The question is how to find the most representative set of features A. The mutual information between the chosen set of features and the target class C, $I(X_A; C)$, captures the relevance of the chosen subset of features. In most cases the selected features are not independent given the class C so the naïve Bayes assumption is not applicable, meaning this is not a pure submodular optimization problem. As mentioned in Section 1, $I(X_A; C)$ can be exactly expressed as a difference between submodular functions $H(X_A)$ and $H(X_A|C)$.

6.1 Modular Cost Feature Selection

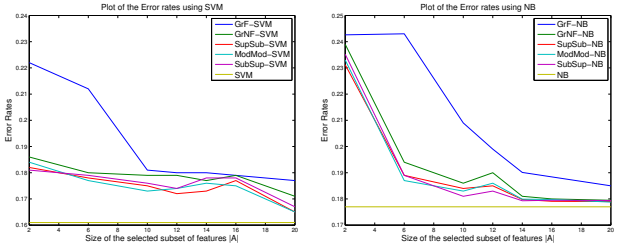
In this subsection, we look at the problem of maximizing $I(X_A; C) - \lambda|A|$, as a regularized feature subset selection problem. Note that a mutual information $I(X_A; C)$ query can easily be estimated from the data by just a single sweep through this data. Further we have observed that using techniques such as Laplace smoothing helps to improve mutual information estimates without increasing computation. In these experiments, therefore, we estimate the mutual information directly from the data and run our algorithms to find the representative subset of features.

We compare our algorithms on two data sets, i.e., the Mushroom data set [12] and the Adult data set [20] obtained from [9]. The Mushroom data set has 8124 examples with 112 features, while the Adult data set has 32,561 examples with 123 features. In our experiments we considered subsets of features of sizes between 5%-20% of the total number of features by varying λ. We tested the following algorithms for the feature subset selection problem. We considered two formulations of the mutual information, one under naïve Bayes, where the conditional entropy $H(X_A|C)$ can be written as $H(X_A|C) = \sum_{j \in A} H(X_i|C)$ and another where we do not assume such factorization. We call these two formulations *factored* and *non-factored* respectively. We then considered the simple greedy algorithm, of iteratively adding features at every step to the factored and non-factored mutual information, which we call GrF and GrNF respectively. Lastly, we use the new algorithms presented in this paper on the non-factored mutual information.

We then compare the results of the greedy algorithms with those of the three algorithms for this problem, using two pattern classifiers based on either a linear kernel SVM (using [4]) or a naïve Bayes (NB) classifier. We call the results obtained from the supermodular-submodular heuristic as "SupSub", the submodular-supermodular procedure [30] as "SubSup", and the modular-modular objective as "ModMod." In the SubSup procedure, we use the minimum norm point algorithm [11] for submodular minimization, and in the SubSup procedure, we use the optimal algorithm of [7] for submodular maximization. We observed that the three heuristics generally outperformed the two greedy procedures, and also that GRF can perform quite poorly, thus justifying our claim that the naïve Bayes assumption can be quite poor. This also shows that although the greedy algorithm in that case is optimal, the features are correlated given the class and hence modeling it as a difference between submodular functions gives the best results. We also observed that the SupSub and ModMod procedures perform comparably to the SubSup procedure, while the SubSup procedure is *much* slower in practice. Comparing the running times, the ModMod and the SupSub procedure are each a few times slower then the greedy algorithm (ModMod is slower due computing the modular semigradients), while the SubSup procedure is around 100 times slower. The SubSup procedure is slower due to general submodular function minimization which can be quite slow.

The results for the Mushroom data set are shown in

Figure 1. We performed a 10 fold cross-validation on the entire data set and observed that when using all the features SVM gave an accuracy rate of 99.6% while the all-feature NB model had an accuracy rate of 95.5%. The results for the Adult database are in Figure 2. In this case with the entire set of features the accuracy rate of SVM on this data set is 83.9% and NB is 82.3%.

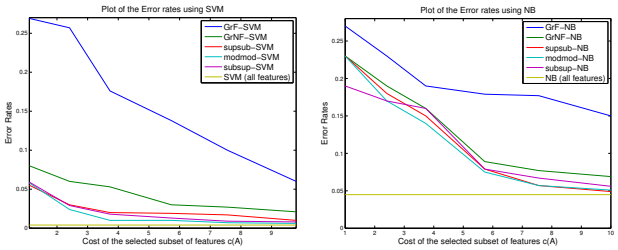


(a) SVM (b) NB

Figure 2: Plot showing the accuracy rates vs. the number of features on the Adult data set.

In the mushroom data, the SVM classifier significantly outperforms the NB classifier and correspondingly GrF performs much worse than the other algorithms. Also, in most cases the three algorithms outperform GrNF. In the adult data set, both the SVM and NB perform comparably although SVM outperforms NB. However in this case also we observe that our algorithms generally outperform GrF and GrNF.

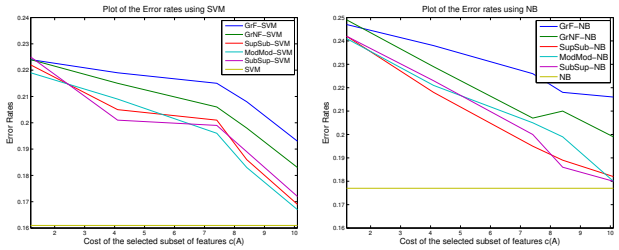
6.2 Submodular cost feature selection



(a) SVM (b) NB

Figure 3: Plot showing the accuracy rates vs. the cost of features for the Mushroom data set

We perform synthetic experiments for the feature subset selection problem under submodular costs. The cost model we consider is $c(A) = \sum_i \sqrt{m(A \cap S_i)}$. We partitioned V into sets $\{S_i\}_i$ and chose the modular function m randomly. In this set of experiments, we compare the accuracy of the classifiers vs. the *cost* associated with the choice of features for the algorithms. Recall, with simple (modular) cardinality costs the



(a) SVM (b) NB

Figure 4: Plot showing the accuracy rates vs. the cost of features for the Adult data set

greedy algorithms performed decently in comparison to our algorithms in the adult data set, where the NB assumption is reasonable. However with submodular costs, the objective is no longer submodular even under the NB assumption and thus the greedy algorithms perform much worse. This is unsurprising since the greedy algorithm is approximately optimal only for monotone submodular functions. This is even more strongly evident from the results of the mushrooms data-set (Figure 3)

7 Discussion

We have introduced new algorithms for optimizing the difference between two submodular functions, provided new theoretical understanding that provides some justification for heuristics, have outlined applications that can make use of our procedures, and have tested in the case of feature selection with modular and submodular cost features. Our new ModMod procedure is fast at each iteration and experimentally does about as well as the SupSub and SubSup procedures. The ModMod procedure, moreover, can also be used under various combinatorial constraints, and therefore the ModMod procedure may hold the greatest promise as a practical heuristic. An alternative approach, not yet evaluated, would be to try the convex-concave procedure [39] on the Lovász extensions of f and g since subgradients in such case are so easy to obtain.

Abstract

We consider Incentive Decision Processes, where a principal seeks to reduce its costs due to another agent's behavior, by offering incentives to the agent for alternate behavior. We focus on the case where a principal interacts with a greedy agent whose preferences are hidden and static. Though IDPs can be directly modeled as partially observable Markov decision processes (POMDP), we show that it is possible to directly reduce or approximate the IDP as a polynomially-sized MDP: when this representation is approximate, we prove the resulting policy is boundedly-optimal for the original IDP. Our empirical simulations demonstrate the performance benefit of our algorithms over simpler approaches, and also demonstrate that our approximate representation results in a significantly faster algorithm whose performance is extremely close to the optimal policy for the original IDP.

1 Introduction

Consider a landlord who pays for her tenant's heating bill, or an insurance company that covers an insuree's health care bills. These are two instances where a principal agent incurs a cost for the behavior of another agent. In such scenarios the principal may be able to provide incentives to attempt to change the agent's behavior; however, the principal typically does not know the preferences of the agent, and these preferences determine which incentives will be accepted by the agent in return for altered behavior.

We formalize this problem as an instance of sequential decision making under uncertainty. Despite much AI interest in this general field, there has been limited research on multi-step decision processes where a principal agent's own costs are a function of another agent's behavior. We call these processes Incentive Decision Processes (IDPs) and in this paper we focus on the case where a principal interacts with a greedy myopic agent whose preferences are hidden and static. The objective is to compute a decision policy for the principal that minimizes its total expected sum of costs over the horizon of interactions with the agent. Computing this policy would be trivial if the agent's preferences were known to the principal: the principal would simply offer the incentive for an agent action that minimized the principal's cost amongst all incentive-action pairs that would be accepted by the agent. However, the agent preferences are typically hidden. It is important to consider the case where a principal cannot simply ask the agent for its preferences. Naturally a strategic rational agent may wish to misrepresent its stated preferences in order to gain additional reward, and we will briefly touch on this issue at the end of the paper. But our focus will be on agents that act myopically and therefore truthfully (as we will later prove). We argue that this model is reasonable for many important situations where the agent is not adversarial, but is either unaware or in denial of its own utility function, such as asking a person about their preference for consuming healthy food or exercising different amounts, or where it is impossible for the agent to directly respond (such as teaching a baby a new behavior).

Our work is most closely related to the research of Zhang and colleagues [12, 13, 4] on environment design. However, Zhang et al.'s work primarily addresses inducing the agent to follow a particular policy within a short number of interactions, whereas our research focuses on how to provide incentives to minimize the total cost incurred by the principal over many interactions with the agent. We believe our objective is likely to be particularly relevant in multiple real-world domains, where the cost of any diagnostic steps to reveal the hidden preferences of the agent, such as a tenant, office employee, or insuree, must be balanced with the expected benefit of that information in reducing the cost to the principal. In this sense our algorithms will

address the exploration versus exploitation tradeoff in the context of Incentive Decision Processes.

We will show constructing a policy for the principal in an IDP may be modeled as a partially observable Markov decision process (POMDP) planning problem. However we will demonstrate that we can leverage the significant structure in IDPs to achieve much more efficient optimal or boundedly-optimal algorithms. Our first contribution is to prove that if there are only two different actions that the agent may choose, then the incentive decision process can be reduced to a polynomially sized MDP. We will also describe a similar approximate mapping for multiple action incentivized decision processes, and also present formal bounds on the quality of policies for the approximate representation. Our empirical simulations demonstrate the performance benefit of our sequential decision-theoretic algorithms over simpler approaches. We will finish by briefly discussing multiple extensions to our model, including dynamic agent preferences and strategically rational agents. When proofs are omitted, they are provided in the appendix.

2 Background

A Markov decision process (MDP) is described by a tuple $\langle S, A, p(s'|s,a), C, \gamma \rangle$. S is a set of states, A is a set of actions, and $p(s'|s,a)$ is the transition model and stores for each state s and action a the probability of transitioning to any state s'. C is the cost model and represents the cost of taking action a in state s and transitioning to state s'. $\gamma \in [0,1]$ is a discount factor. A stationary policy $\pi : S \rightarrow A$ is a mapping from states to actions.[1] The value of a policy π for a horizon H from state s is the expected sum of costs over H steps when following the policy from state s,

$$V_\pi^H(s) = \sum_{s'} p(s'|s,\pi(s))[c(s,\pi(s),s') + \gamma V_\pi^{H-1}(s')]$$

This equation is also known as the Bellman equation [1]. In a slightly modified form (known as a Bellman update) it can be used to iteratively compute the optimal value function and optimal policy. If the horizon is infinite, then the value function is independent of the time step. The optimal policy is the policy that has the lowest value.

Partially observable MDPs (POMDPs) [10, 6] are often used to describe decision processes where the state is not directly observable. POMDPs are represented by a tuple $\langle S, A, O, p(s'|s,a), p(o|s',a), C, \gamma \rangle$. Here O is a set of observations, and $p(o|s',a)$ is the probability of observing o after taking action a and transitioning to state s'. A belief b is a probability distribution over the possible world states, given the prior history of actions taken and observations received. b is a sufficient statistic for the history, and can be updated as new actions are taken, and new observations are received, using a Bayes filter. In POMDP planning the objective is to compute a policy $\pi : b \rightarrow a$ that maximizes the expected sum of future rewards.

[1]The policy can also depend on the time step.

3 Related Work

Since the agent's preferences are unknown to the principal, our work is loosely related to research on preference elicitation [3]. However, preference elicitation only focuses on identifying an agent's hidden reward model, or identifying it sufficiently to make a single decision. In contrast, in our work the principal seeks to minimize its expected sum of costs. Similarly, inverse reinforcement learning [9] seeks to identify an agent's hidden reward model given the agent's behavior, but our focus is on minimizing the cost to a principal by altering the agent's behavior through the offering of incentives, which may not involve fully identifying the agent's hidden reward model.

Research on multiple agents interacting includes sophisticated models for representing and updating each agent's internal estimate of the state of the other agent. Such representations can lead to infinite nestings of state estimates [11]. Interactive POMDPs (I-POMDPs) are used to represent such problems, and use a finite representation of each agent's state for tractability [5]. Such rich representations remain very expressive, but at the price of computational intractability for all but very small domains.

The closest work to our own is that of Zhang and colleagues [12, 14, 13, 4] on policy teaching and environment design. Their earliest work [12] focuses on finding a set of incentives for the agent that minimizes the principal's expected cost. Their setting is quite general: the agent acts in a MDP and the principal provides a set of incentives over the MDP states. Zhang et al. provide an algorithm for identifying the optimal incentives to provide within a finite (but unknown) number of episodes, where in each multi-step episode the agent follows their optimal policy given their (hidden) reward function plus the provided incentives. Our presented work focuses on a more restrictive setting of a greedy agent selecting among a fixed set of actions at each step, but within this context we provide formal guarantees of our algorithm's performance over a *single* multi-step episode as the principal and agent interact. Our IDP model is most similar to Zhang et al.'s recent work [4] on an incentivized multi-armed bandit. However, this work focuses on inducing a particular action selection by the agent given some budget, whereas our focus is on minimizing the total expected cost for

the principal. Also, we are interested in long horizon decision processes, versus their algorithmic work only considers short (≤ 3 step) horizons.

4 Incentive Decision Process Model

Consider a principal interacting multiple times with an agent. At each time step the agent chooses an action from a set of agent actions $A = \{a_1, a_2, \cdots, a_N, a_{N+1}\}$. We assume that the agent has an internal reward R_{a_n} for every action a_n such that $R_{a_i} > R_{a_j}$ if $i > j$. Therefore a_{N+1} will yield the highest reward for the agent, and so we define a_{N+1} as the default agent action that the agent will select if no incentives are provided. All other actions $a_1, \cdots, a_N$ will be referred to as alternate agent actions. The agent's rewards are hidden from the principal, but due to the assumed structure, the principal does know that action a_{N+1} is the agent's default action. Each agent action a_i is also associated with a particular cost c_i to the principal and the costs are such that $c_i < c_j$ if $i < j$. Therefore by definition the default agent action a_{N+1} is of highest cost to the principal.

