in Q_i$ is processed, eliminating variable X_i, we first perform an LP-tightening update to the mini-bucket functions f_q. For storage and computational efficiency reasons, we perform a single update on all buckets simultaneously, matching their max-marginals on their joint intersection. See Algorithm 5.

Viewing the matching update as a cost-shifting procedure, our MBE-MM algorithm is closely related to the work of (Rollon & Larrosa, 2006), who also proposed several dynamic cost-shifting updates for mini-bucket, with different update patterns. Their updates correspond to a "dynamic programming"-like heuristic that shifts all cost into a single function. In our case, we mimic the "balanced" cost shifting used by optimal iterative tightening but restrict our updates to a single bucket rather than to the whole global problem.

It is worth noting that, although any max-marginal

Algorithm 5 Algorithm MBE-MM

Input: Graphical model $\langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \sum \rangle$; variable order $o = \{X_1, \ldots, X_n\}$; parameter z.
Output: Upper bound on the optimum value

1: Place each function f_α in its latest bucket in o
2: **for** $i \leftarrow n$ down to 1 (processing bucket $\mathbf{B}_i$) **do**
3: Partition functions in $\mathbf{B}_i$ into $Q_i = \{q_i^1, \ldots, q_i^p\}$, where each q_i^k has no more than $z+1$ variables.
4: Find the set of variables common to all the mini-buckets: $S_i = S_i^1 \cap \cdots \cap S_i^p$, where $S_i^k = var(q_i^k)$
5: Find the function of each mini-bucket q_i^k: $F_{ik} \leftarrow \prod_{f \in q_i^k} f$
6: Find the max-marginals of each mini-bucket q_i^k: $\gamma_{ik} = \max_{var(q_i^k) \setminus S_i}(F_{ik})$
7: Update functions of each mini-bucket q_i^k: $F_{ik} \leftarrow F_{ik} - \gamma_{ik} + \frac{1}{p}\sum_l \gamma_{il}$
8: Generate messages $\lambda_i^k = \max_{X_i} F_{ik}$ and place each in the latest variable in $var(q_i^k)$'s bucket.
9: **end for**
10: **Return:** The buckets and cost bound from $\mathbf{B}_1$

matching step strictly tightens the fully decomposed bound (3) within each bucket, it does not necessarily tighten the overall solution found by MBE (which corresponds to fully optimizing the MBE subtree's edges); thus MBE-MM is not guaranteed to be tighter than ordinary MBE. However, it is reasonable to expect that the update will help, and in practice we find that the bounds are almost always significantly improved (see the experiments, Section 6).

Like "soft" arc-consistency, our algorithms are also related to known methods in constraint satisfaction. MBE(z) and JGLP(z), parameterized by a z-bound, are analogous to directional z-consistency and full z-consistency, respectively. Our algorithm MBE-MM represents an intermediate step between these two, and is analogous to an improvement of directional i-consistency with full iterative relational consistency schemes within each bucket (Dechter, 2003).

5 HEURISTICS FOR SEARCH

Mini-bucket is also a powerful mechanism for generating heuristics for informed search algorithms (Kask & Dechter, 2001). The intermediate functions λ recorded by MBE (see Figure 1(b)) are used to express upper bounds on the best extension of any partial assignment, and so can be used as admissible heuristics guiding Best-First or Branch and Bound search.

Algorithms JGLP and FGLP do not produce heuristic functions directly; we obtain one by applying MBE to the modified (re-parameterized) functions output by the iterative algorithms. As noted in Section 3, for JGLP constructed with the same clique size bound z, this additional pass does not change the value of the bound. In contrast, applying MBE to the (much smaller) functions re-parameterized by FGLP forms new clusters and typically tightens the bound, yielding a hybrid heuristic generator "FGLP+MBE". Being a straightforward extension of "ordinary" MBE, the MBE-MM algorithm also directly yields a heuristic function suitable for informed search.

In our experiments (Section 6.2) we apply the output bounds as admissible heuristics for one of the most effective informed search approaches: the AND/OR Branch and Bound (AOBB) algorithm (Marinescu & Dechter, 2009a). This algorithm explores in a depth-first manner an AND/OR search space that is defined using a pseudo-tree arrangement of the problem's primal graph and takes advantage of the problem decomposition. The AND/OR search space is usually much smaller than the corresponding standard OR search space. AOBB keeps track of the value of the best solution found so far (a lower bound on the optimal cost) and uses this value and the heuristic function to prune away portions of the search space that are guaranteed not to contain the optimal solution in a typical branch-and-bound manner. For details on AOBB guided by MBE see (Marinescu & Dechter, 2009a).

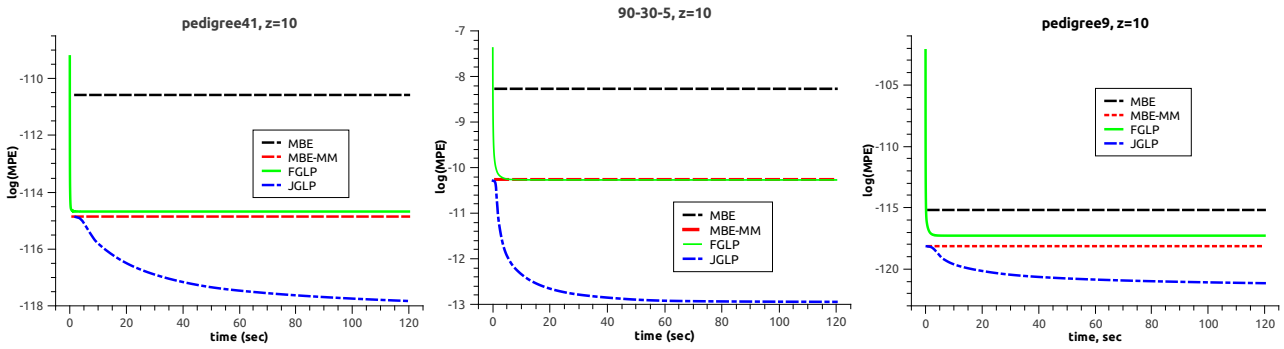
6 EMPIRICAL EVALUATION

We investigate the impact of single-pass and iterative LP-tightening in conjunction with the MBE scheme for the task of finding the most probable explanation (MPE) over Bayesian networks. Specifically, we evaluate the performance of MBE-MM, Factor Graph LP-Tightening (denoted FGLP) applied to the original functions, and Join Graph LP-Tightening (JGLP) which is applied over the mini-bucket-based join graph. We compare these three algorithms against each other and against "pure" MBE, both as stand-alone bounding algorithms (Section 6.1) and as generator of heuristic evaluation functions that guides search algorithms such as Branch and Bound (Section 6.2).

Our benchmark problems include three sets of instances from genetic linkage analysis networks (Fishelson & Geiger, 2002) (denoted `pedigrees`, `type4b` and `LargeFam`) and grid networks from the UAI 2008 competition (Darwiche *et al.*, 2008). In total we evaluated 10 `pedigrees`, 10 `type4` instances, 40 `LargeFam` instances and 32 `grid` networks. The algorithms were implemented in C++ (64-bit).

6.1 LP-TIGHTENING ALGORITHMS AS BOUNDING SCHEMES

We compare the upper bounds' accuracy obtained by the non-iterative MBE and MBE-MM schemes and against the iterative FGLP and JGLP schemes. The iterative schemes ran for 5, 300 and 3600 seconds.



(a) (b) (c)

Figure 2: Upper bound on optimum (log scale) as a function of time (sec). Non-iterative bounds MBE, MBE-MM are shown for comparison.

Table 1: Upper bound (log scale) and runtime (# seconds) for a typical set of instances, $z = 10$ and $z = 20$. FGLP is not affected by z. Lower values are better. OOM shows that the algorithm ran out of memory (4 Gb). We report the number of variables n, largest domain size k, and the induced width w along the ordering used.

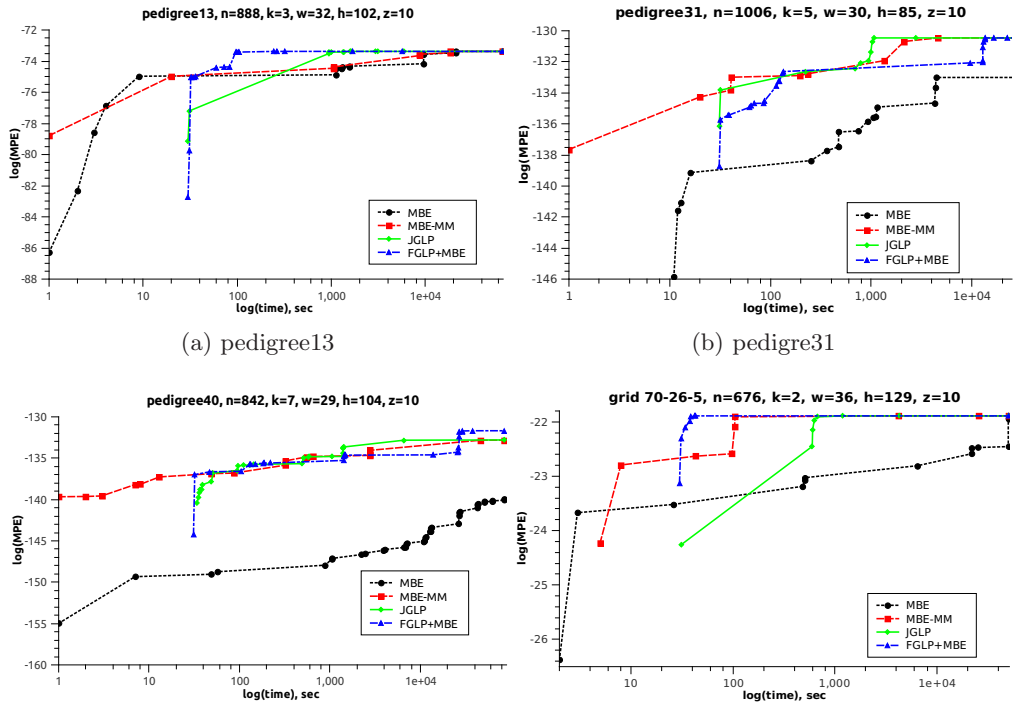
In Table 1 we present a subset of the results obtained from all 4 instance sets for the z-bound values of $z = 10$ and $z = 20$. Results for $z = 15$ are similar and are omitted for lack of space. Note, that the value of z does not influence the results of FGLP, that runs on the original functions. For every problem instance described via its parameters (i.e., number of variables n, largest domain size k, and induced width w), for each algorithm we report the upper bound obtained and the CPU time (or time-bound) in seconds.

We observe clearly that for all instances MBE-MM is superior to pure MBE, since it produces considerably more accurate bounds in a comparable time. For most instances the MBE-MM bounds are also better than pure FGLP (at the comparable point in time), especially for $z = 20$, but only if the memory required by MBE-MM is not too high. As example behavior see instances `75-25-5` and `largeFam4_11_51`.

Figure 2 illustrates the anytime performance of the iterative schemes FGLP and JGLP. (Note that the single-pass algorithms MBE and MBE-MM do not change as a function of time.) As we expect, FGLP improves the bound rapidly, but converges to a suboptimal solution, while JGLP improves at a slower pace but eventually produces the most accurate results.

From both the table and the figure we see that given enough time and memory, JGLP produces the most accurate bounds eventually. However, when time and memory are bounded, MBE-MM can present a cost-effective hybrid of bounded inference (as indicated by



(a) pedigree13 (b) pedigre31

(c) pedigree40 (d) grid-75-26-5

Figure 3: Lower bounds by the AOBB as a function of time (sec) for z=10, memory limit 3 Gb, timelimit 24h.

the cluster size) and bounded LP-tightening. Note that the memory requirement of MBE-MM is slightly less than the comparable JGLP, since some memory can be freed by the single-pass algorithm; this behavior is evidenced in `pedigree7` and `pedigree41` for $z = 20$.

6.2 LP-TIGHTENING ALGORITHMS AS SEARCH GUIDING HEURISTICS

We also evaluated the impact of each of the bounding schemes as a generator of heuristic evaluation functions for the AOBB algorithm, as described in Section 5. We tested four schemes: AOBB guided by heuristics generated by pure MBE (denoted "AOBB-MBE"), AOBB guided by MBE and max-marginal matching heuristics ("AOBB-MBE-MM"), AOBB whose heuristics are generated from FGLP followed by MBE ("AOBB-FGLP+MBE") and AOBB guided by JGLP-produced heuristics ("AOBB-JGLP"). All the heuristic functions were generated in a preprocessing phase, prior to search. The iterative FGLP and JGLP algorithms were run for 30 seconds each. The total time bound for AOBB with each of the heuristics was set to 24 hours (including the preprocessing), memory limit was 3 Gb, and the mini-bucket z-bound parameters for generating the heuristics was set to $z \in \{10, 15, 20\}$.