At each time step the principal offers an incentive δ for a particular action a_n ($n \in (1, N)$) to the agent if the agents chooses action a_n on this time step. The offered incentive is selected from a set of K incentives $\Delta = \{\delta_1, \cdots, \delta_K\}$ where $\delta_i < \delta_j$ if $i < j$. We assume that the agent acts to maximize its immediate reward, and will accept the offered incentive and take action a_n if doing so yields a higher reward than the default action, $R_{a_n} + \delta > R_{a_{N+1}}$. Otherwise the agent will reject the incentive and take the default action a_{N+1} and receive reward $R_{a_{N+1}}$. If the agent accepts the offered incentive for action a_n, the principal will incur an immediate cost of $c_n + \delta$; otherwise, the principal's immediate cost is c_{N+1}. We will assume that the cost of each alternate agent actions, plus the maximum possible incentive, is always less than the cost of the default agent action: $c_N + \delta_K < c_{N+1}$. This implies that the principal would always prefer the agent to accept an incentive and take one of the alternate agent actions. We also assume that for each alternate agent action a_n, there exists an incentive in Δ such that if that incentive is offered, the agent would prefer to accept that incentive and take the alternate agent action instead of the default action. Let $t_n = R_{a_{N+1}} - R_{a_n} \in \Delta$ be the least incentive for which the agent prefers action a_n to the default agent action a_{N+1}. Observe that lower indexed actions have lower rewards to the agent, and therefore will require incentives equal or greater than higher indexed rewards, $t_i \geq t_j$ for $i < j$. We use $I = (t_1, \cdots, t_N)$ to denote the tuple of true incentives for the N alternate agent actions. These incentives are initially unknown to the principal. The principal is provided with an initial joint probability distribution P_0 which gives the probability that $t_i = \delta_{\mathbf{k}}$ for all $n \in \{1, \cdots, N\}$ and $k \in \{1, \cdots, K\}$.

Note the set of alternate actions and set of possible internal rewards for each action for the agent is common knowledge. The agent's actual reward for each alternate action is prive knowledge to the agent. Since the agent is assumed to act in a myopic fashion, it does not matter if the principal's costs for each alternate action, and its set of possible incentives, are private or common knowledge.

The objective of the principal is to minimize its expected sum of costs over H interactions with the agent. The costs may be multiplied by a discount factor $\gamma \in [0, 1]$. We will consider both the finite horizon case and the discounted infinite horizon case ($H = \infty$). In this paper we will design tractable algorithms that compute a decision policy to achieve the principal's objective.

For example, the landlord-tenant scenario can be modeled as an IDP where the tenant's (agent's) default temperature setting is the default action, and other temperatures correspond to alternate agent actions. Each temperature maps to a cost to the landlord (principal). At each step the principal offers an incentive to the agent if the agent sets the thermostat to an alternate temperature that the principal specifies.

An IDP can also be modeled as a POMDP. In the IDP POMDP the state is the agent's hidden t_n for all $n \in \{1, \cdots, N\}$, the actions are the cross product of all alternate agent actions with the possible incentives Δ (since the principal can offer any incentive paired with any alternate agent action), and the observations are the binary accept or reject response of the agent. For most of this paper we assume that the agent's hidden preferences are static, and so the state transition model is a delta function. The observation model is that an agent's acceptance of an offer of δ_k for alternate action a_n indicates that $t_n \leq \delta_k$ (since an agent will accept any incentive equal or greater than t_n for alternate action a_n), and a reject indicates that $t_n > \delta_k$. Note that the observation model depends on how we assume the agent acts, which is a function of its internal hidden reward and the offered incentive. Since we assumed that the agent is myopically greedy, the agent will accept an incentive if the sum of offered incentive and the agent's internal reward is greater than the agent's hidden reward for its default action choice. The initial belief in the POMDP is given by P_0. Computing the optimal policy for this POMDP will enable the principal to optimally offer (a_n, δ_k) pairs that balance reducing the uncertainty over the agent's hidden true incentives I with minimizing the expected cost to the principal, given the current belief state over I.

However, computing an optimal policy for a POMDP can take doubly exponential time and existing methods often struggle to scale to large state or action spaces or long time horizons, all of which can feature in IDPs.

Fortunately there is significant structure in IDPs. We will now show how we can leverage this structure to reduce the problem to simpler decision processes, and we will present efficient algorithms for computing exact or boundedly-optimal policies.

5 Single Alternate Agent Action IDPs

We first consider IDPs when there is a single alternate action a_1. It is known that a POMDP can be reduced to a continuous state MDP where each state represents a belief: note that since the states are probability distributions, the MDP has an infinite state space. Here we show the surprising result that a single alternate agent action IDP can be reduced to a polynomially sized MDP, which means they can be solved much more efficiently than standard POMDPs.

We first describe how to perform belief updating in a single alternate agent action IDP. Let the possible range of incentives for alternate agent action a_1 be $S_1 = [s_1, e_1]$ if and only if $\delta_{s_1} \leq t_1 \leq \delta_{e_1}$. $S = [S_1, \cdots, S_N]$ are the incentive ranges for all alternate agent actions; for $N = 1$, $S = S_1$. We are interested in maintaining the probability that $t_1 = \delta_i$ for all $\delta_i \in \Delta$. Given the initial probability distribution P_0, we can directly compute the initial incentive range S_1. The initial probability that $t_1 = \delta_i$ is

$$p_{1,S}(\delta_i) = \frac{P_0(\delta_i)\mathbb{1}(\delta_i, S)}{\sum_{k=1}^{K} P_0(\delta_k)\mathbb{1}(\delta_k, S)}, \quad (1)$$

where $\mathbb{1}(\delta_i, S) = 1$ if $\delta_{s_1} \leq \delta_i \leq \delta_{e_1}$ (if incentive δ_i is within the possible incentive range), and, with a slight abuse of notation, we use $P_0(\delta_i)$ to represent the initial probability that the agent's $t_1 = \delta_i$. Note that initially the denominator will be 1, because the range will cover all incentives δ_i for which $P_0(\delta_i) > 0$. On the first time step the principal will offer the agent an incentive δ_i to take the alternate agent action a_1. If the agent accepts, the principal knows that $t_1 \leq \delta_i$, due to the assumed monotonic structure of the incentives and the greedy myopic agent behavior. Therefore the new possible incentive range if the agent accepts δ_i is $S_1 = [s_1, i]$, since the upper bound on the possible index is at most i. If the agent rejects the offered incentive, then $t_1 > \delta_i$ and so the new incentive range must be $S_1 = [i{+}1, e_1]$. In either case the new probability of the agent accepting a particular incentive δ_j is identical to Equation 1 using the updated incentive range S_1.

Each offered incentive, and associated agent response, can set the probability of some incentives to zero. Since t_1 is static, we prove it is sufficient to maintain and update S_1 in order to compute the current $p_{1,S}(\delta_j)$ given the history of offered incentives and agent responses. Therefore, the belief state over the agent's incentive t_1 will be of the form $B^1_{i,j} = (0, \cdots, 0, p^1_{i,S}, \cdots, p^1_{j,S}, 0, \cdots, 0)$ where $S_1 = (i, j)$ and $p^1_{j,S} = p_{1,S}(\delta_j)$. We will shortly prove that there are only $O(K^2)$ possible such states.

Before we do so, we first note that an IDP-MDP is an instance of a deterministic POMDP, since the observations are a deterministic function of the underlying agent's preferences, and the transition model is a delta function because these preferences are assumed to be static. Prior work [7, 2] has proved that a deterministic POMDP with N_s states can be converted to a finite-state MDP with a number of states that is an *exponential function* $((1 + N_s)^{N_s})$ of the number of POMDP states. This is significantly smaller MDP than generic POMDPs which map to a MDP with an infinite number of states. However, we will show that an IDP with $N = 1$ can be mapped to a MDP with $B^1_{i,j}$ as the MDP states. We now prove that the resulting MDP has a number of states that is only a *polynomial* function of the number of POMDP states (K).

Theorem 5.1. *An IDP with $N = 1$ alternate agent actions is equivalent to an MDP with $O(K^2)$ states.*

Proof. We see that $B^1_{1,K}$ is the initial state of the IDP-MDP. Suppose $B^1_{i,j}$ is the current state. Consider the case where incentive δ_k is offered. The agent might either accept or reject the incentive. As stated, the agent's response to each offer can eliminate certain range of the incentives but the ratio amongst the remaining ones does not change. If the agent accepts the incentive, the new probability vector will be $B^1_{i,k}$ since the response indicates that $t_1 \in [\delta_i, \delta_k]$, otherwise if the agent rejects the incentive, the new probability vector will be $B^1_{k+1,j}$, since $t_1 \in [\delta_{k+1}, \delta_j]$. Hence, by induction, at the t^{th} step, the probability vector is of the form $B^1_{i,j}$ and only states of this form are reachable from the initial probability vector. Now i and j can each take on at most K values, so the maximum number of possible $B^1_{i,j}$ is at most $O(K^2)$. Therefore the number of belief states is bounded by $O(K^2)$ and therefore the IDP with one alternate agent action can be reduced to a MDP with $O(K^2)$ states. □

We now define the IDP-MDP for a single alternate agent action. We use $v(l)$ to denote the l-th element of a vector v. The state space is the $B^1_{i,j}$ vectors just described. The action space is the incentive space Δ. The MDP transition model is the probability of transitioning from one $B^1_{i,j}$ to other belief states after the principal offers the agent an incentive. For a given

Return $[V^h(B^1_{i,j}), V, \pi]$

state $B^1_{i,j}$, and a given offered incentive δ_k, with probability $\sum_{i \le l \le k} B^1_{i,j}(l)$ the agent will accept the offer and the new state will be $B^1_{i,k}$, and with probability $1 - \sum_{i \le l \le k} B^1_{i,j}(l)$ the agent will reject the offer, and the new state will be $B^1_{k+1,j}$. The cost model of the MDP takes the form $c(B^1_{i,j}, \delta_k, B^1_{i,k}) = \delta_k + c_1$ for transitions where the agent accepts the incentive, and $c(B^1_{i,j}, \delta_k, B^1_{k+1,j}) = c_2$ when the agent rejects.

We now show the special structure of this problem allows us to introduce more efficient planning algorithms that require only $O(K^3)$ and $O(min(H, K)\, K^3)$ computation time for the infinite and finite horizon case, respectively. First note that the principal only needs to consider offering incentives δ_k within the range of $i \le k \le j$ for a state $B^1_{i,j}$, as other incentives will be automatically rejected (or accepted but at higher cost than necessary for the principal). We start by considering the infinite horizon case. Let the expected sum of discounted costs of state $B^1_{i,j}$ be $V(B^1_{i,j})$. We define a MDP state s to be non-recurring with respect to a policy π if the state can only be reached once while executing the π. A state s of the MDP is called self-absorbing if executing π from s results in a self-transition to state s with probability 1. A policy π is NonRecur-Absorb if each MDP state is either non-recurring or self-absorbing with respect to π.

First recall that for an infinite horizon MDP, there always exists an optimal policy that is stationary (the decision depends on only the current state and is independent of the time step). Therefore we will consider only stationary policies. Next note that for an infinite horizon IDP-MDP, if incentive δ_j is offered in state $B^1_{i,j}$, then the MDP remains in same state $B^1_{i,j}$. If one of the other possible actions (offering incentives $\delta_i, \cdots, \delta_{j-1}$) is taken, then the MDP will transition to a new state, and will never return to the state $B^1_{i,j}$ since the number of non-zero entries in the probability vector $B^1_{i,j}$ monotonically decreases. This implies all infinite-horizon policies for an IDP-MDP are NonRecur-Absorb. As each state can only be reached once (or is an absorbing state) during execution, we only need to compute a Bellman backup for the state-action values Q once for each state-action pair. We compute a decision policy by computing the state-action values of the initial state by recursively computing the value of each reachable state. The values of subsequent states are stored and cached so that they can be re-used if the same state is reached through a different trajectory of offered incentives and responses. There are $O(K^2)$ MDP states and $O(K)$ actions for each state, so there are $O(K^3)$ state-action pairs. The cost of computing the Bellman backup for a given state-action pair can be done in constant time given the values of the possible next states (since there are only at most 2 possible next states). Therefore the algorithm takes $O(K^3)$ time. Note this is significantly faster than value iteration on generic MDPs with N_s states and N_a actions which requires $O(\frac{N_a N_s^2}{1-\gamma})$ time to compute a near-optimal policy.

For the finite horizon case, let $V^h(B^1_{i,j})$ denote the expected sum of costs to the principal for state $B^1_{i,j}$ for a horizon of h future interactions with the agent. Every policy is not NonRecur-Absorb because the principal could offer the same incentive for multiple time steps (staying in the same state) and then offer a new incentive and transition to another state. However, we can prove the following result:

Theorem 5.2. *There exists an optimal policy for an* IDP-MDP *with* $N = 1$ *that is* NonRecur-Absorb.

The proof intuition is that we can always re-order an optimal policy so that it only offers incentives that keep the MDP in the same state at the final time steps.

The algorithm for the finite horizon case is displayed in Algorithm 1. Here the state's value and policy will depend on the time step. Each time the horizon decreases, either a state becomes self-absorbing with a cost of $\delta_j h$ or least one non-zero element of the probability vector $B^1_{i,j}$ becomes zero. Since the initial state $B^1_{1,K}$ has K non-zero elements, it will take at most K time steps until a state is reached

which is self-absorbing (as all single-element beliefs are self-absorbing). Therefore, the algorithm takes $O(min(H, K)\, K^3)$ running time

6 Multiple Alternate Action IDPs

We next consider IDPs with multiple alternate agent actions, namely $N > 1$. We now need to maintain a belief state over the joint of the alternate agent actions crossed with the incentives. As stated in the definition of the IDP, we assume we are provided with an initial probability distribution over the true incentives t_n for each alternate action a_n, P_0. We know from the prior section that all beliefs for an $N = 1$ IDP are of the form $B^1_{i,j} = (0, \cdots, 0, p^1_{i,S}, \cdots, p^1_{j,S}, 0, \cdots, 0)$ where $S_1 = (i, j)$. We now extend the model to handle multiple actions. Let $B_S = (B^n_S)\,|^N_{n=1}$ where B^n_S denotes the probability vector $(0, \cdots, 0, p^n_{i,S}, \cdots, p^n_{j,S}, 0, \cdots, 0)$ where $S_n = (i, j)$ and $p^n_{i,S}$ is the probability that $t_n = \delta_i$ given the initial joint distribution P_0 and the possible incentive ranges S_n for each alternate agent action. $S_n = (s_n, e_n)$, for all $n \in \{1, \cdots, N\}$.