In Table 2 we show some of the results. For space reasons and clarity we pick a representative set from the full 92 instances. The table reports the total runtime in seconds and the number of nodes expanded by each of the AOBB schemes.

We see that, as expected, the heuristic generated by MBE-MM are more cost-effective compared with "pure" MBE, both in runtime and nodes expanded. We see that the two iterative schemes are quite powerful as heuristic generators. For most instances FGLP+MBE presents a good balance[3]. But on some hard instances and as long as memory is available JGLP is the overall best-performing scheme.

We also observe the impact of the z bounds. As expected, with larger z we obtain more accurate heuristics, but this increases the memory requirements (see, for example, AOBB-JGLP on `pedigree13`).

Figure 3 shows the anytime behaviour of AOBB with each heuristic, plotting the solution value found over time (both on log scale) on four typical instances. Higher values are better. As expected, AOBB-MBE-MM has a more precise heuristic and consistently outputs better solutions faster compared with AOBB-MBE. Algorithms AOBB-FGLP-MBE and AOBB-JGLP perform very well as anytime schemes. We see

[3]We did not test a "pure" FGLP heuristic, since its performance should be inferior to FGLP-MBE (FGLP followed by pure MBE).

Table 2: Search time (seconds) / # nodes expanded for selected instances. FGLP and JGLP ran for 30 seconds. "OOM" indicates that search ran out of memory (3Gb) and "— / —" that it ran out of time (24h). In **bold** we highlight the best runtime for each instance, *italics* indicate the smallest search space explored.

that they output the first solution later than the other two schemes due to initial 30 seconds pre-processing step. However, if desired, a shorter time bound for computing heuristic can be used.

In summary, based on our empirical evaluation we can conclude that some level of LP-tightening can significantly improve the power of the MBE heuristics, yielding an improved search, sometimes by orders of magnitudes. The question of instance-based balance, namely tailoring the right level of z-bound and LP-tightening to the problem instance is clearly a central issue and a direction of future research. Overall, in this study we observed that MBE-MM always improves upon MBE, using comparable time and memory, while FGLP quickly converges and is less memory-consuming than the other schemes. On the other hand, given sufficient time and memory JGLP produces the tightest bound.

7 CONCLUSION

The paper presents the first systematic combination of iterative cost-shifting updates with elimination-order based clustering algorithms and provides extensive empirical evaluation demonstrating its effectiveness. Specifically, we present Join Graph Linear Programming, a new bounding scheme for optimization tasks in graphical models that combines MBE bounds with LP-based cost-shifting or soft arc-consistency. Empirically, larger clusters improved the iterative updates' performance in all instances. We also demonstrated that JGLP can often find better bounds faster than LP-tightening on the original model, even for relatively small z. Most importantly, we showed the algorithms' ability to improve informed search algorithms; without requiring significantly more computational power (for fixed z) than classical MBE they can drastically reduce the search space. Notably, the algorithm that used as a heuristic generator all three cost-shifting schemes in a sequence (FGLP+JGLP+MBE-MM) won the first place in all optimization categories in this year's Probabilistic Inference Challenge.

Abstract

We extend the work of Narasimhan and Bilmes [30] for minimizing set functions representable as a difference between submodular functions. Similar to [30], our new algorithms are guaranteed to monotonically reduce the objective function at every step. We empirically and theoretically show that the per-iteration cost of our algorithms is much less than [30], and our algorithms can be used to efficiently minimize a difference between submodular functions under various combinatorial constraints, a problem not previously addressed. We provide computational bounds and a hardness result on the multiplicative inapproximability of minimizing the difference between submodular functions. We show, however, that it is possible to give worst-case additive bounds by providing a polynomial time computable lower-bound on the minima. Finally we show how a number of machine learning problems can be modeled as minimizing the difference between submodular functions. We experimentally show the validity of our algorithms by testing them on the problem of feature selection with submodular cost features.

1 Introduction

Discrete optimization is important to many areas of machine learning and recently an ever growing number of problems have been shown to be expressible as submodular function minimization or maximization (e.g., [19, 23, 25, 28, 27, 29]). The class of submodular functions is indeed special since submodular function minimization is known to be polynomial time, while submodular maximization, although NP complete, admits constant factor approximation algorithms. Let $V = \{1, 2, \cdots, n\}$ refer a ground set, then $f : 2^V \rightarrow \mathbb{R}$ is said to be submodular if for sets $S, T \subseteq V$, $f(S)+f(T) \geq f(S \cup T)+f(S \cap T)$ (see [10] for details on submodular, supermodular, and modular functions). Submodular functions have a diminishing returns property, wherein the gain of an element in the context of bigger set is lesser than the gain of that element in the context of a smaller subset. This property occurs naturally in many applications in machine learning, computer vision, economics, operations research, etc.

In this paper, we address the following problem. Given two submodular functions f and g, and define $v(X) \triangleq f(X) - g(X)$, solve the following optimization problem:

$$\min_{X \subseteq V} [f(X) - g(X)] \equiv \min_{X \subseteq V} [v(X)]. \tag{1}$$

A number of machine learning problems involve minimization over a difference between submodular functions. The following are some examples:

- **Sensor placement with submodular costs:** The problem of choosing sensor locations A from a given set of possible locations V can be modeled [23, 24] by maximizing the mutual information between the chosen variables A and the unchosen set $V \backslash A$ (i.e., $f(A) = I(X_A; X_{V \backslash A})$). Alternatively, we may wish to maximize the mutual information between a set of chosen sensors X_A and a fixed quantity of interest C (i.e., $f(A) = I(X_A; C)$) under the assumption that the set of features X_A are conditionally independent given C [23]. These objectives are submodular and thus the problem becomes maximizing a submodular function subject to a cardinality constraint. Often, however, there are costs $c(A)$ associated with the locations that naturally have a diminishing returns property. For example, there is typically a discount when purchasing sensors in bulk. Moreover, there may be diminished cost for placing a sensor in a particular location given placement in certain other locations (e.g., the additional equipment needed to install a sensor in, say, a precarious environment

could be re-used for multiple sensor installations in like environments). Hence, along with maximizing mutual information, we also want to simultaneously minimize the cost and this problem can be addressed by minimizing the difference between submodular functions $f(A) - \lambda c(A)$ for tradeoff parameter λ.

- **Discriminatively structured graphical models and neural computation:** An application suggested in [30] and the initial motivation for this problem is to optimize the EAR criterion to produce a discriminatively structured graphical model. EAR is basically a difference between two mutual information functions (i.e., a difference between submodular functions). [30] shows how classifiers based on discriminative structure using EAR can significantly outperform classifiers based on generative graphical models. Note also that the EAR measure is the same as "synergy" in a neural code [2], widely used in neuroscience.

- **Feature selection:** Given a set of features $X_1, X_2, \cdots, X_{|V|}$, the feature selection problem is to find a small subset of features X_A that work well when used in a pattern classifier. This problem can be modeled as maximizing the mutual information $I(X_A; C)$ where C is the class. Note that $I(X_A; C) = H(X_A) - H(X_A|C)$ is always a difference between submodular functions. Under the naïve Bayes model, this function is submodular [23]. It is not submodular under general classifier models such as support vector machines (SVMs) or neural networks. Certain features, moreover, might be cheaper to use given that others are already being computed. For example, if a subset $S_i \subseteq V$ of the features for a particular information source i are spectral in nature, then once a particular $v \in S_i$ is chosen, the remaining features $S_i \setminus \{v\}$ may be relatively inexpensive to compute, due to grouped computational strategies such as the fast Fourier transform. Therefore, it might be more appropriate to use a submodular cost model $c(A)$. One such cost model might be $c(A) = \sum_i \sqrt{m(A \cap S_i)}$ where $m(j)$ would be the cost of computing feature j. Another might be $c(A) = \sum_i c_i \min(|A \cap S_i|, 1)$ where c_i is the cost of source i. Both offer diminishing cost for choosing features from the same information source. Such a cost model could be useful even under the naïve Bayes model, where $I(X_A; C)$ is submodular. Feature selection becomes a problem of maximizing $I(X_A; C) - \lambda c(A) = H(X_A) - [H(X_A|C) + \lambda c(A)]$, the difference between two submodular functions.

- **Probabilistic Inference:** We are given a distribution $p(x) \propto \exp(-v(x))$ where $x \in \{0,1\}^n$ and v is a pseudo-Boolean function [1]. It is desirable to compute $\text{argmax}_{x \in \{0,1\}^n} p(x)$ which means minimizing $v(x)$ over x, the most-probable explanation (MPE) problem [33]. If p factors with respect to a graphical model of tree-width k, then $v(x) = \sum_i v_i(x_C)$ where C_i is a bundle of indices such that $|C| \leq k+1$ and the sets $\{C_i\}_i$ form a junction tree, and it might be possible to solve inference using dynamic programming. If k is large and/or if hypertree factorization does not hold, then approximate inference is typically used [38]. On the other hand, defining $x(X) = \{x \in \{0,1\}^n : x_i = 1 \text{ whenever } i \in X\}$, if the set function $\bar{v}(X) = v(x(X))$ is submodular, then even if p has large tree-width, the MPE problem can be solved exactly in polynomial time [17]. This, in fact, is the basis behind inference in many computer vision models where v is often not only submodular but also has limited sized $|C_i|$. For example, for submodular v and if $|C_i| \leq 2$ then graph-cuts can solve the MPE problem extremely rapidly [22] and even some cases with v non-submodular [21]. An important challenge is to consider non-submodular v that can be minimized efficiently and for which there are approximation guarantees, a problem recently addressed in [18]. On the other hand, if v can be expressed as a difference between two submodular functions (which it can, see Lemma 3.1), or if such a decomposition can be computed (which it sometimes can, see Lemma 3.2), then a procedure to minimize the difference between two submodular functions offers new ways to solve probabilistic inference.

Previously, Narasimhan and Bilmes [30] proposed an algorithm inspired by the convex-concave procedure [39] to address Equation (1). This algorithm iteratively minimizes a submodular function by replacing the second submodular function g by it's modular lower bound. They also show that any set function can be expressed as a difference between two submodular functions and hence every set function optimization problem can be reduced to minimizing a difference between submodular functions. They show that this process converges to a local minima, however the convergence rate is left as an open question.

In this paper, we first describe tight modular bounds on submodular functions in Section 2, including lower bounds based on points in the base polytope as used in [30], and recent upper bounds first described in a result in [15]. In section 2.2, we describe the submodular-supermodular procedure proposed in [30]. We further provide a constructive procedure for finding the submodular functions f and g for any arbitrary set function v. Although our construction is NP hard in general, we show how for certain classes of set functions v, it is possible to find the decompositions f and g in polynomial time. In Section 4, we propose two new algorithms both of which are guaranteed to monotonically reduce

the objective at every iteration and which converge to a local minima. Further we note that the per-iteration cost of our algorithms is in general much less than [30], and empirically verify that our algorithms are orders of magnitude faster on real data. We show that, unlike in [30], our algorithms can be extended to easily optimize equation (1) under cardinality, knapsack, and matroid constraints. Moreover, one of our algorithms can actually handle complex combinatorial constraints, such as spanning trees, matchings, cuts, etc. Further in Section 5, we give a hardness result that there does not exist any polynomial time algorithm with any polynomial time multiplicative approximation guarantees unless P=NP, even when it is easy to find or when we are given the decomposition f and g, thus justifying the need for heuristic methods to solve this problem. We show, however, that it is possible to get additive bounds by showing polynomial time computable upper and lower bound on the optima. We also provide computational bounds for all our algorithms (including the submodular-supermodular procedure), a problem left open in [30].

Finally we perform a number of experiments on the feature selection problem under various cost models, and show how our algorithms used to maximize the mutual information perform better than greedy selection (which would be near optimal under the naïve Bayes assumptions) and with less cost.

2 Modular Upper and Lower bounds

The Taylor series approximation of a convex function provides a natural way of providing lower bounds on such a function. In particular the first order Taylor series approximation of a convex function is a lower bound on the function, and is linear in x for a given y and hence given a convex function ϕ, we have:

$$\phi(x) \geq \phi(y) + \langle \nabla\phi(y), x - y \rangle. \tag{2}$$

Surprisingly, any submodular function has both a tight lower [6] **and** upper bound [15], unlike strict convexity where there is only a tight first order lower bound.