Theorem 6.1. *The number of states of* IDP-MDP *for $N > 1$ is $O(K^{2N})$ states.*

Proof. Assume that the current state is B_S, where $S_n = (s_n, e_n)$ for $1 \le n \le N$. Consider the case where incentive δ_i is offered for action a_n. The agent will accept this offer with the probability that its true incentive t_n for a_n is $\le \delta_i$, which is equal to $\sum_{j \le i} p^n_{j,S}$. If the offer is accepted, then $s_n \le t_n \le i$, which implies $S_n = (s_n, i)$. In addition, all alternate agent actions $m > n$ with higher agent reward than alternate agent action a_n will also all accept t_n, so the incentive range of all such actions will also be updated $S_m = (s_m, i)$ for all $m > n$. This defines a new S, which together with P_0, completely defines the new distribution over the probability of each incentive for each alternate agent action. If the agent rejects the offered incentive, then $s_n \ge i + 1$, and so $S_n = (i + 1, e_n)$. All alternate agent actions $m < n$ with a lower agent reward than action a_n will also reject the reward, which results in $S_m = (i + 1, e_m)$ for all $m < n$. There are N alternate agent actions, and we know from Theorem 5.1 that there are at $O(K^2)$ states per individual action, therefore there are at most $O(K^{2N})$ possible states. Due to the relationship among the agent costs and rewards, this number will often be much lower. □

An IDP with $N > 1$ alternate agent actions has many of the same properties as an IDP with $N = 1$ actions, and therefore we can use algorithms similar to those described in the prior section (see the text and Algorithm 1) to solve the IDP-MDP with $N > 1$. Excluding the cost for the belief updates, this requires $O(NK^{2N+1})$ and $O(min(H, NK)K^{2N+1})$ computation time for the infinite and finite horizon case, respectively. While this is computationally tractable for small N, this scales poorly as N increases.

To address this, we will now provide efficient approximate algorithms for computing a decision policy in IDPs with large N. Note that computing the probability of the next possible states, given an offered incentive δ_k for alternate agent action a_n involves computing the marginal probabilities $p^n_{k,S}$ that $t_n = \delta_k$ given the current S. This is an $O(K^N)$ operation due to summing over all other action-incentive probabilities. Hence, any approximation algorithm will take at least $O(K^N)$ time due to the bottleneck of belief updating. This cost can be reduced by assuming structure in the joint probability distribution, such as using graphical models with bounded treewidth. We leave further exploration of this issue for future work.

We now define a new special form of a Markov decision process. Let a SEQ-MDP be an IDP-MDP with $N > 1$ with the following additional restrictions on the allowable principal's actions at different states:

1. For the initial state, the principal can offer any incentive for only alternate agent action a_1 (assuming that initially $S_1 = (s_1, e_1)$ and $s_1 \ne e_1$).

2. For any other state, the principal can offer any incentive for alternate agent action a_n, only when $S_i = (s_i, e_i)$ and $e_i = s_i$ for all $i < n$. In other words, t_i must be known for all alternate agent actions $i < n$ before the principal can offer an incentive for a_n.

A SEQ-MDP restricts the possible decision policy set Π to policies that only provide incentives for alternate agent actions with higher cost to the principal only after finding the true incentive for the lower cost actions. Note that the SEQ-MDP policy may not identify the true incentive for all actions, but can decide to stick with a previously identified a_n, δ_k pair.

We now analyze the number of states in a SEQ-MDP. Consider that at the present state the principal is offering incentives for alternate agent action a_n. We know that $S_i = (s_i, e_i)$ for $i > n$ and $s_i = e_i$ for $i < n$. Define $c_i + \delta_j$ as the minimum action cost + true incentive across all $i < n$. Since we would never take any other $i' < n$ with a higher cost, $c_i + \delta_j$ is sufficient to summarize all useful information from prior offered actions. Therefore we can represent a state in the SEQ-MDP as the tuple (a_i, δ_j, B_{S_n}). For each offered alternate agent action, there can be $O(K^2)$ states, as in the IDP-MDP with $N = 1$. We also must track the current minimal cost alternate agent action and offered incentives, and there are $O(NK)$ such combinations. Finally we also have to monitor

the current alternate agent action, and there are $O(N)$ possibilities. The product of these quantities yields a state space of $O(N^2K^3)$. For similar arguments as given in Section 5, we can construct optimal policies that are NonRecur-Absorb for SEQ-MDP and use planning methods similar to those described in Section 5. There are $O(K)$ possible actions for each state in a SEQ-MDP. Therefore, again excluding costs for computing the marginal probabilities, the computational cost of computing an optimal infinite-horizon policy for a SEQ-MDP is $O(N^2K^4)$, and the finite horizon H cost is $O(\min(H, NK)N^2K^4)$.

We now prove that computing the optimal policy for a SEQ-MDP yields a boundedly-optimal policy for the original IDP-MDP with $N > 1$.

Theorem 6.2. *An optimal policy for a* SEQ-MDP *that is a transformation of an* IDP-MDP *with $N > 1$, has an expected cost V^{seq} which is bounded by $V^{seq} = V^* + \sum_{k=1}^{K}(\delta_k - \delta_1) + N(c_{N+1} - c_1)$, where V^* is the optimal value for the* IDP-MDP.

Proof. We will make a constructive argument by providing a policy $\pi \in \Pi$ that realizes the bound V^{seq}. Consider a policy π that starts with the lowest cost action, and offers the highest possible incentive. The policy proceeds by sequentially decreasing the offered incentive δ_k for alternate agent action a_1 until the agent rejects the offered incentive. Let this highest incentive at which the agent rejects be δ_{j-1}. That means that the true incentive t_1 for alternate agent action a_1 is δ_j. Since a_1 is the lowest cost and lowest reward alternate action, we know that δ_j will be accepted for all other alternate agent actions $i > 1$, since all such actions yield higher reward to the agent. Therefore we need not offer δ_j for any other agent actions. The policy then moves on to offering incentives for alternate agent action a_2, starting with offering δ_{j-1}. The policy again continues to incrementally decrease the offered incentive until it reaches a reject, at which it then starts to provide incentives for a_3, and so on. The policy is similarly defined for all subsequent alternate agent actions. The defined policy π operates only on the SEQ-MDP version of the IDP-MDP.

Note that after the principal makes an offer, either an incentive for a particular action, or a particular incentive for all actions can be eliminated. Since there can at most be K accepts, and at most N rejects (as at most one offer can be rejected for each action), there are at most $K + N$ steps.

Each of the at most N rejected offers will cause the algorithm to incur at most $c_{N+1} - c_1$ additional cost compared to the optimal policy, since the principal will pay the cost of the default action c_{N+1}. Each offer that was accepted that is above the true incentive will result in an additional cost of at most $\delta_i - \delta_1$. Note that each incentive δ_i is offered only once if it is accepted for an action a_n. Therefore, the total cost is bounded by $V^{seq} = V^* + N(c_{N+1} - c_1) + \sum_{k=1}^{K}(\delta_k - \delta_1)$. This is true irrespective of the distribution over incentives. It can be easily seen that the policy $\pi \in \Pi$, as required. □

This bound does not use any information about the probability distribution. A tighter bound using the probability distribution can be obtained but is not presented here for ease of exposition. Also, an alternate algorithm with bound $V^* + K(c_{N+1} - c_1) + \sum_{i=1}^{N}(c_N - c_i)$ is possible by starting from action a_N rather than a_1 and progressing to lower cost actions only after identifying the true incentive for the higher cost actions. An argument similar to the one made in Theorem 6.2 can be used to prove this bound. In next section, our empirical results show the optimal policy for a SEQ-MDP performs well in practice.

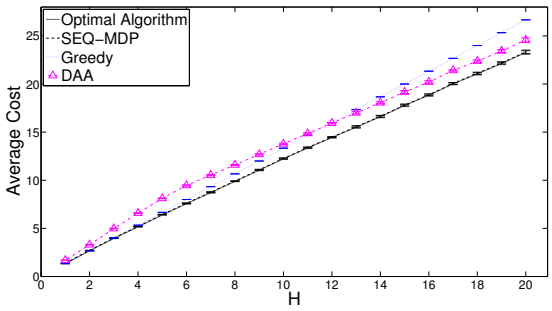
7 Experiments

We now empirically evaluate our algorithms.

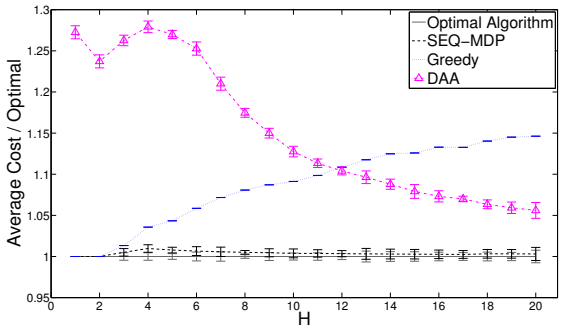
In our simulations the cost of the default agent action was set to $c_{N+1} = 2$. For N alternate agent actions, the cost to the principal of the agent taking action a_n was set to $c_n = \left(\frac{n}{N}\right)^{\eta}$ where η is a constant. For K incentives, the value of the k-th incentive was $\delta_k = k/K$. Note the maximum cost of the alternate agent actions is 1, and the maximum incentive is 1. Therefore the cost to the principal of an agent accepting an incentive $c_n + \delta_k$ is always less than or equal than the cost to the principal of the agent's default action c_{N+1}, as our IDP model assumed (Section 4). The initial belief was set to a uniform joint distribution over the possible incentive-alternate agent action space: recall that this distribution must always respect the constraints that $t_i \geq t_j$ for $i < j$ since $R_{a_i} < R_{a_j}$. In each experimental run we fixed K,N,η and the horizon H, and sampled a true hidden vector of incentives for the agent from the initial belief. We then executed the policy of each algorithm and recorded the total cost accumulated over H steps. We simulated 1000 runs and averaged over each run's total sum of costs. We repeated this for 10 rounds (each of 1000 runs) and computed the standard deviation error bars for the average total cost.

We compare the performance of our algorithms to two natural methods. The first is a greedy algorithm. In the greedy algorithm, given a current state B_S (with $S_n = (s_n, e_n)$), the principal offers the incentive δ_k for alternate action a_n that minimizes the expected immediate cost to the principal,

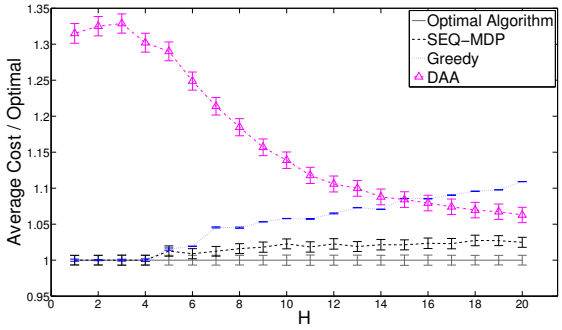
$$[\delta_k, a_n] = \underset{\delta_k, a_n}{\operatorname{argmin}} \sum_{k'=s_n}^{k} p^n_{k',S}(\delta_k + c_n) + \sum_{k'=k+1}^{e_n} p^n_{k',S}(c_{N+1}).$$



(a) Avg total cost over H (w/1 std. error bars).$N = 3, K = 5$.



(b) Ratio of avg. total cost to optimal. $N = 3, K = 5$.

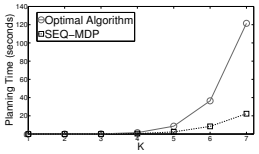


(c) Ratio of costs. $N = 5, K = 3$.

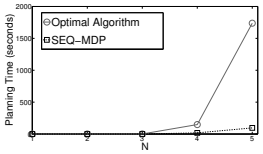
Figure 1: Average total cost for varying horizons H.

The second method first uses a binary-search-like procedure, starting from a_1, to identify the true incentive for each alternate agent action. It then selects the alternate agent action, and incentive, with the lowest immediate cost, and then offers that for all remaining steps. We label this algorithm "diagnose-and-act (DAA)." It should be noted that DAA can be viewed as a first running a simple inverse reinforcement learning approach.

Figure 1(a) displays the average total cost incurred for different horizons for $N = 3$ alternate agent actions, and $K = 5$ incentives. Here we set $\eta = 1$ and $N \leq 5$ but results from varying η (from 0.75 to 1.25) and N yielded similar results. As expected, the optimal policy performs best for all horizons. To better explore the difference between the algorithms, we replotted the results by dividing by the optimal algorithm's average total cost at each horizon H, resulting in a figure where the optimal algorithm is always 1, and all other algorithms are displayed as their ratio to the optimal performance (see Figure 1(b)). For low horizons the greedy algorithm performs very close to optimal, because there is little benefit to gathering information to find a lower cost alternate since there is little time to use such information. However, as H increases, greedy performs significantly worse than the optimal algorithm. DAA algorithm performs poorly at low horizons because it tries to identify the optimal incentive for each action, and this can take longer than the available horizon to accomplish. At larger horizons DAA performs better. For very large horizons we expect that DAA would converge to the performance of the optimal policy: in such cases the loss incurred from not identifying the best action-incentive pair will likely become very high, meaning that it will be optimal to identify the minimal cost incentive.



(a) $N = 3$, $H = 20$



(b) $K = 4$, $H = 20$

Figure 2: Planning time (sec) as a function of K or N for the optimal algorithm and SEQ-MDP.

The SEQ-MDP approach has very good performance. Indeed it is was visually and statistically indistinguishable from the optimal algorithm for all horizons H for $K = 5, N = 3$. SEQ-MDP is not always identical to the optimal algorithm's performance: for example, in Figure 1(c) we display results for $K = 3$ and $N = 5$. Here there are a larger number of possible incentive-action combinations (3^5) relative to the available horizon, and so consecutively stepping through the alternate agent actions may not be the optimal strategy.

However SEQ-MDP performs very close to the optimal algorithm's performance, and it is significantly better than other approaches. The SEQ-MDP approximation also requires much less computation time than the optimal algorithm. Figures 2(a) and 2(b) compare the average computational time to execute a single run ($H = 20$). Figure 2(a) fixes the number $N = 3$ of alternate agent actions, and varies the number of offered incentives K, and Figure 2(b) fixes $K = 4$ and varies N. The SEQ-MDP algorithm scales much better than the optimal algorithm in both cases.

8 Discussion and Extensions

So far we have focused on Incentive Decision Processes where a principal interacts with a myopic greedy agent whose preferences are hidden and static. Here we briefly consider two extensions of this model.

Dynamic Preferences: In many real applications the agent's preferences will change over time, and the principal may not know if the agent's preferences have changed. This significantly complicates the decision problem. One important common class of dynamic changes is where the preferences change locally. For example, a tenant's thermal preferences may locally shift during seasonal changes. Let us assume that if true incentive t_n for alternate agent action a_n is δ_k, then t_n remains the same with probability λ_0, shifts to δ_{k+d} with probability λ_1, and shifts to δ_{k-d} with probability λ_2 after each potential preference change[2]. We will restrict our attention to the case where the maximum number of times the agent might change its preferences is at most L. For simplicity we will also assume that we know the time epochs at which changes can occur, but our results also apply when we do not have prior information about these time epochs. Similarly, we will state our results for $N = 1$ but these results can be extended to $N > 1$.