2.1 Modular Lower Bounds

Recall that for submodular function f, the submodular polymatroid, base polytope and the sub-differential with respect to a set Y [10] are respectively:

$$\mathcal{P}_f = \{x : x(S) \leq f(S), \forall S \subseteq V\} \tag{3}$$

$$\mathcal{B}_f = \mathcal{P}_f \cap \{x : x(V) = f(V)\} \tag{4}$$

$$\partial f(Y) = \{y \in \mathbb{R}^V : \forall X \subseteq V, f(Y) - y(Y) \leq f(X) - y(X)\}$$

The extreme points of this sub-differential are easy to find and characterize, and can be obtained from a greedy algorithm ([6, 10]) as follows:

Theorem 2.1. *([10], Theorem 6.11) A point y is an extreme point of $\partial f(Y)$, iff there exists a chain $\emptyset = S_0 \subset S_1 \subset \cdots \subset S_n$ with $Y = S_j$ for some j, such that $y(S_i \setminus S_{i-1}) = y(S_i) - y(S_{i-1}) = f(S_i) - f(S_{i-1})$.*

Let σ be a permutation of V and define $S^\sigma_i = \{\sigma(1), \sigma(2), \ldots, \sigma(i)\}$ as σ's chain containing Y, meaning $S^\sigma_{|Y|} = Y$ (we say that σ's chain contains Y). Then we can define a sub-gradient h^f_Y corresponding to f as:

$$h^f_{Y,\sigma}(\sigma(i)) = \begin{cases} f(S^\sigma_1) & \text{if } i = 1 \\ f(S^\sigma_i) - f(S^\sigma_{i-1}) & \text{otherwise} \end{cases}.$$

We get a modular lower bound of f as follows:

$$h^f_{Y,\sigma}(X) \leq f(X), \forall X \subseteq V, \text{ and } \forall i, h^f_{Y,\sigma}(S^\sigma_i) = f(S^\sigma_i),$$

which is parameterized by a set Y and a permutation σ. Note $h(X) = \sum_{i \in X} h(i)$, and $h^f_{Y,\sigma}(Y) = f(Y)$. Observe the similarity to convex functions, where a linear lower bound is parameterized by a vector y.

2.2 Modular Upper Bounds

For f submodular, [31] established the following:

$$f(Y) \leq f(X) - \sum_{j \in X \setminus Y} f(j | X \setminus j) + \sum_{j \in Y \setminus X} f(j | X \cap Y),$$

$$f(Y) \leq f(X) - \sum_{j \in X \setminus Y} f(j | (X \cup Y) \setminus j) + \sum_{j \in Y \setminus X} f(j | X)$$

Note that $f(A|B) \triangleq f(A \cup B) - f(B)$ is the gain of adding A in the context of B. These upper bounds in fact characterize submodular functions, in that a function f is a submodular function *iff* it follows either of the above bounds. Using the above, two tight modular upper bounds ([15]) can be defined as follows:

$$f(Y) \leq m^f_{X,1}(Y) \triangleq f(X) - \sum_{j \in X \setminus Y} f(j | X \setminus j) + \sum_{j \in Y \setminus X} f(j | \emptyset),$$

$$f(Y) \leq m^f_{X,2}(Y) \triangleq f(X) - \sum_{j \in X \setminus Y} f(j | V \setminus j) + \sum_{j \in Y \setminus X} f(j | X).$$

Hence, this yields two tight (at set X) modular upper bounds $m^f_{X,1}, m^f_{X,2}$ for any submodular function f. For briefness, when referring either one we use m^f_X.

3 Submodular-Supermodular Procedure

We now review the submodular-supermodular procedure [30] to minimize functions expressible as a difference between submodular functions (henceforth called DS functions). Interestingly, any set function

Algorithm 1 The submodular-supermodular (SubSup) procedure [30]

1: $X^0 = \emptyset$; $t \leftarrow 0$;
2: **while** not converged (i.e., $(X^{t+1} \neq X^t)$) **do**
3: Randomly choose a permutation σ^t whose chain contains the set X^t.
4: $X^{t+1} := \text{argmin}_X f(X) - h^g_{X^t,\sigma^t}(X)$
5: $t \leftarrow t + 1$
6: **end while**

can be expressed as a DS function using suitable submodular functions as shown below. The result was first shown in [30] using the Lovász extension. We here give a new combinatorial proof, which avoids Hessians of polyhedral convex functions and which provides a way of constructing (a non-unique) pair of submodular functions f and g for an arbitrary set function v.

Lemma 3.1. *[30] Given any set function v, it can be expressed as a DS functions $v(X) = f(X) - g(X), \forall X \subseteq V$ for some submodular functions f and g.*

Proof. Given a set function v, we can define $\alpha = \min_{X \subset Y \subseteq V \setminus j} v(j|X) - v(j|Y)$[1]. Clearly $\alpha < 0$, since otherwise v would be submodular. Now consider any (strictly) submodular function g, i.e., one having $\beta = \min_{X \subset Y \subseteq V \setminus j} g(j|X) - g(j|Y) > 0$. Define $f'(X) = v(X) + \frac{|\alpha'|}{\beta} g(X)$ with any $\alpha' \leq \alpha$. Now it is easy to see that f' is submodular since $\min_{X \subset Y \subseteq V \setminus j} f'(j|X) - f'(j|Y) \geq \alpha + |\alpha'| \geq 0$. Hence $v(X) = f'(X) - \frac{|\alpha'|}{\beta} g(X)$, is a difference between two submodular functions. □

The above proof requires the computation of α and β which has, in general, exponential complexity. Using the construction above, however, it is easy to find the decomposition f and g under certain conditions on v.

Lemma 3.2. *If α or at least a lower bound on α for any set function v can be computed in polynomial time, functions f and g corresponding to v can obtained in polynomial time.*

Proof. Define g as $g(X) = \sqrt{|X|}$. Then $\beta = \min_{X \subset Y \subseteq V \setminus j} \sqrt{|X|+1} - \sqrt{|X|} - \sqrt{|Y|+1} + \sqrt{|Y|} = \min_{X \subset V \setminus j} \sqrt{|X|+1} - \sqrt{|X|} - \sqrt{|X|+2} + \sqrt{|X|+1} = 2\sqrt{n-1} - \sqrt{n} - \sqrt{n-2}$. The last inequality follows since the smallest difference in gains will occur at $|X| = n - 2$. Hence β is easily computed, and given a lower bound on α, from Lemma 3.1 the decomposition can be obtained in polynomial time. A similar argument holds for g being other concave functions over $|X|$. □

[1] We denote $j, X, Y : X \subset Y \subseteq V \setminus \{j\}$ by $X \subset Y \subseteq V \setminus j$.

The submodular supermodular (SubSup) procedure is given in Algorithm 1. At every step of the algorithm, we minimize a submodular function which can be performed in strongly polynomial time [32, 35] although the best known complexity is $O(n^5\eta + n^6)$ where η is the cost of a function evaluation. Algorithm 1 is guaranteed to converge to a local minima and moreover the algorithm monotonically decreases the function objective at every iteration, as we show below.

Lemma 3.3. *[30] Algorithm 1 is guaranteed to decrease the objective function at every iteration. Further, the algorithm is guaranteed to converge to a local minima by checking at most $O(n)$ permutations at every iteration.*

Due to space constraints, we omit the proof of this lemma which is in any case described in [30, 13].

Algorithm 1 requires performing a submodular function minimization at every iteration which while polynomial in n is (due to the complexity described above) not practical for large problem sizes. So while the algorithm reaches a local minima, it can be costly to find it. A desirable result, therefore, would be to develop new algorithms for minimizing DS functions, where the new algorithms have the same properties as the SubSup procedure but are much faster in practice. We give this in the following sections.

4 Alternate algorithms for minimizing DS functions

In this section we propose two new algorithms to minimize DS functions, both of which are guaranteed to monotonically reduce the objective at every iteration and converge to local minima. We briefly describe these algorithms in the subsections below.

4.1 The supermodular-submodular (SupSub) procedure

In the submodular-supermodular procedure we iteratively minimized $f(X) - g(X)$ by replacing g by it's modular lower bound at every iteration. We can instead replace f by it's modular upper bound as is done in Algorithm 2, which leads to the *supermodular-submodular* procedure.

In the SupSub procedure, at every step we perform submodular maximization which, although NP complete to solve exactly, admits a number of fast constant factor approximation algorithms [7, 8]. Notice that we have two modular upper bounds and hence there are a number of ways we can choose between them. One way is to run both maximization procedures with the two modular upper bounds at every iteration in parallel,

Algorithm 2 The supermodular-submodular (SupSub) procedure

1: $X^0 = \emptyset$; $t \leftarrow 0$;
2: **while** not converged (i.e., $(X^{t+1} \neq X^t)$) **do**
3: $\quad X^{t+1} := \text{argmin}_X \, m^f_{X^t}(X) - g(X)$
4: $\quad t \leftarrow t + 1$
5: **end while**

and choose the one which is better. Here by better we mean the one in which the function value is lesser. Alternatively we can alternate between the two modular upper bounds by first maximizing the expression using the first modular upper bound, and then maximize the expression using the second modular upper bound. Notice that since we perform approximate submodular maximization at every iteration, we are not guaranteed to monotonically reduce the objective value at every iteration. If, however, we ensure that at every iteration we take the next step only if the objective v does not increase, we will restore monotonicity at every iteration. Also, in some cases we converge to local optima as shown in the following theorem.

Theorem 4.1. *Both variants of the supermodular-submodular procedure (Algorithm 2) monotonically reduces the objective value at every iteration. Moreover, assuming a submodular maximization procedure in line 3 that reaches a local maxima of $m^f_{X^t}(X) - g(X)$, then if Algorithm 2 does not improve under both modular upper bounds then it reaches a local optima of v.*

Proof. For either modular upper bound, we have:

$$\begin{aligned} f(X^{t+1}) - g(X^{t+1}) &\overset{a}{\leq} m^f_{X^t}(X^{t+1}) - g(X^{t+1}) \\ &\overset{b}{\leq} m^f_{X^t}(X^t) - g(X^t) \\ &\overset{c}{=} f(X^t) - g(X^t), \end{aligned}$$

where (a) follows since $f(X^{t+1}) \leq m^f_{X^t}(X^{t+1})$, and (b) follows since we assume that we take the next step only if the objective value does not increase and (c) follows since $m^f_{X^t}(X^t) = f(X^t)$ from the tightness of the modular upper bound.

To show that this algorithm converges to a local minima, we assume that the submodular maximization procedure in line 3 converges to a local maxima. Then observe that if the objective value does not decrease in an iteration under both upper bounds, it implies that $m^f_{X^t}(X^t) - g(X^t)$ is already a local optimum in that (for both upper bounds) we have $m^f_{X^t}(X^t \cup j) - g(X^t \cup j) \geq m^f_{X^t}(X^t) - g(X^t), \forall j \notin X^t$ and $m^f_{X^t}(X^t \backslash j) - g(X^t \backslash j) \geq m^f_{X^t}(X^t) - g(X^t), \forall j \in X^t$. Note that $m^f_{X^t,1}(X^t \backslash j) = f(X^t) - f(j|X^t \backslash j) = f(X^t \backslash j)$ and $m^f_{X^t,2}(X^t \cup j) = f(X^t) + f(j|X^t) = f(X^t \cup j)$ and hence if both modular upper bounds are at a local optima, it implies $f(X^t) - g(X^t) = m^f_{X^t,1}(X^t) - g(X^t) \leq m^f_{X^t,1}(X^t \backslash j) - g(X^t \backslash j) = f(X^t \backslash j) - g(X^t \backslash j)$. Similarly $f(X^t) - g(X^t) = m^f_{X^t,2}(X^t) - g(X^t) \leq m^f_{X^t,2}(X^t \cup j) - g(X^t \cup j) = f(X^t \cup j) - g(X^t \cup j)$. Hence X^t is a local optima for $v(X) = f(X) - g(X)$, since $v(X^t) \leq v(X^t \cup j)$ and $v(X^t) \leq v(X^t \backslash j)$. □

To ensure that we take the largest step at each iteration, we can use the recently proposed tight (1/2)-approximation algorithm in [7] for unconstrained non-monotone submodular function maximization — this is the best possible in polynomial time for the class of submodular functions independent of the P=NP question. The algorithm is a form of bi-directional randomized greedy procedure and, most importantly for practical considerations, is linear time [7]. Lastly, note that this algorithm is closely related to a local search heuristic for submodular maximization [8]. In particular, if instead of using the greedy algorithm entirely at every iteration, we take only one local step, we get a local search heuristic. Hence, via the SupSub procedure, we may take larger steps at every iteration as compared to a local search heuristic.