Such dynamic preference IDPs can be represented as a POMDP with $O(K^3)$ states: in a static IDP there are $O(K^2)$ belief states; a change in preference shifts the non-zero elements of the belief state; there are at most $O(K)$ possible shifts; and as we don't know whether a shift occurs or not, this becomes the hidden state of our POMDP. Interestingly, we can reduce this POMDP to a finite state MDP:

Theorem 8.1. *A dynamic preference IDP ($N=1$) can be represented as a MDP with $O(K^{2(L+1)})$ states.*

This result is significant because we have mapped a non-deterministic POMDP to a finite state MDP. While a similar result is known to hold for deterministic POMDPs, it does not hold for general POMDPs, which typically map to a MDP with an infinite number of states. It is important to emphasize that this result holds for infinite horizon dynamic preference IDPs.

We believe that substantial further reductions in the state space may be possible with minimal performance loss since each possible change is local and small.

Rational Strategic Agents: Often the agent itself will seek to optimize its long term expected sum of rewards, reasoning about the potential future incentives the principal might provide if the agent chooses to accept or reject different offers. In such situations, the previous reduction to a MDP will no longer hold because the principal cannot trust that the agent's responses reflect its true hidden incentives.

Many of the policies we have considered so far will provide a higher incentive when an offer is rejected, and a lower incentive if the offer is accepted. Let us denote such policies π^{simple}. Such policies are strategy proof for a horizon of $H = 1$:

Theorem 8.2. *The agent will act truthfully for $H=1$.*

Indeed it is fairly easy to see that acting truthfully will always maximize the agent's immediate reward. However, this does not hold for longer horizons.

Theorem 8.3. *π^{simple} is not a strategy proof policy for arbitrary horizons.*

The proof provides an example of a $H = 2$ IDP where the agent can increase its reward by acting in discord with its true preferences. In the future we intend to develop algorithms for automatically constructing equilibrium decision policies for the principal and agent, and to design strategy proof policies.

Other directions: There are multiple other extensions to the Incentive Design Problems we have considered in this paper. Another interesting variant is when there are multiple agents (say U), and the principal can only provide incentives to 1 agent at each time step. It can be shown that an approach similar to binary search will lead to an $O((c_2-c_1)U \log K)$ additive bound with respect to the optimal algorithm in case of single alternate action. Interestingly, this problem can also be reduced to multi-arm bandit (MAB) problem with superprocesses [8]. Though computing optimal policies for superprocess MABs is generally difficult, it may be possible to leverage the IDP structure to compute efficient algorithms. We also plan to use IDPs to construct personalized adaptive incentives for reducing energy consumption.

9 Conclusion

We have introduced Incentive Decision Processes, where the objective is to compute a decision policy for a principal to minimize its expected sum of costs by providing incentives to a myopic agent. If the agent's hidden preferences are static, then we can represent an IDP (either exactly for 1 alternate action, or approximately for multiple actions) as a polynomially-sized Markov decision process, instead of as a standard POMDP. Our empirical results showed our sequential decision theoretic techniques significantly outperform simpler comparison algorithms.

Abstract

In standard passive imitation learning, the goal is to learn a target policy by passively observing full execution trajectories of it. Unfortunately, generating such trajectories can require substantial expert effort and be impractical in some cases. In this paper, we consider active imitation learning with the goal of reducing this effort by querying the expert about the desired action at individual states, which are selected based on answers to past queries and the learner's interactions with an environment simulator. We introduce a new approach based on reducing active imitation learning to i.i.d. active learning, which can leverage progress in the i.i.d. setting. Our first contribution, is to analyze reductions for both non-stationary and stationary policies, showing that the label complexity (number of queries) of active imitation learning can be substantially less than passive learning. Our second contribution, is to introduce a practical algorithm inspired by the reductions, which is shown to be highly effective in four test domains compared to a number of alternatives.

1 Introduction

Traditionally, passive imitation learning involves learning a policy that performs nearly as well as an expert's policy based on a set of trajectories of that policy. However, generating such trajectories is often tedious or even impractical for an expert (e.g. real-time low-level control of multiple game agents). In order to address this issue, we consider active imitation learning where full trajectories are not required, but rather the learner asks queries about specific states, which the expert labels with the correct actions. The goal is to learn a policy that is nearly as good as the expert's policy using as few queries as possible.

The active learning problem for i.i.d. supervised learning has received considerable attention both in theory and practice (Settles, 2009), which motivates attempting to leverage that work for active imitation learning. However, the direct application of i.i.d. approaches to active imitation learning can be problematic. This is because i.i.d. active learning algorithms assume access to either a target distribution over unlabeled input data (in our case states) or a large sample drawn from it. The goal then is to select the most informative query to ask, usually based on some combination of label (in our case actions) uncertainty and unlabeled data density. Unfortunately, in active imitation learning, the learner does not have direct access to the target state distribution, which is the state distribution induced by the unknown expert policy.

In principle, one could approach active imitation learning by assuming a uniform or an arbitrary distribution over the state space and then apply an existing i.i.d. active learner. However, such an approach can perform very poorly. This is because if the assumed distribution is considerably different from that of the expert, then the learner is prone to ask queries in states rarely or even never visited by the expert. For example, consider a bicycle balancing problem. Clearly, asking queries in states where the bicycle has entered an unavoidable fall is not very useful because no action can prevent a crash. However, i.i.d. active learning technique will tend to query in such uninformative states, leading to poor performance, as shown in our experiments. Furthermore, in the case of a human expert, a large number of such queries poses serious usability issues, since labeling such states is clearly a wasted effort from the expert's perspective.

In this paper, we consider the problem of reducing active imitation learning to i.i.d. active learning both in theory and practice. Our first contribution is to analyze the PAC label complexity (number of expert queries) of a reduction for learning non-stationary policies, which requires only minor modification to exist-

ing results for passive learning. Our second contribution is to introduce a reduction for learning stationary policies resulting in a new algorithm *Reduction-based Active Imitation Learning (RAIL)* and an analysis of the label complexity. The resulting complexities for active imitation learning are expressed in terms of the label complexity for the i.i.d. case and show that there can be significant query savings compared to existing results for passive imitation learning. Our third contribution is to describe a new practical algorithm, RAIL-DW, inspired by the RAIL algorithm, which makes a series of calls to an i.i.d. active learning algorithm. We evaluate RAIL-DW in four test domains and show that it is highly effective when used with an i.i.d. algorithm that takes the unlabeled data density into account.

2 Related Work

Active learning has been studied extensively in the i.i.d. supervised learning setting (Settles, 2009) but to a much lesser degree for sequential decision making, which is the focus of active imitation learning. Several studies have considered active learning for *reinforcement learning (RL)* (Clouse, 1996; Mihalkova and Mooney, 2006; Gil et al., 2009; Doshi et al., 2008), where learning is based on both autonomous exploration and queries to an expert. Rather, in our imitation learning framework, we do not assume a reward signal and learn only from expert queries. Other prior work (Shon et al., 2007) studies active imitation learning in a multiagent setting where the expert is itself a reward seeking agent and hence is not necessarily a helpful expert. Here we consider only helpful experts.

One approach to imitation learning is *inverse RL (IRL)* (Ng and Russell, 2000), where a reward function is learned based on a set of target policy trajectories. The learned reward function and transition dynamics are then given to a planner to obtain a policy. There has been limited work on active IRL. This includes a Bayesian approach (Lopes et al., 2009), where a posterior over reward functions is used to select a "most informative" query. Another Bayesian approach (Cohn et al., 2010) models uncertainty about the entire MDP model and uses Expected Myopic Gain (EMG) to select a query about transition dynamics and rewards. While promising, the scalability of these approaches is hindered by the assumptions made by IRL and have only been demonstrated on small problems. In particular, they require that the exact domain dynamics are provided or can be learned and that an efficient planner is available.

To facilitate scalability, rather than follow an IRL framework we consider a *direct imitation* framework where we attempt to directly learn a policy instead of the reward function and/or transition dynamics. Unlike inverse RL, this framework does not require an exact dynamic model nor an efficient planner. Rather, our approach requires only a simulator of the environment dynamics that is able to generate trajectories given a policy. Such a simulator is often available, even when a compact description of the transition dynamics and/or a planner are not.

Recent active learning work in the direct imitation framework includes confidence based autonomy (Chernova and Veloso, 2009), and the related dogged learning framework (Grollman and Jenkins, 2007), where a policy is learned as it is executed. When the learner is uncertain about what to do at a state, the policy is paused and the expert is queried about what action to take, resulting in a policy update. One difficulty in applying this approach is setting the uncertainty threshold for querying the expert. While an automated threshold selection approach is suggested (Chernova and Veloso, 2009), our experiments show that it is not always effective. Like our work, this approach requires a dynamics simulator.

Recently, Ross and Bagnell (2010); Ross et al. (2011) proposed algorithms for imitation learning that are able to actively query the expert at particular states during policy execution. They show that under certain assumptions these algorithms have better theoretical performance guarantees than pure passive imitation learning. Unfortunately, these algorithms query the expert quite aggressively making them impractical for human experts or computationally expensive with automated experts. In contrast, our work focuses on active querying for the purpose of minimizing the expert's labeling effort. Like our work, they also require a dynamics simulator to help select queries.

3 Problem Setup and Background

We consider imitation learning in the framework of Markov decision processes (MDPs). An MDP is a tuple $\langle S, A, T, R, I \rangle$, where S is the set of states, A is the finite set of actions, $T(s, a, s')$ is the transition function denoting the probability of transitioning to state s' upon taking action a in state s, $R(s) \in [0, 1]$ is the reward function giving the immediate reward in state s, and I is the initial state distribution. A stationary policy $\pi : S \mapsto A$ is a deterministic mapping from states to actions such that $\pi(s)$ indicates the action to take in state s when executing π. A non-stationary policy is a tuple $\pi = (\pi_1, \ldots, \pi_T)$ of T stationary policies such that $\pi(s, t) = \pi_t(s)$ indicates the action to take in state s and at time t when executing π, where T is the time horizon. The expert's policy, which we assume is deterministic, is denoted as π^*.

The T-horizon value of a policy $V(\pi)$ is the expected total reward of trajectories that start in $s_1 \sim I$ at

time $t = 1$ and then execute π for T steps. We use d_π^t to denote the state distribution induced at time step t by starting in $s_1 \sim I$ and then executing π. Note that $d_\pi^1 = I$ for all policies. We use $d_\pi = \frac{1}{T}\sum_{t=1}^{T} d_\pi^t$ to denote the state distribution induced by policy π over T time steps. To sample an (s, a) pair from d_π^t, we start in $s_1 \sim I$, execute π to generate a trajectory $\mathcal{T} = (s_1, a_1, \ldots, s_T, a_T, s_{T+1})$ and set $(s, a) = (s_t, a_t)$. Similarly, to sample from d_π, we first sample a random time step $t \in \{1, \ldots, T\}$, and then sample an (s, a) pair from d_π^t. Note that in order to sample from d_{π^*} (or $d_{\pi^*}^t$), we need to execute π^*. Throughout the paper, we assume that the only way π^* can be executed is by querying the expert for an action in the current state and executing the given action, which puts significant burden on the expert.

The regret of a policy π with respect to an expert policy π^* is equal to $V(\pi^*) - V(\pi)$. In imitation learning, the goal is to learn a policy π from a hypothesis class H (e.g. linear action classifiers), that has a small regret. In the passive setting of imitation learning, the learner is provided with a training set of full execution trajectories of π^* and the state-action pairs (or a sample of them) are passed to an i.i.d. supervised learning algorithm. To help avoid the cost of generating full trajectories, active imitation learning allows the learner to pose *action queries*. In an action query, a state s is presented to the expert and the expert returns the desired action $\pi^*(s)$.

In addition to having access to the expert for answering queries, we assume that the learner has access to a simulator of the MDP. The input to the simulator is a policy π and a horizon T. The simulator output is a state trajectory that results from executing π for T steps starting in the initial state. The learner is allowed to interact with this simulator as part of its query selection process. The simulator is not assumed to provide a reward signal, which means that the learner cannot find π by pure reinforcement learning.

Since our analysis in the next two sections is based on reducing to i.i.d. active learning and comparing to i.i.d. passive learning, we briefly review the *Probably Approximately Correct (PAC)* (Valiant, 1984) learning formulation for the i.i.d. setting. Here we consider the realizable PAC setting, which will be the focus of our initial analysis. Section 4.3, extends to the non-realizable, or agnostic setting. In passive i.i.d. supervised learning, N i.i.d. data samples are drawn from an unknown distribution $D_\mathcal{X}$ over an input space $\mathcal{X}$ and are labeled according to an unknown target classifier $f : \mathcal{X} \mapsto \mathcal{Y}$, where $\mathcal{Y}$ denotes the label space. In the realizable PAC setting it is assumed that f is an element of a known class of classifiers H and given a set of N examples a learner then outputs a hypothesis $h \in H$. Let $e_f(h, D_\mathcal{X}) = \mathbb{E}_{x \sim D_\mathcal{X}}[h(x) \neq f(x)]$ denote the generalization error of the returned classifier h. Standard PAC learning theory provides a bound on the number of labeled examples that are sufficient to guarantee that for any distribution $D_\mathcal{X}$, with probability at least $1-\delta$, the returned classifier h will satisfy $e_f(h, D_\mathcal{X}) \leq \epsilon$. We will denote this bound by $N_p(\epsilon, \delta)$, which corresponds to the label/query complexity of i.i.d. passive supervised learning for a class H. We will also denote a passive learner that achieves this label complexity as $L_p(\epsilon, \delta)$.

In i.i.d. active learning, the learner is given access to two resources rather than just a set of training data: 1) A "cheap" resource (Sample) that can draw an unlabeled sample from $D_\mathcal{X}$ and provide it to the learner when requested, 2) An "expensive" resource (Label) that can label a given unlabeled sample according to target concept f when requested. Given access to these two resources, an active learning algorithm is required to learn a hypothesis $h \in H$ while posing as few queries to Label as possible. It can, however, pose a much larger number of queries to Sample (though still polynomial) as it is cheap. We use $N_a(\epsilon, \delta)$ to denote the label complexity (i.e. number of calls to Label) that is sufficient for an active learner to return an h that for any $D_\mathcal{X}$ with probability at least $1 - \delta$ satisfies $e_f(h, D_\mathcal{X}) \leq \epsilon$. Similarly, we will denote an active learner that achieves this label complexity as $L_a(\epsilon, \delta, D)$, where the final argument D indicates that the Sample function used by L_a samples from distribution D. It has been shown that often N_a can be exponentially smaller than N_p for hypothesis classes with bounded complexity (e.g. VC-dimension). In particular, in the realizable case, ignoring δ, $N_p = O(\frac{1}{\epsilon})$ whereas $N_a = O(\log(\frac{1}{\epsilon}))$ giving exponential improvement in label complexity over passive learning.

4 Reductions for Active Imitation Learning

We now consider reductions from active imitation learning to active i.i.d. learning for the cases of deterministic non-stationary and stationary policies.