4.2 The modular-modular (ModMod) procedure

The submodular-supermodular procedure and the supermodular-submodular procedure were obtained by replacing g by it's modular lower bound and f by it's modular upper bound respectively. We can however replace both of them by their respective modular bounds, as is done in Algorithm 3.

Algorithm 3 Modular-Modular (ModMod) procedure

1: $X^0 = \emptyset$; $t \leftarrow 0$;
2: **while** not converged (i.e., $(X^{t+1} \neq X^t)$) **do**
3: $\quad$ Choose a permutation σ^t whose chain contains the set X^t.
4: $\quad X^{t+1} := \text{argmin}_X \, m^f_{X^t}(X) - h^g_{X^t,\sigma^t}(X)$
5: $\quad t \leftarrow t + 1$
6: **end while**

In this algorithm at every iteration we minimize only a modular function which can be done in $O(n)$ time, so this is extremely easy (i.e., select all negative elements for the smallest minimum, or all non-positive elements for the largest minimum). Like before, since we have two modular upper bounds, we can use any of the variants discussed in the subsection above. Moreover, we are still guaranteed to monotonically decrease the objective at every iteration and converge to a local minima.

Theorem 4.2. *Algorithm 3 monotonically decreases the function value at every iteration. If the function value does not increase on checking $O(n)$ different permutations with different elements at adjacent positions and with both modular upper bounds, then we have reached a local minima of v.*

Proof. Again we can use similar reasoning as the earlier proofs and observe that:

$$\begin{aligned} f(X^{t+1}) - g(X^{t+1}) &\leq m^f_{X^t}(X^{t+1}) - h^g_{X^t,\sigma^t}(X^{t+1}) \\ &\leq m^f_{X^t}(X^t) - h^g_{X^t,\sigma^t}(X^t) \\ &= f(X^t) - g(X^t) \end{aligned}$$

We see that considering $O(n)$ permutations each with different elements at $\sigma^t(|X^t|-1)$ and $\sigma^t(|X^t|+1)$, we essentially consider all choices of $g(X^t \cup j)$ and $g(X^t \backslash j)$, since $h^g_{X^t,\sigma^t}(S_{|X^t|+1}) = f(S_{|X^t|+1})$ and $h^g_{X^t,\sigma^t}(S_{|X^t|-1}) = f(S_{|X^t|-1})$. Since we consider both modular upper bounds, we correspondingly consider every choice of $f(X^t \cup j)$ and $f(X^t \backslash j)$. Note that at convergence we have that $m^f_{X^t}(X^t) - h^g_{X^t,\sigma^t}(X^t) \leq m^f_{X^t}(X) - h^g_{X^t,\sigma^t}(X), \forall X \subseteq V$ for $O(n)$ different permutations and both modular upper bounds. Correspondingly we are guaranteed that (since the expression is modular) $\forall j \notin X^t, v(j|X^t) \geq 0$ and $\forall j \in X^t, v(j|X^t \backslash j) \geq 0$, where $v(X) = f(X) - g(X)$. Hence the algorithm converges to a local minima. □

An important question is the choice of the permutation σ^t at every iteration X^t. We observe experimentally that the quality of the algorithm depends strongly on the choice of permutation. Observe that $f(X) - g(X) \leq m^f_{X^t}(X) - h^g_{X^t,\sigma^t}(X)$, and $f(X^t) - g(X^t) = m^f_{X^t}(X^t) - h^g_{X^t,\sigma^t}(X^t)$. Hence, we might obtain the greatest local reduction in the value of v by choosing permutation $\sigma^* \in \text{argmin}_\sigma \min_X (m^f_{X^t}(X) - h^g_{X^t,\sigma^t}(X))$, or the one which maximizes $h^g_{X^t,\sigma^t}(X)$. We in fact might expect that choosing σ^t ordered according to greatest gains of g, with respect to X^t, we would achieve greater descent at every iteration. Another choice is to choose the permutation σ based on the ordering of gains of v (or even $m^f_{X^t}$). Through the former we are guaranteed to at least progress as much as the local search heuristic. Indeed, we observe in practice that the first two of these heuristics performs much better than a random permutation for both the ModMod and the SubSup procedure, thus addressing a question raised in [30] about which ordering to use. Practically for the feature selection problem, the second heuristic seems to work the best.

4.3 Constrained minimization of a difference between submodular functions

In this section we consider the problem of minimizing the difference between submodular functions subject to constraints. We first note that the problem of minimizing a submodular function under even simple cardinality constraints in NP hard and also hard to approximate [36]. Since there does not yet seem to be a reasonable algorithm for constrained submodular minimization at every iteration, it is unclear how we would use Algorithm 1. However the problem of submodular maximization under cardinality, matroid, and knapsack constraints though NP hard admits a number of constant factor approximation algorithms [31, 26] and correspondingly the cardinality constraints can be easily introduced in Algorithm 2. Moreover, since a non-negative modular function can be easily, directly and even exactly optimized under cardinality, knapsack and matroid constraints [16], Algorithm 3 can also easily be utilized. In addition, since problems such as finding the minimum weight spanning tree, min-cut in a graph, etc., are polynomial time algorithms in a number of cases, Algorithm 3 can be used when minimizing a non-negative function v expressible as a difference between submodular functions under combinatorial constraints. If v is non-negative, then so is its modular upper bound, and then the ModMod procedure can directly be used for this problem — each iteration minimizes a non-negative modular function subject to combinatorial constraints which is easy in many cases [16, 14].

5 Theoretical results

In this section we analyze the computational and approximation bounds for this problem. For simplicity we assume that the function v is normalized, i.e $v(\emptyset) = 0$. Hence we assume that v achieves it minima at a negative value and correspondingly the approximation factor in this case will be less than 1.

We note in passing that the results in this section are mostly negative, in that they demonstrate theoretically how complex a general problem such as $\min_X [f(X) - g(X)]$ is, even for submodular f and g. In this paper, rather than consider these hardness results pessimistically, we think of them as providing justification for the heuristic procedures given in Section 4 and [30]. In many cases, inspired heuristics can yield good quality and hence practically useful algorithms for real-world problems. For example, the ModMod procedure (Algorithm 3) and even the SupSub procedure (Algorithm 2) can scale to very large problem sizes, and thus can provide useful new strategies for the applications listed in Section 1.