4.1 Non-Stationary Policies

Syed and Schapire (2010) analyze the traditional reduction from passive imitation learning to passive i.i.d. learning for non-stationary policies. The algorithm uses queries to sample N expert trajectories, noting that the state-action pairs at time t can be viewed as i.i.d. draws from distribution $d_{\pi^*}^t$. The algorithm, then returns the non-stationary policy $\hat{\pi} = (\hat{\pi}_1, \ldots, \hat{\pi}_T)$, where $\hat{\pi}_t$ is the policy returned by running the learner L_p on examples from time t. Let $\epsilon_t = e_{\pi_t^*}(\hat{\pi}_t, d_{\pi^*}^t)$ be the generalization error at time

t. Lemma 3[1] in (Syed and Schapire, 2010) shows that if for each time step $\epsilon_t \leq \epsilon$, then $V(\hat{\pi}) \geq V(\pi^*) - \epsilon T^2$. Hence, if we are interested in learning a $\hat{\pi}$ whose overall regret is no more than ϵ, then we need to provide at least $N_p(\frac{\epsilon}{T^2}, \frac{\delta}{T})$ examples to L_p to ensure that $\epsilon_t \leq \frac{\epsilon}{T^2}$ holds at all time steps with probability at least $1 - \delta$. Therefore, the passive label complexity of this algorithm is $T \cdot N_p(\frac{\epsilon}{T^2}, \frac{\delta}{T})$.

Our goal now is to provide a reduction from active imitation learning to i.i.d. active learning that can achieve an improved label complexity. This is not as simple as replacing the calls to L_p in the above approach with calls to an active learner L_a. This is because the active learner at time step t would require the ability to sample from the unlabeled distribution $d^t_{\pi^*}$, which requires executing the expert policy for t steps, which in turn requires t label queries to the expert that would count against the label complexity.

It turns out that for a slightly more sophisticated reduction to i.i.d. passive learning introduced by Ross and Bagnell (2010), it is possible to simply replace L_p with L_a and maintain the potential benefit of active learning. Ross and Bagnell (2010) introduced the forward training algorithm for non-stationary policies, which trains a non-stationary policy in a series of T iterations. In particular, iteration t trains policy $\hat{\pi}_t$ by calling a passive learner L_p on a labeled data set drawn from the state distribution induced at time t by the non-stationary policy $\hat{\pi}^{t-1} = (\hat{\pi}_1, \ldots, \hat{\pi}_{t-1})$, where $\hat{\pi}_1$ is learned on states drawn from the initial distribution I. The motivation for this approach is to train the policy at time step t based on the same state-distribution that it will encounter when being run after learning. By doing this, Ross and Bagnell (2010) show that the algorithm has a worst case regret of $T^2\epsilon$ and under certain assumptions can achieve a regret as low as $O(T\epsilon)$.

Importantly, the state-distribution used to train $\hat{\pi}_t$ given by $d^t_{\hat{\pi}^{t-1}}$ is easy for the learner to sample from without making queries to the expert. In particular, to generate a sample the learner can simply simulate $\hat{\pi}^{t-1}$, which is available from previous iterations, from a random initial state and return the state at time t. Thus, we can simply replace the call to L_p at iteration t with a call to L_a with unlabeled state distribution $d^t_{\hat{\pi}^{t-1}}$ as input. More formally, the *active forward training algorithm* is given by the following iteration: $\hat{\pi}_t = L_a(\epsilon, \frac{\delta}{T}, D^t)$, where $D^1 = I$ and $D^t = d^t_{\hat{\pi}^{t-1}}$.

Theorem 3.1 in (Ross and Bagnell, 2010) gives the worst case bound on the regret of the forward training algorithm which assumes the generalization error at each iteration is bounded by ϵ. Since we also maintain that assumption when replacing L_p with L_a (the active variant) we immediately inherit that bound.

Proposition 1. *Given a PAC i.i.d. active learning algorithm L_a, if active forward training is run by giving L_a parameters ϵ and $\frac{\delta}{T}$ at each step, then with probability at least $1-\delta$ it will return a non-stationary policy $\hat{\pi}^T$ such that $V(\hat{\pi}^T) \geq V(\pi^*) - \epsilon T^2$.*

Note that L_a is run with $\frac{\delta}{T}$ as the reliability parameter to ensure that all T iterations succeed with the desired probability. Proposition 1 shows that the overall label complexity of active forward training in order to achieve a regret less than ϵ with probability at least $1 - \delta$ is $T \cdot N_a(\frac{\epsilon}{T^2}, \frac{\delta}{T})$. Comparing to the corresponding label complexity of passive imitation learning $T \cdot N_p(\frac{\epsilon}{T^2}, \frac{\delta}{T})$ we see that an improved label complexity of active learning in the i.i.d. case translates to improved label complexity of active imitation learning. In particular, in the realizable learning case, we know that N_a can be exponentially smaller than N_p in terms of its dependence on $\frac{1}{\epsilon}$.

4.2 Stationary Policies

A drawback of active forward training is that it is impractical for large T and the resulting policy cannot be run indefinitely. We now consider the case of learning stationary policies, first reviewing the existing results for passive imitation learning.

In the traditional approach, a stationary policy $\hat{\pi}$ is trained on the expert state distribution d_{π^*} using a passive learning algorithm L_p returning a stationary policy $\hat{\pi}$. Theorem 2.1 in (Ross and Bagnell, 2010) states that if the generalization error of $\hat{\pi}$ with respect to the i.i.d. distribution d_{π^*} is bounded by ϵ then $V(\hat{\pi}) \geq V(\pi^*) - \epsilon T^2$. Since generating i.i.d. samples from d_{π^*} can require up to T queries (see Section 3) the passive label complexity of this approach for guaranteeing a regret less than ϵ with probability at least $1 - \delta$ is $T \cdot N_p(\frac{\epsilon}{T^2}, \delta)$.

The above approach cannot be converted into an active imitation learner by simply replacing the call to L_p with L_a, since again we cannot sample from the unlabeled distribution d_{π^*} without querying the expert. To address this issue, we introduce a new algorithm called *RAIL (Reduction-based Active Imitation Learning)* which makes a sequence of T calls to an i.i.d. active learner, noting that it is likely to find a useful stationary policy well before all T calls are issued. RAIL is an idealized algorithm intended for analysis, which achieves the theoretical goals but has a number of inefficiencies from a practical perspective. Later in Section 5 we describe the practical instantiation that

[1]The main result of (Syed and Schapire, 2010) holds for stochastic expert policies and requires a more complicated analysis that results in a looser bound. Lemma 3 is strong enough for deterministic expert policies, which is the assumption made in our work.

is used in our experiments.

RAIL is similar in spirit to active forward training, though its analysis is quite different and more involved. Like forward-training RAIL iterates for T iterations, but on each iteration, RAIL learns a new stationary policy $\hat{\pi}^t$ that can be applied across all time steps. Iteration $t+1$ of RAIL learns a new policy $\hat{\pi}^{t+1}$ that achieves a low error rate at predicting the expert's actions with respect to the state distribution of the previous policy $d_{\hat{\pi}^t}$. More formally, given an i.i.d. active learner L_a, the RAIL algorithm is defined by the following iteration:

- **(Initialize)** $\hat{\pi}^0$ is an arbitrary policy, possibly based on prior knowledge or existing data,
- **(Iterate** $t = 1 \cdots, T$**)** $\hat{\pi}^t = L_a(\epsilon, \frac{\delta}{T}, d_{\hat{\pi}^{t-1}})$.

Thus, similar to active forward training, RAIL makes a sequence of T calls to an active learner. Unlike forward training, however, the unlabeled data distributions used at each iteration contains states from all time points within the horizon, rather than being restricted to a states arising at a particular time point. Because of this difference, the active learner is able to ask queries across a range of time point and we might expect policies learned in earlier iterations to achieve non-trivial performance throughout the entire horizon. In contrast, at iteration t the policy produced by forward training is only well defined up to time t.

The complication faced by RAIL, however, compared to forward training, is that the distribution used to train $\hat{\pi}^{t+1}$ differs from the state distribution of the expert policy d_{π^*}. This is particularly true in early iterations of RAIL since $\hat{\pi}^0$ is initialized arbitrarily. We now show that as the iterations proceed, we can bound the similarity between the state distributions of the learned policy and the expert, which allows us to bound the regret of the learned policy. We first state the main result which we prove below.

Theorem 1. *Given a PAC i.i.d. active learning algorithm L_a, if RAIL is run with parameters ϵ and $\frac{\delta}{T}$ passed to L_a at each iteration, then with probability at least $1-\delta$ it will return a stationary policy $\hat{\pi}^T$ such that $V(\hat{\pi}^T) \geq V(\pi^*) - \epsilon T^3$.*

From this we see that the impact of moving from non-stationary to stationary policies in the worst case is a factor of T in the regret bound. Similarly the bound is a factor of T worse than the comparable result above for passive imitation learning, which suffered a worst-case regret of ϵT^2. From this we see that the total label complexity for RAIL required to guarantee a regret of ϵ with probability $1-\delta$ is $T \cdot N_a(\frac{\epsilon}{T^3}, \frac{\delta}{T})$ compared to the above label complexity of passive learning $T \cdot N_p(\frac{\epsilon}{T^2}, \delta)$. Thus, for a given policy class, if the label complexity of i.i.d. active learning is substantially less than the label complexity of passive learning, then our reduction can leverage those savings. For example, in the realizable learning case, ignore the dependence on δ (which is only logarithmic), we get an active label complexity of $T \cdot O(\log \frac{T^3}{\epsilon})$ versus the corresponding passive complexity of $T \cdot O(\frac{T^2}{\epsilon})$.

For the proof we introduce the quantity $P_\pi^t(M)$, which is the probability that a policy π is consistent with a length t trajectory generated by the expert policy π^* in MDP M. It will also be useful to index the state distribution of π by the MDP M, denoted by $d_\pi(M)$. The main idea is to show that at iteration t, $P_{\hat{\pi}^t}^t(M)$ is not too small, meaning that the policy at iteration t mostly agrees with the expert for the first t actions. We first state two lemmas, which are useful for the final proof. First, we bound the regret of a policy in terms of $P_\pi^T(M)$.

Lemma 1. *For any policy π, if $P_\pi^T(M) \geq 1-\epsilon$, then $V(\pi) \geq V(\pi^*) - \epsilon T$.*

Proof. Let Γ^* and Γ be all state-action sequences of length T that are consistent with π^* and π respectively. If $R(\mathcal{T})$ is the total reward for a sequence $\mathcal{T}$ then we get the following:

$$\begin{aligned}
V(\pi) &= \sum_{\mathcal{T}\in\Gamma} \Pr(\mathcal{T} \mid M, \pi) R(\mathcal{T}) \\
&\geq \sum_{\mathcal{T}\in\Gamma\cap\Gamma^*} \Pr(\mathcal{T} \mid M, \pi) R(\mathcal{T}) \\
&= \sum_{\mathcal{T}\in\Gamma^*} \Pr(\mathcal{T} \mid M, \pi^*) R(\mathcal{T}) - \sum_{\mathcal{T}\in\Gamma^*-\Gamma} \Pr(\mathcal{T} \mid M, \pi^*) R(\mathcal{T}) \\
&= V(\pi^*) - \sum_{\mathcal{T}\in\Gamma^*-\Gamma} \Pr(\mathcal{T} \mid M, \pi^*) R(\mathcal{T}) \\
&\geq V(\pi^*) - T \cdot \sum_{\mathcal{T}\in\Gamma^*-\Gamma} \Pr(\mathcal{T} \mid M, \pi^*) \\
&\geq V(\pi^*) - \epsilon T
\end{aligned}$$

The last two inequalities follow since the reward for a sequence must be no more than T and our assumption about $P_\pi^T(M)$. □

Next, we show how the value of $P_\pi^t(M)$ changes across one iteration of learning.

Lemma 2. *For any policies π and $\hat{\pi}$ and $1 \leq t < T$, if $e_{\pi^*}(\hat{\pi}, d_\pi(M)) \leq \epsilon$, then $P_{\hat{\pi}}^{t+1}(M) \geq P_\pi^t(M) - T\epsilon$.*

Proof. We define $\hat{\Gamma}$ to be all sequences of state-action pairs of length $t+1$ that are consistent with $\hat{\pi}$. Also define Γ to be all length $t+1$ state-action sequences that are consistent with π on the first t state-action pairs (so need not be consistent on the final pair). We also define $\hat{M}$ to be an MDP that is identical to M, except that the transition distribution of any state-action pair (s,a) is equal to the transition distribution

of action $\pi(s)$ in state s. That is, all actions taken in a state s behave like the action selected by π in s.

We start by arguing that if $e_{\pi^*}(\hat{\pi}, d_\pi(M)) \leq \epsilon$ then $P_{\hat{\pi}}^{t+1}(\hat{M}) \geq 1 - T\epsilon$, which relates our error assumption to the MDP $\hat{M}$. To see this note that for MDP $\hat{M}$, all policies including π^*, have state distribution given by d_π. Thus by the union bound $1 - P_{\hat{\pi}}^{t+1}(\hat{M}) \leq \sum_{i=1}^{t+1} \epsilon_i$, where ϵ_i is the error of $\hat{\pi}$ at predicting π^* on distribution d_π^i. This sum is bounded by $T\epsilon$ since $e_{\pi^*}(\hat{\pi}, d_\pi(M)) = \frac{1}{T}\sum_{i=1}^{T} \epsilon_i$. Using this fact we can now derive the following:

$$
\begin{aligned}
P_{\hat{\pi}}^{t+1}(M) &= \sum_{\mathcal{T} \in \hat{\Gamma}} \Pr(\mathcal{T} \mid M, \pi^*) \\
&\geq \sum_{\mathcal{T} \in \Gamma \cap \hat{\Gamma}} \Pr(\mathcal{T} \mid M, \pi^*) \\
&= \sum_{\mathcal{T} \in \Gamma} \Pr(\mathcal{T} \mid M, \pi^*) - \sum_{\mathcal{T} \in \Gamma - \hat{\Gamma}} \Pr(\mathcal{T} \mid M, \pi^*) \\
&= P_\pi^t(M) - \sum_{\mathcal{T} \in \Gamma - \hat{\Gamma}} \Pr(\mathcal{T} \mid M, \pi^*) \\
&= P_\pi^t(M) - \sum_{\mathcal{T} \in \Gamma - \hat{\Gamma}} \Pr(\mathcal{T} \mid \hat{M}, \pi^*) \\
&\geq P_\pi^t(M) - \sum_{\mathcal{T} \notin \hat{\Gamma}} \Pr(\mathcal{T} \mid \hat{M}, \pi^*) \\
&\geq P_\pi^t(M) - T\epsilon
\end{aligned}
$$

The equality of the fourth line follows since Γ contains all sequences whose first t actions are consistent with π with all possible combinations of the remaining action and state transition. Thus, summing over all such sequences yields the probability that π^* agrees with the first t steps. The equality of the fifth line follows because $\Pr(\mathcal{T} \mid M, \pi^*) = \Pr(\mathcal{T} \mid \hat{M}, \pi^*)$ for any $\mathcal{T}$ that is in Γ and for which π^* is consistent (has non-zero probability under π^*). The final line follows from the above observation that $P_{\hat{\pi}}^{t+1}(\hat{M}) \geq 1 - T\epsilon$. □

We can now complete the proof of the main theorem.