5.1 Hardness

Observe that the class of DS functions is essentially the class of general set functions, and hence the problem of finding optimal solutions is NP-hard. This is not surprising since general set function minimization is inapproximable and there exist a large class of functions where all (adaptive, possibly randomized) algorithms perform arbitrarily poorly in polynomial time [37]. Clearly as is evident from Theorem 3.1, even the problem of finding the submodular functions f and g requires exponential complexity. We moreover show in the following theorem, however, that this problem is multiplicatively inapproximable even when the functions f and g are easy to find.

Theorem 5.1. *Unless $P = NP$, there cannot exist any polynomial time approximation algorithm for $\min_X v(X)$ where $v(X) = [f(X) - g(X)]$ is a positive set function and f and g are given submodular functions. In particular, let n be the size of the problem instance, and $\alpha(n) > 0$ be any positive polynomial time computable function of n. If there exists a polynomial-time algorithm which is guaranteed to find a set $X' : f(X') - g(X') < \alpha(n)OPT$, where OPT=$\min_X f(X) - g(X)$, then $P = NP$.*

The proof of this theorem is in [13]. In fact we show below that independent of the $P = NP$ question, there cannot exist a sub-exponential time algorithm for this problem. The theorem below gives information theoretic hardness for this problem.

Theorem 5.2. *For any $0 < \epsilon < 1$, there cannot exist any deterministic (or possibly randomized) algorithm for $\min_X[f(X) - g(X)]$ (where f and g are given submodular functions), that always finds a solution which is at most $\frac{1}{\epsilon}$ times the optimal, in fewer than $e^{\epsilon^2 n/8}$ queries.*

Again the proof of this theorem is in [13]. Essentially the theorems above say that even when we are given (or can easily find) a decomposition such that $v(X) = f(X) - g(X)$, there exist set functions such that any algorithm (either adaptive or randomized) will perform arbitrarily poorly and this problem is inapproximable. Hence any algorithm trying to find the global optimum for this problem [3] can only be exponential.

5.2 Polynomial time lower and upper bounds

The decomposition theorem of [5] shows that any submodular function can be decomposed into a modular function plus a monotone non-decreasing and *totally normalized* polymatroid rank function. Specifically, given submodular f, g we have $f'(X) \triangleq f(X) - \sum_{j \in X} f(j|V\backslash j)$ and $g'(X) \triangleq g(X) - \sum_{j \in X} g(j|V\backslash j)$ with f', g' being totally normalized polymatroid rank functions. Hence we have: $v(X) = f'(X) - g'(X) + k(X)$, with modular $k(X) = \sum_{j \in X} v(j|V\backslash j)$.

The algorithms in the previous sections are all based on repeatedly finding upper bounds for v. The following lower bounds directly follow from the results above. (The proof of this is in [13])

Theorem 5.3. *We have the following two lower bounds on the minimizers of $v(X) = f(X) - g(X)$:*

$$\min_X v(X) \geq \min_X f'(X) + k(X) - g'(V)$$
$$\min_X v(X) \geq f'(\emptyset) - g'(V) + \sum_{j \in V} \min(k(j), 0)$$

The above lower bounds essentially provide bounds on the minima of the objective and thus can be used to obtain an additive approximation guarantee. The algorithms described in this paper are all polynomial time algorithms (as we show below) and correspondingly from the bounds above we can get an estimate on how far we are from the optimal.

5.3 Computational Bounds

We now provide computational bounds for ϵ-approximate versions of our algorithms. Note that this was left as an open question in [30]. Finding the local minimizer of DS functions is PLS complete since it generalizes the problem of finding the local optimum of the MAX-CUT problem [34]. However we show that an ϵ-approximate version of this algorithm will converge in polynomial time.

Definition 5.1. *An ϵ-approximate version of an iterative monotone non-decreasing algorithm for minimizing a set function v is defined as a version of that algorithm, where we proceed to step $t+1$ only if $v(X^{t+1}) \leq v(X^t)(1+\epsilon)$.*

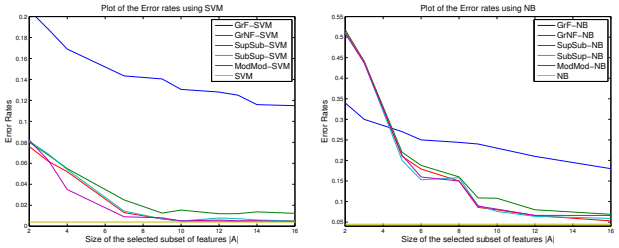
Note that the ϵ-approximate versions of algorithms 1, 2 and 3, are guaranteed to converge to ϵ-approximate local optima. W.l.o.g., assume that $X^0 = \emptyset$. Then we have the following computational bounds:

Theorem 5.4. *The ϵ-approximate versions of algorithms 1, 2 and 3 have a worst case complexity of $O(\frac{\log(|M|/|m|)}{\epsilon} T)$, where $M = f'(\emptyset) + \sum_{j \in V} \min(v(j|V\backslash j), 0) - g'(V)$, $m = v(X^1)$ and $O(T)$ is the complexity of every iteration of the algorithm (which corresponds to respectively the submodular minimization, maximization, or modular minimization in algorithms 1, 2 and 3)..*

The proof of this theorem is in [13]

Observe that for the algorithms we use, $O(T)$ is strongly polynomial in n. The best strongly polynomial time algorithm for submodular function minimization is

$O(n^5\eta + n^6)$ [32] (the lower bound is currently unknown). Further the worst case complexity of the greedy algorithm for maximization is $O(n^2)$ while the complexity of modular minimization is just $O(n)$. Note finally that these are worst case complexities and actually the algorithms run much faster in practice.



(a) SVM (b) NB

Figure 1: Plot showing the accuracy rates vs. the number of features on the Mushroom data set.

6 Experiments

We test our algorithms on the feature subset selection problem in the supervised setting. Given a set of features $X_V = \{X_1, X_2, \cdots, X_{|V|}\}$, we try to find a subset of these features A which has the most information from the original set X_V about a class variable C under constraints on the size or cost of A. Normally the number of features $|V|$ is quite large and thus the training and testing time depend on $|V|$. In many cases, however, there is a strong correlation amongst features and not every feature is novel. We can thus perform training and testing with a much smaller number of features $|A|$ while obtaining (almost) the same error rates.