Proof of Theorem 1. Using failure parameter $\frac{\delta}{T}$ ensures that with at least probability $1 - \delta$ that for all $1 \leq t < T$ we will have $e_{\pi^*}(\hat{\pi}^{t+1}, d_{\hat{\pi}^t}(M)) \leq \epsilon$. As a base case, we have $P_{\hat{\pi}^1}^1 \geq 1 - T\epsilon$, since the the error rate of $\hat{\pi}^1$ relative to the initial state distribution at time step $t = 1$ is at most $T\epsilon$. Combining these facts with Lemma 2 we get that $P_{\hat{\pi}^T}^T \geq 1 - \epsilon T^2$. Combining this with Lemma 1 completes the proof. □

4.3 Agnostic Case

Above we considered the realizable setting, where the expert's policy was assumed to be in a known hypothesis class H. In the agnostic case, we do not make such an assumption. The learner still outputs a hypothesis from a class H, but the unknown policy is not necessarily in H. The agnostic i.i.d. PAC learning setting is defined similarly to the realizable setting, except that rather than achieving a specified error bound of ϵ with high probability, a learner must guarantee an error bound of $\inf_{\pi \in H} e_f(\pi, D_\mathcal{X}) + \epsilon$ with high probability (where f is the target), where $D_\mathcal{X}$ is the unknown data distribution. That is, the learner is able to achieve close to the best possible accuracy given class H. In the agnostic case, it has been shown that exponential improvement in label complexity with respect to $\frac{1}{\epsilon}$ is achievable when $\inf_{\pi \in H} e_f(\pi, D_\mathcal{X})$ is relatively small compared to ϵ (Dasgupta, 2011). Further, there are many empirical results for practical active learning algorithms that demonstrate improved label complexity compared to passive learning.

It is straightforward to extend our above results for non-stationary and stationary policies to the agnostic case by using agnostic PAC learners for L_p and L_a. Space precludes full details and here we outline the extension for RAIL. Note that the RAIL algorithm will call L_a using a sequence of unlabeled data distributions, where each distribution is of the form d_π for some $\pi \in H$ and each of which may yield a different minimum error given H. For this purpose, we define $\epsilon^* = \sup_{\pi \in H} \inf_{\hat{\pi} \in H} e_{\pi^*}(\hat{\pi}, d_\pi)$ to be the minimum generalization error achievable in the worst case considering all possible state distributions d_π that RAIL might possibly encounter. With minimal changes to the proof of Theorem 1, we can get an identical result, except that the regret is $(\epsilon^* + \epsilon)T^3$ rather than just ϵT^3. A similar change in regret holds for passive imitation learning. This shows that in the agnostic setting we can get significant improvements in label complexity via active imitation learning when there are significant savings in the i.i.d. case.

5 Practical Instantiation of RAIL

Despite the theoretical guarantees, a potential drawback of RAIL is that the unlabeled state distributions used at early iterations may be quite different from d_{π^*}. In particular, at iteration t, the distributions at times $t' > t$ have no guarantees with respect to $d_{\pi^*}^{t'}$. Thus, early iterations may focus substantial query effort on parts of the state-space that are not relevant to π^*. Another issue is that the idealized version does not share data across iterations, which is potentially wasteful. We now describe our practical instantiation of RAIL, called RAIL-DW (for density weighted), which addresses these issues in several ways.

First, we use an incremental version of RAIL that asks only one query per iteration and accumulates data across iterations. This allows rapid updating of state distributions and prevents RAIL from wasting its query budget on earlier inaccurate distributions but rather focus on later more accurate distributions.

Second, recall that at iteration $t+1$, RAIL learns using an unlabeled data distribution $d_{\hat{\pi}^t}$, where $\hat{\pi}^t$ is the policy learned at iteration t. In order to help improve the

accuracy of this unlabeled distribution (with respect to d_{π^*}), instead of using a point estimate for $\hat{\pi}^t$, we treat $\hat{\pi}^t$ as a Bayesian classifier for purposes of defining $d_{\hat{\pi}^t}$. In particular, at iteration t let D_t be the set of state-action pairs collected from previous iterations. We use this to define a posterior $P(\hat{\pi}|\mathcal{D})$ over policies in our policy class H. This, in turn, defines a posterior unlabeled state distribution $d_{D_t} = \mathbb{E}_{\hat{\pi}\sim P(\hat{\pi}|\mathcal{D})}[d_{\hat{\pi}}(s)]$ which is used in place of $d_{\hat{\pi}^t}$ in RAIL. Note that we can sample from this distribution by first sampling a policy $\hat{\pi}$ and then sampling a state from $d_{\hat{\pi}}$, all of which can be done without interaction with the expert. We observe that in practice d_{D_t} is a significantly more useful estimate of d_{π^*} than the point estimate, since its more highly weighted states tend to carry significant weight according to d_{π^*}.

To summarize, iteration t of RAIL-DW carries out the following steps, adding one state-action pair to the data set: (D_1 is the initial, possibly empty, data set)

1. Run active learner L_a using unlabeled data distribution d_{D_t} to select a single query state s.
2. Query the expert about s to obtain action $\pi^*(s)$ and let $D_{t+1} = D_t \cup \{(s, \pi^*(s))\}$.

The iteration repeats until the query budget is exceeded. It remains to specify the specific i.i.d. active learning algorithm that we use and how we sample from d_{D_t}.

Since it is important that the i.i.d. active learner be sensitive to the unlabeled data distribution, we employ a density-weighted learning algorithm (hence the name RAIL-DW). In particular, we use density-weighted query-by-committee (McCallum and Nigam, 1998) in our implementation. Given a sample of unlabeled data points, this approach uses bagging (Breiman, 1996) to generate a committee for query selection and also uses a density estimator to estimate the density of the unlabeled data points. The selected query is the state that maximizes the product of state density and committee disagreement. We use the entropy of the vote distribution (Dagan and Engelson, 1995) as a typical measure of committee disagreement. We use a committee of size 5 in our experiments and estimate density of unlabeled points via simple distance based binning.

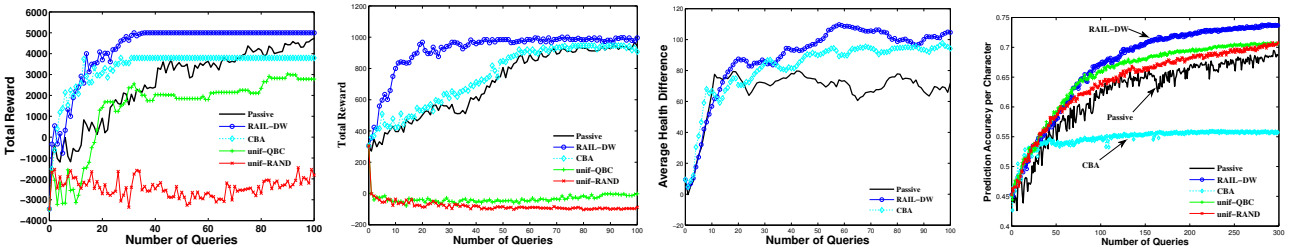
Finally, for sampling we assume a class of linear parametric policies and assume a uniform prior over the parameters. We approximate sampling from d_{D_t} via bagging: where we generate K bootstrap samples of D_t and a policy is learned from each using a supervised learner. This produces a set of K policies and each is executed to generate K trajectories. The states on those trajectories are given to the active learner as the unlabeled data set. We set $K = 5$ in our experiments.

6 Experiments

We empirically evaluate RAIL-DW on four domains: 1) Cart-pole, 2) Bicycle, 3) Wargus and 4) The structured prediction domain NETtalk. We compare RAIL-DW against the following baselines: 1) *Passive*, which simulates the traditional approach by starting at the initial state and querying the expert about what to do at each visited state, 2) *unif-QBC*, which views all the states as i.i.d. according to the uniform distribution and applies the standard query-by-committee (QBC) (Seung et al., 1992) active learning approach. Intuitively, this approach will select the state with highest action uncertainty according to the current data set and ignore the state distribution, 3) *unif-RAND*, which selects states to query uniformly at random, and 4) *Confidence based autonomy (CBA)* (Chernova and Veloso, 2009), which, starting at the initial state, executes the current policy until the learner's confidence falls below an automatically determined threshold at which point it queries the expert for an action. CBA may decide to stop asking queries once the confidence exceeds the threshold in all states. We use the exact automated threshold adjustment strategy proposed in (Chernova and Veloso, 2009). For all of these methods, we employed the SimpleLogistic classifier in Weka (Hall et al., 2009) to learn policies.

Cart-Pole. Cart-pole is an RL benchmark where a cart must balance an attached vertical pole by applying left or right forces to the cart. An episode ends when either the pole falls or the cart goes out of bounds. There are two actions, left and right, and four state variables describing the position and velocity of the cart and the angle and angular velocity of the pole. We made slight modifications to the usual setting where we allow the pole to fall down and become horizontal and the cart to go out of bounds (we used default [-2.4, 2.4] as the bounds for the cart). We let each episode run for a fixed length of 5000 time steps. This opens up the possibility of generating several "undesirable" states where either the pole has fallen or the cart is out of bounds that are rarely or never generated by the expert's state distribution. The expert policy was a hand-coded policy that can balance the pole indefinitely. For each learner, we ran experiments from 30 random initial states close to the equilibrium start state, generating learning curves for each one and averaging the results. We report total reward with a reward function (unknown to the learner) that is +1 for each time step where the pole is balanced and the cart is in bounds and -1 otherwise.

Figure 1(a) shows the results for cart-pole. We observe that RAIL learns quickly and achieves optimal performance with only 30-35 queries. Passive, on the other hand, takes 100 queries to get close to the optimal per-



(a) (b) (c) (d)

formance. The reason for this difference is clear when one visualizes the states queried by RAIL versus Passive (not shown for space reasons). The queries posed by RAIL tend to be close to the decision boundary of the expert policy, while passive asks many uninformative queries that are not close to the boundary. However, a naive reduction to active learning can be dangerous, as demonstrated by the poor performance of unif-QBC. Further, RAIL performs much better than random query selection as demonstrated by the performance of unif-RAND. By ignoring the real data distribution altogether and incorrectly assuming it to be uniform, these naive methods end up asking many queries that are not relevant to learning the expert policy (e.g. states where the pole is in an unrecoverable fall or the cart is out of bounds). CBA, like RAIL, learns quickly but settles at a suboptimal performance. This is because it becomes confident and stops asking queries prematurely. This shows that CBA's automatic threshold adjustment mechanism did not work well in this domain. We did try several adjustments to the threshold adjustment strategy, but were unable to find one that was robust across our four domains and thus we report results for the original strategy.

We also conducted experiments to study the effects of using i.i.d. active learners that ignore the data distribution in RAIL. Figure 2(a) shows the performance of RAIL with three different base active learners, the density-weighted QBC, the standard QBC (without density weighting), and random selection of unlabeled data points. We see that RAIL-DW performs better than both RAIL-QBC and RAIL-RAND. This shows that it is critical for the i.i.d. active learner to exploit the state density information that is estimated by RAIL at each iteration.

Bicycle Balancing. Bicycle balancing is a variant of the Bicycle RL benchmark (Randløv and Alstrøm, 1998). The goal is to balance a bicycle moving at a constant speed for 1000 time steps. If the bicycle falls, it remains fallen for the rest of the episode. The state space is described using nine variables measuring various angles, angular velocities, and positions of the bicycle. There are five possible actions each specifying a particular handle-bar torque and rider displacement. The learner's policy is represented as a linear logistic regression classifier over features of state-action pairs. A feature vector is defined as follows: Given a state s, a set of 20 basis functions is computed. This set is repeated for each of the 5 actions giving a feature vector of length 100. The expert policy was hand coded and can balance the bicycle for up to 26K time steps.

We used a similar evaluation procedure as for Cart-pole giving +1 reward for each time step where the bicycle is kept balanced and -1 otherwise. Figure 1(b) compares each approach. The results are similar to those of Cart-pole with RAIL-DW being the top performer. Unif-RAND and Unif-QBC show notably poor performance in this domain. This is because bicycle balancing is a harder learning problem than cart-pole with many more uninformative states (an unrecoverable fall or fallen state). Similarly, 2(b) shows very poor performance for versions of RAIL that use distribution unaware active learners.

Wargus. We consider controlling a group of 5 friendly close-range military units against a group of 5 enemy units in the real-time strategy game Wargus, similar to the setup in (Judah et al., 2010). The objective is to win the battle while minimizing the loss in total health of friendly units. The set of actions available to each friendly unit is to attack any one of the remaining units present in the battle (including other friendly units, which is always a bad choice). In our setup, we allow the learner to control one of the units throughout the battle whereas the other friendly units are controlled by a fixed "reasonably good" policy. This situation

would arise when training the group via coordinate ascent on the performance of individual units. The expert policy corresponds to the same policy used by the other units. Note that poor behavior from even a single unit generally results in a huge loss. Providing full demonstrations in real time in such tactical battles is very difficult for human players and quite time consuming if demonstrations are done in slow motion, which motivates state-based active learning.

We designed 21 battle maps differing in the initial unit positions, using 5 for training and 16 for testing. We average results across five learning trials. Passive learns along the expert's trajectory in each map on all 5 maps considered sequentially according to a random ordering. For RAIL, in each iteration a training map is selected randomly and a query is posed in the chosen map. For CBA, a map is selected randomly and CBA is allowed to play an episode in it, pausing and querying as and when needed. If the episode ends, another map is chosen randomly and CBA continues to learn in it. After each query, the learned policy is tested on the 16 test maps. We use the difference in the total health of friendly and enemy units at the end of the battle as the performance metric (which is positive for a win). We did not run experiments for unif-QBC and unif-RAND because it is difficult to define the space of feasible states over which to sample uniformly.

The results are shown in figure 1(c). We see that although Passive learns quickly for the first 10 queries, it fails to improve further. This shows that the states located in this initial prefix of the expert's trajectory are very useful, but thereafter Passive gets stuck on the uninformative part of the trajectory till its query budget is over. On the other hand, RAIL and CBA continue to improve beyond Passive, with RAIL being slightly better, which indicates that they are able to locate and query more informative states.

NETTalk. We evaluate RAIL on a structured prediction task of stress prediction in the NETtalk data set (Dietterich et al., 2008). Given a word, the goal is to assign one of the five stress labels to each letter of the word in the left to right order. It is straightforward to view structured prediction as imitation learning (see for example Ross and Bagnell, 2010) where at each time step (letter location), the learner has to execute the correct action (i.e. predict correct stress label) given the current state. The state consists of features describing the input (the current letter and its immediate neighbors) and previous L predictions made by the learner (the prediction context). In our experiments, we use $L = 1, 2$ and show results only for $L = 2$ noting that $L = 1$ was qualitatively similar.

We use character accuracy as a measure of performance. Passive learns along the expert's trajectory on each training sequence considered in the order it appears in the training set. Therefore, Passive always learns on the correct context, i.e. previous L characters correctly labeled. RAIL and Unif-QBC can select the best query across the entire training set. CBA, like Passive, considers training sequences in the order they appear in the training set and learns on each sequence by querying at each sequence position. In order to minimize the impact of the ordering of training examples on Passive and CBA, we ran five learning trials for each learner, each with a randomized ordering. We report final performance as the learning curves averaged across all five trials.

Figure 1(d) presents the NETtalk results. The results are qualitatively similar to Cart-Pole, except that Unif-QBC and Unif-RAND do quite well in this domain but not as well as RAIL-DW. Again we see that CBA performs poorly because in all five trials it prematurely stops asking queries, showing its sensitivity to its threshold adjustment mechanism.

Overall Observations. Overall, we can draw a number of conclusions from the experiments. First, RAIL-DW proved to be the most robust and effective active imitation learning approach in all of our domains. Second, the choice of the i.i.d. active learner used for RAIL is important. In particular, performance can be poor when the active learning algorithm does not take density information into account. Using density weighted query-by-committee was effective in all of our domains. Third, we found that CBA is quite sensitive to the threshold adjustment mechanism and we were unable to find an alternative mechanism that works across our domains. Fourth, we showed that a more naive application of i.i.d. active learning in the imitation setting is not effective.

7 Summary

We considered reductions from active imitation learning based on i.i.d. active learning, which allow for advances in the i.i.d. setting to translate to imitation learning. First, we analyzed the label complexity of reductions for both non-stationary and stationary policies, showing that the complexity of active imitation learning can be significantly less than passive learning. Second, we introduced RAIL-DW, a practical variant of the reduction for stationary policies, and showed empirically in four domains that it is highly effective compared to a number of alternatives.

Abstract

Stochastic Shortest Path (SSP) MDPs is a problem class widely studied in AI, especially in probabilistic planning. They describe a wide range of scenarios but make the restrictive assumption that the goal is reachable from any state, i.e., that dead-end states do not exist.Because of this, SSPs are unable to model various scenarios that may have catastrophic events (e.g., an airplane possibly crashing if it flies into a storm). Even though MDP algorithms have been used for solving problems with dead ends, a principled theory of SSP extensions that would allow dead ends, including theoretically sound algorithms for solving such MDPs, has been lacking. In this paper, we propose three new MDP classes that admit dead ends under increasingly weaker assumptions. We present Value Iteration-based as well as the more efficient heuristic search algorithms for optimally solving each class, and explore theoretical relationships between these classes. We also conduct a preliminary empirical study comparing the performance of our algorithms on different MDP classes, especially on scenarios with unavoidable dead ends.

1 Introduction

Stochastic Shortest Path (SSP) MDPs [Bertsekas, 1995] is a class of probabilistic planning problems thoroughly studied in AI. They describe a wide range of scenarios where the objective of the agent is to reach a goal state in the least costly way in expectation from any non-goal state using actions with probabilistic outcomes.

While SSPs are a popular model, they have a serious limitation. They assume that a given MDP has at least one *complete proper policy*, a policy that reaches the goal from any state with 100% probability. Basic algorithms for solving SSP MDPs, such as Value Iteration (VI) [Bellman, 1957], fail to converge if this assumption does not hold. In the meantime, this requirement effectively disallows the existence of *dead ends*, states from which reaching the goal is impossible, and of catastrophic events that lead to these states. Such catastrophic failures are a possiblity to be reckoned with in many real-world planning problems, be it sending a rover on Mars or navigating a robot in a building with staircases. Thus, insisting on the absence of dead ends significantly limits the applicability of SSPs. Moreover, verifying that a given MDP has no dead ends can be nontrivial, further complicating the use of this model.

Researchers have realized that allowing dead ends in goal-oriented MDPs would break some existing methods for solving them [Little and Thiebaux, 2007]. They have also suggested algorithms that are aware of the possible presence of dead-end states [Kolobov et al., 2010] and try to avoid them when computing a policy [Keyder and Geffner, 2008, Bonet and Geffner, 2005]. However, these attempts have lacked a theoretical analysis of how to incorporate dead ends into SSPs in a principled way, and of what the optimization criteria in the presence of dead ends should be. This paper bridges the gap by introducing three new MDP classes with progressively weaker assumptions about the existence of dead ends, analyzing their properties, and presenting optimal VI-like and the more efficient heuristic search algorithms for them.

The first class we present, SSPADE, is a small extension of SSP that has well-defined easily-computable optimal solutions if dead ends are present but are avoidable *provided that the process starts at a known initial state* s_0.

The second and third classes introduced in this paper admit that dead ends may exist and the probability of running into them from the initial state may be positive no matter how hard the agent tries. If the chance of a catastrophic event under any policy is nonzero, a key question is: should we prefer policies that minimize the expected cost of getting to the goal even at the expense of an increased risk of failure, or those that reduce the risk of failure above all else?

The former criterion characterizes scenarios where entering a dead end, while highly undesirable, has a finite "price". For instance, suppose the agent buys an expensive ticket for a concert of a favorite band in another city, but remem-

bers about it only on the day of the event. Getting to the concert venue requires a flight, either by hiring a business jet or by a regular airline with a layover. The first option is very expensive but almost guarantees making the concert on time. The second is much cheaper but, since the concert is so soon, missing the connection, a somewhat probable outcome, means missing the concert. Nonetheless, the cost of missing the concert is only the price of the ticket, so a rational agent would choose to travel with a regular airline. Accordingly, one of the MDP classes we propose, fSSPUDE, assumes that the agent can put a price (penalty) on ending up in a dead end state and wants to compute a policy with the least expected cost (including the possible penalty). While seemingly straightforward, this intuition is tricky to operationalize because of several subtleties. We overcome these subtleties and show how fSSPUDE can be solved with easy modifications to existing SSP algorithms.

In the third MDP class we introduce, iSSPUDE, not only are dead ends unavoidable, but the cost of hitting one is assumed to be infinitely large. Consider, for example, the task of planning an ascent to the top of Mount Everest for a group of human alpinists. Such an ascent is fraught with inherent lethal risks, and to any human, the price of their own life can be taken as infinite. Note the conceptual difficulty with this setting: since every policy reaches an infinite-cost state, the expected cost of any policy is also infinite. This makes SSP's cost-minimization criterion uninformative. Instead, for an undertaking as above, a natural primary objective is to maximize the *probability* of getting to the goal (i.e., to minimize the chance of getting into a lethal accident, a dead-end state). However, of all policies maximizing this chance, we would prefer the least costly one (in expectation). This is exactly the multiobjective criterion we propose for this class of MDPs. Solving iSSPUDE is much more involved than handling the previous two classes, and we introduce two novel algorithms for it.

Intuitively, the objectives of fSSPUDE and iSSPUDE MDPs are related — as fSSPUDE's dead-end penalty gets bigger, the optimal policies of the two classes coincide. We provide a theoretical and an empirical analysis of this insight, showing that solving fSSPUDE yields an optimal policy for iSSPUDE if the dead-end penalty is high enough.

Thus, the paper makes four contributions: (1) three new goal-oriented MDP models that admit the existence of dead-end states; (2) optimal VI and heuristic search algorithms for solving them; (3) theoretical results describing equivalences among problems in these classes; and (4) an empirical evaluation tentatively answering the question: which class should be used when modeling a given scenario involving unavoidable dead ends?

2 Background and Preliminaries

SSP MDPs. In this paper, we extend an MDP class known as the Stochastic Shortest Path (SSP) problems with an optional initial state, defined as tuples of the form $\langle \mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{C}, \mathcal{G}, s_0 \rangle$, where $\mathcal{S}$ is a finite set of states, $\mathcal{A}$ is a finite set of actions, $\mathcal{T}$ is a transition function $\mathcal{S} \times \mathcal{A} \times \mathcal{S} \to [0, 1]$ that gives the probability of moving from s_i to s_j by executing a, $\mathcal{C}$ is a map $\mathcal{S} \times \mathcal{A} \to \mathbb{R}$ that specifies action costs, $\mathcal{G}$ is a set of (absorbing) goal states, and s_0 is an optional start state. For each $g \in G$, $\mathcal{T}(g, a, g) = 1$ and $\mathcal{C}(g, a) = 0$ for all $a \in A$, which forces the agent to stay in g forever while accumulating no reward.

An SSP must also satisfy two conditions: (1) It must have at least one *complete proper policy*, a rule prescribing an action for every state with which an agent can reach a goal state from any state with probability 1. (2) Every *improper* policy must incur the cost of ∞ from all states from which it cannot reach the goal with probability 1.

When the initial state is unknown, solving an SSP MDP means finding a policy whose execution from any state allows an agent to reach a goal state while incurring the least expected cost. We call such a policy *complete optimal*, and denote any complete policy as π. When the initial state is given, we are interested in computing an *optimal (partial) policy rooted at* s_0, i.e., one that reaches the goal in the least costly way from s_0 and is defined for every state it can reach from s_0 (though not necessarily for other states).

To make the notion of policy cost more concrete, we define a *cost function* as a mapping $J : \mathcal{S} \to \mathbb{R} \cup \{\infty\}$ and let random variables S_t and A_t denote, respectively, the state of the process after t time steps and the action selected in that state. Then, the cost function J^π of policy π is

$$J^\pi(s) = \mathbb{E}^\pi_s \left[\sum_{t=0}^{\infty} \mathcal{C}(S_t, A_t) \right] \quad (1)$$

In other words, the cost of a policy π at a state s is the expectation of the total cost the policy incurs if the execution of π is started in s. In turn, every cost function J has a policy π^J that is *J-greedy*, i.e., that satisfies

$$\pi^J(s) = \arg\min_{a \in \mathcal{A}} \left[\mathcal{C}(s, a) + \sum_{s' \in \mathcal{S}} \mathcal{T}(s, a, s') J(s') \right] \quad (2)$$

Optimally solving an SSP MDP means finding a policy that minimizes J^π. Such policies are denoted π^*, and their cost function $J^* = J^{\pi^*}$, called the *optimal cost function*, is defined as $J^* = \min_\pi J^\pi$. J^* also satisfies the following condition, the *Bellman equation*, for all $s \in \mathcal{S}$:

$$J(s) = \min_{a \in \mathcal{A}} \left[\mathcal{C}(s, a) + \sum_{s' \in \mathcal{S}} \mathcal{T}(s, a, s') J(s') \right] \quad (3)$$

Value Iteration for SSP MDPs. The Bellman equation suggests a dynamic programing method of solving SSPs, known as Value Iteration (VI_{SSP}) [Bellman, 1957]. VI_{SSP} starts by initializing state costs with an arbitrary *heuristic cost function* $\hat{J}$. Afterwards, it executes several sweeps of the state space and updates every state during every sweep by using the Bellman equation (3) as an assignment operator, the *Bellman backup operator*. Denoting the cost func-

tion after the i-th sweep as J_i, it can be shown that the sequence $\{J_i\}_{i=1}^{\infty}$ converges to J^*. A complete optimal policy π^* can be derived from J^* via Equation 2 .

Heuristic Search for SSP MDPs. Because it stores and updates the cost function for the entire $\mathcal{S}$, VI$_{SSP}$ can be slow and memory-inefficient even on relatively small SSPs. However, if the initial state s_0 is given we are interested in computing $\pi^*_{s_0}$, an optimal policy from s_0 only, which typically does not visit (and hence does not need to be defined for) all states. This can be done with a family of algorithms based on VI called *heuristic search*. Like VI, these algorithms need to be initialized with a heuristic $\hat{J}$. However, if $\hat{J}$ is *admissible*, i.e., satisfies $\hat{J}(s) \leq J^*(s)$ for all states, then heuristic search algorithms can often compute J^* for the states relevant to reaching the goal from s_0 without updating or even memoizing costs for many of the other states. At an abstract level, the operation of any heuristic search algorithm is represented by the FIND-AND-REVISE framework [Bonet and Geffner, 2003a]. As formalized by FIND-AND-REVISE, any heuristic search algorithm starts with an admissible $\hat{J}$ and explicitly or implicitly maintains the graph of a policy greedy w.r.t. the current J, updating the costs of states *only in this graph* via Bellman backups. Since the initial $\hat{J}$ makes many states look "bad" a-priori, they never end up in the greedy graph and hence never have to be stored or updated. This makes heuristic search algorithms, e.g., LRTDP [Bonet and Geffner, 2003b], work more efficiently than VI and still produce an optimal $\pi^*_{s_0}$.

GSSP and MAXPROB MDPs. Unfortunately, many interesting probabilistic planning scenarios fall outside of the SSP MDP class. One example is MAXPROB MDPs [Kolobov et al., 2011], goal-oriented problems where the objective is to maximize the probability of getting to the goal, not minimize the cost. To discuss MAXPROB, we need the following definition:

Definition For an MDP with a set of goal states $\mathcal{G} \subset \mathcal{S}$, the *goal-probability function* of a policy π, denoted P^π, gives the probability of reaching the goal from any state s. Mathematically, letting $S_t^{\pi_s}$ be a random variable denoting a state the MDP may end up if policy π is executed starting in state s for t time steps,

$$P^\pi(s) = \sum_{t=1}^{\infty} P[S_t^{\pi_s} = g \in \mathcal{G}, S_{t'}^{\pi_s} = s \notin \mathcal{G} \; \forall \, 1 \leq t' < t] \quad (4)$$

Each term in the above summation denotes the probability that, if π is executed starting at s, the MDP ends up in a goal state at step t and not earlier. Once the system enters a goal state, it stays in that goal state forever, so the sum of all such terms is the probability of the system ever entering a goal state under π.

To introduce MDPs with dead ends, we will only need the following informal definition of MAXPROB MDPs. A MAXPROB MDP is a problem that can be derived from any goal-oriented MDP (e.g., an SSP) by disregarding the cost function $\mathcal{C}$ and maximizing the *probability* of reaching the goal instead of the expected cost. More specifically, solving a MAXPROB means finding the optimal goal-probability function from the above definition, one that satisfies $P^*(s) = \arg\max_\pi P^\pi(s)$ for all states. Alternatively, $1 - P^*(s)$ can be interpreted as the smallest probability of running into a dead end from s for any policy. Thus, solving a MAXPROB derived from a goal-oriented MDP by discarding action costs can be viewed as a way to identify *dead ends*:

Definition For a goal-oriented MDP, a *dead-end state* (or dead end, for short) is a state s for which $P^*(s) = 0$.

MAXPROBs, SSPs themselves, and many other MDPs belong to the broader class of Generalized SSP MDPs (GSSPs) [Kolobov et al., 2011]. GSSPs are defined as tuples $\langle \mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{C}, \mathcal{G}, s_0 \rangle$ of the same form as SSPs, but relax both of the additional conditions in the SSP definition. In particular, they do not require the existence of a complete proper policy as SSPs do. To state the main results of this paper, we will not need the specifics of GSSP's technical definition, and will only refer to the GSSP properties and algorithms described below.

Value Iteration for GSSP MDPs. In the case of SSPs, VI$_{SSP}$ yields a complete optimal policy for these MDPs independently of the initializing heuristic $\hat{J}$. For a GSSP MDP, such a policy need not exist, so there is no analog of VI$_{SSP}$ that works for all problems in this class. However, for MAXPROB, a subclass of GSSP particularly important to us in this paper, such an algorithm, called VI$_{MP}$, can be designed. Like VI$_{SSP}$, VI$_{MP}$ can be initialized with an arbitrary heuristic function, but instead of the Bellman backup operator it uses its generalized version that we call *Bellman backup with Escaping Traps* (BET) in this paper. BET works by updating the initial heuristic function with Bellman backup, until it arrives at a fixed-point function $P^\times$. For SSPs, Bellman backup has only one fixed point, the optimal P^*, so if we were working with SSPs, we would stop here. However, for GSSPs (and MAXPROB in particular) this is not the case — P^* is only *one of* Bellman backup's fixed points, and the current fixed point $P^\times$ may not be equal to P^*. Crucially, to check whether $P^\times$ is optimal, BET applies the *trap elimination* operator to it, which involves constructing the transition graph that uses actions of *all* policies greedy w.r.t. $P^\times$. If $P^\times \neq P^*$, trap elimination generates a new, non-fixed-point $P^{\times'}$, on which BET again acts with Bellman backup, and so on. The fact that VI$_{MP}$ and FRET, the heuristic search framework for GSSPs considered below, sometimes need to build a greedy transition graph w.r.t. a cost function is important for analyzing the performance of algorithms introduced in this paper (Section 8).

VI$_{MP}$'s main property, whose proof is a straightforward extension of the results in the GSSP paper [Kolobov et al., 2011], is similar to VI$_{SSP}$'s:

Theorem 1. *On MAXPROB MDPs, VI_{MP} converges to the optimal goal-probability function P^* independently of the initializing heuristic function $\hat{J}$.*

Heuristic Search for GSSP MDPs. Although a complete optimal policy does not necessarily exist for a GSSP, one rooted at s_0 always does and can be found by any heuristic search algorithm conforming to an FIND-AND-REVISE analogue for GSSPs, FRET [Kolobov et al., 2011]. Like FIND-AND-REVISE on SSPs, FRET guarantees convergence to $\pi^*_{s_0}$ if the initializing heuristic is admissible.

3 MDPs with Avoidable Dead Ends

All definitions of the SSP class in the literature [Bertsekas, 1995, Bonet and Geffner, 2003a, Kolobov et al., 2011] require that the goal be reachable with 100%-probability from every state in the state space, even when initial state s_0 is known and the objective is to find an optimal policy rooted only at that state. We first extend SSPs to the easiest case — when dead ends exist but can be avoided entirely from s_0.

Definition A Stochastic Shortest Path MDP with Avoidable Dead Ends (SSPADE) is a tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{C}, \mathcal{G}, s_0 \rangle$ where $\mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{C}, \mathcal{G}$, and s_0 are as in the SSP MDP definition, under the following conditions:

- The initial state s_0 is known.
- There exists at least one proper policy rooted at s_0.
- Every *improper* policy has $J^\pi(s_0) = \infty$.

Solving a SSPADE MDP means finding a policy $\pi^*_{s_0}$ rooted at s_0 that satisfies $\pi^*(s_0) = \arg\min_\pi J^\pi(s_0)$.

SSPADE has only two notable differences from SSP — the former assumes the initial state to be known, and only requires the existence of a partial proper policy. However, even such small departures from the SSP definition prevent some SSP algorithms from working on SSPADE, as we are about to see.

Value Iteration: Even though dead ends may be avoided from s_0 with an optimal policy, they are still present in the state space. Thus, VI_{SSP}, which operates on the entire state space, does not converge on SSPADEs, since the optimal costs for dead ends are infinite. One might think that we may be able to adapt VI_{SSP} to SSPADE by restricting computation to the subset of states reachable from s_0. However, even this is not true, because SSPADE requirements do not preclude dead ends reachable from s_0. Overall, for VI_{SSP} to work on SSPADEs, we need to detect divergence of state cost sequences – an unsolved problem, to our knowledge.

Heuristic Search: Although VI does not terminate for SSPADE, heuristic search algorithms do. This is because:

Theorem 2. $SSPADE \subset GSSP$.

Proof sketch. SSPADE directly satisfies all requirements of the GSSP definition [Kolobov et al., 2011]. □

In fact, we can also show that heuristic search for SSPADE only needs the regular Bellman backup operator (instead of the BET operator). That is, the FIND-AND-REVISE framework applies to SSPADE without modification. In particular, FIND-AND-REVISE starts with admissible state costs, i.e., underestimates of their optimal costs. As FIND-AND-REVISE updates them, costs of dead ends grow without bound, while costs of other states converge to finite values. Thus, dead ends become unattractive and drop out of the greedy policy graph rooted at s_0, leaving FIND-AND-REVISE with an optimal, proper policy.

At the same time, some of the specific heuristic search algorithms for SSP that implement the FIND-AND-REVISE template may fail to terminate on SSPADE. For instance, LAO* and LRTDP may try to update values of dead ends until convergence, which can never be reached. However, each of them can be easily amended to halt on SSPADE problems with an optimal solution. Thus, the existing heuristic search techniques carry over to SSPADE with little adaptation.

4 MDPs with Unavoidable Dead Ends

In this section, our objective is threefold: (1) to motivate the semantics of SSP extensions that admit unavoidable dead ends; (2) to state intuitive policy evaluation criteria and thereby induce the notion of optimal policy for models in which the agent pays finite and infinite penalty for visiting dead ends; (3) to formally define MDP class SSPUDE with subclasses fSSPUDE and iSSPUDE that model such finite- and infinite-penalty scenarios.

As a motivation, consider an *improper* SSP MDP, one that conforms to the SSP definition except for the requirement of proper policy existence, and hence has unavoidable dead ends. In such an MDP, the objective of finding a policy that minimizes the expected cost of reaching the goal becomes ill-defined. It implicitly assumes that for at least one policy, the cost incurred by all of the policy's trajectories is finite; however, this cost is finite only for proper policies, all of whose trajectories terminate at the goal. Thus, all policies in an improper SSP may have an infinite expected cost, making the cost criterion unhelpful for selecting the "best" policy.

We suggest two ways of amending the optimization criterion to account for unavoidable dead ends. The first is to assign a finite positive penalty D for visiting a dead end. The semantics of an improper SSP altered this way would be that the agent pays D when encountering a dead end, and the process stops. However, this straightforward modification to the MDP cannot be directly operationalized, since the set of dead-ends is not known a-priori and needs to be inferred while planning. Moreover, this definition also has a caveat – it may cause non-dead-end states that lie on potential paths to a dead end to have higher costs than dead ends themselves. For instance, imagine a state s whose only action leads with probability $(1 - \epsilon)$ to a dead end,

with probability $\epsilon > 0$ to the goal, and costs $\epsilon(D+1)$. A simple calculation shows that $J^*(s) = D + \epsilon > D$, even though reaching the goal from s *is* possible. Moreover, notice that this semantic paradox cannot be resolved just by increasing the penalty D, because the cost of s will always exceed the dead-end penalty by ϵ.

Therefore, we change the semantics of the finite-penalty model as follows. Whenever the agent reaches *any* state with the expected cost of reaching the goal equaling D or greater, the agent simply pays the penalty D and "gives up", i.e., the process stops. Intuitively, this setting describes scenarios where the agent can put a price on how desirable reaching the goal is. For instance, in the example from the introduction involving a concert in another city, paying the penalty corresponds to deciding not to go to the concert, i.e., foregoing the pleasure the agent would have derived from attending the performance.

The benefit of putting a "cap" on any state's cost as described above is that the cost of a state under any policy becomes finite, formally defined as

$$\textsc{J}\textsc{f}^{\pi}(s) = \min_{\pi} \left\{ D, \mathbb{E}\left[\sum_{t=0}^{\infty} \mathcal{C}(S_t^{\pi_s}, A_t^{\pi_s})\right] \right\} \tag{5}$$

It can be shown that for an improper SSP, there exists an optimal policy π^* [1], one that satisfies

$$\pi^*(s) = \arg\min_{\pi} \textsc{J}\textsc{f}^{\pi}(s) \; \forall \; s \in \mathcal{S} \tag{6}$$

As we show shortly, we can find such a policy using the expected-cost analysis similar to that for ordinary SSP MDPs. The intuitions just described motivate the fSSPUDE MDP class, defined at the end of this section.

The second way of dealing with dead ends we consider in this paper is to view them as truly irrecoverable situations and assign $D = \infty$ for visiting them. As a motivation, recall the example of planning a climb to the top of Mount Everest. Since dead ends here cannot be avoided with certainty and the penalty of visiting them is ∞, comparing policies based on the expected cost of reaching the goal breaks down — they all have an infinite expected cost. Instead, we would like to find a policy that maximizes the probability of reaching the goal and whose expected cost *over the trajectories that reach the goal* is the smallest.

To describe this policy evaluation criterion more precisely, let $S_t^{\pi_s+}$ be a random variable denoting a distribution over states s' for which $P^{\pi}(s') > 0$ and in which the MDP may end up if policy π is executed starting from state s for t steps. That is, $S_t^{\pi_s+}$ differs from the variable $S_t^{\pi_s}$ used previously by considering *only* states from which π can reach the goal. Using the $S_t^{\pi_s+}$ variables, we can mathematically evaluate π with two ordered criteria by defining the cost of a state as an ordered pair

$$\textsc{Ji}^{\pi}(s) = (P^{\pi}(s), [J^{\pi}|P^{\pi}](s)) \tag{7}$$

$$\text{where} \quad [\mathrm{J}^{\pi}|\mathrm{P}^{\pi}](\mathrm{s}) = \mathbb{E}\left[\sum_{\mathrm{t}=0}^{\infty} \mathcal{C}(\mathrm{S}_{\mathrm{t}}^{\pi_s+}, \mathrm{A}_{\mathrm{t}}^{\pi_s})\right] \tag{8}$$

Specifically, we write $\pi(s) \prec \pi'(s)$, meaning π' is preferable to π at s, whenever $\textsc{Ji}^{\pi}(s) \prec \textsc{Ji}^{\pi'}(s)$, i.e., when either $P^{\pi}(s) < P^{\pi'}(s)$, or $P^{\pi}(s) = P^{\pi'}(s)$ and $[J^{\pi}|P^{\pi}](s) > [J^{\pi'}|P^{\pi'}](s)$. Notice that the second criterion is used conditionally, only if two policies are equal in terms of the probability of reaching the goal, since maximizing this probability is the foremost priority. Note also that if $P^{\pi}(s) = P^{\pi'}(s) = 0$, then both $[J^{\pi}|P^{\pi}](s)$ and $[J^{\pi'}|P^{\pi'}](s)$ are ill-defined. However, since that means that neither π nor π' can reach the goal from s, we define $[J^{\pi}|P^{\pi}](s) = [J^{\pi'}|P^{\pi'}](s) = 0$ for such cases, and hence $\textsc{Ji}^{\pi}(s) = \textsc{Ji}^{\pi'}(s)$.

As in the finite-penalty case, we can demonstrate that there exists a policy π^* that is at least as large as all others at all states under the $\prec$-ordering above, and hence optimal, i.e.

$$\pi^*(s) = \arg\max_{\prec\pi} \textsc{Ji}^{\pi}(s) \; \forall \; s \in \mathcal{S} \tag{9}$$

We are now ready to capture the above intuitions in a definition of the SSPUDE MDP class and its subclasses fSSPUDE and iSSPUDE:

Definition An SSP with Unavoidable Dead Ends (SSPUDE) MDP is a tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{C}, \mathcal{G}, D, s_0 \rangle$, where $\mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{C}, \mathcal{G}$, and s_0 are as in the SSP MDP definition, $D \in \mathbb{R}^+ \cup \{\infty\}$ is a penalty incurred if a dead-end state is visited. In a SSPUDE MDP, every improper policy must incur an infinite expected cost as defined by Eq. 1 at all states from which it can't reach the goal with probability 1.

If $D < \infty$, the MDP is called an fSSPUDE MDP, and its optimal solution is a policy π^* satisfying $\pi^*(s) = \min_{\pi} \textsc{J}\textsc{f}^{\pi}(s)$ for all $s \in \mathcal{S}$.

If $D = \infty$, the MDP is called an iSSPUDE MDP, and its optimal solution is a policy π^* satisfying $\pi^*(s) = \max_{\prec\pi} \textsc{Ji}^{\pi}(s)$ for all $s \in \mathcal{S}$.

Our iSSPUDE class is related to multi-objective MDPs, which model problems with several competing objectives, e.g., total time, monetary cost, etc. [Chatterjee et al., 2006, Wakuta, 1995]. Their solutions are Pareto-sets of all non-dominated policies. Unfortunately, such solutions are impractical due to high computational requirements. Moreover, maximizing the probability of goal achievement converts the problem into a GSSP and hence cannot be easily included in those models. A related criterion has also been studied in robotics [Koenig and Liu, 2002].

5 The Case of a Finite Penalty

Equation 5 tells us that for an fSSPUDE instance, the cost of any policy at any state is finite. Intuitively, this implies

[1] We implicitly assume that one of the optimal policies is *deterministic Markovian* — a detail we can actually prove but choose to gloss over in this paper for clarity.

that fSSPUDE should be no harder to solve than SSP. This intuition is confirmed by this following result:

Theorem 3. *fSSPUDE = SSP.*

Proof sketch. To show that every fSSPUDE MDP $M_{fSSPUDE}$ can be converted to an SSP MDP, we augment the action set $\mathcal{A}$ of fSSPUDE with a special action a' that causes a transition to a goal state with probability 1 and that costs D. This MDP is an SSP, since reaching the goal with certainty is possible from every state. At the same time, the optimization criteria of fSSPUDE and SSP clearly yield the same set of optimal policies for it.

To demonstrate that every SSP MDP M_{SSP} is also an fSSPUDE MDP, for every M_{SSP} we can construct an equivalent fSSPUDE MDP by setting $D = J^*(s)$. The set of optimal policies of both MDPs will be the same. (Note, however, that the conversion procedure is impractical, since it assumes that we know $J^*(s)$ before solving the MDP.) □

The above conversion from fSSPUDE to SSP immediately suggests solving fSSPUDE with modified versions of standard SSP algorithms, as we describe next.

Value Iteration: Theorem 3 implies that J^{F*}, the optimal cost function of an fSSPUDE MDP, must satisfy the following modified Bellman equation:

$$J(s) = \min \left\{ D, \min_{a \in \mathcal{A}} \left[\mathcal{C}(s,a) + \sum_{s' \in \mathcal{S}} \mathcal{T}(s,a,s') J(s') \right] \right\} \quad (10)$$

Moreover, it tells us that π^* of an fSSPUDE must be greedy w.r.t. J^{F*}. Thus, an fSSPUDE can be solved with arbitrarily initialized VI_{SSP} that uses Equation 10 for updates.

Heuristic Search: By the same logic as above, all FIND-AND-REVISE algorithms and their guarantees apply to fSSPUDE MDPs if they use Equation 10 in lieu of Bellman backup. Thus, all heuristic search algorithms for SSP work for fSSPUDE.

We note that, although this theoretical result is new, some existing MDP solvers use Equation 10 implicitly to cope with goal-oriented MDPs that have unavoidable dead ends. One example is the miniGPT package [Bonet and Geffner, 2005]; it allows the user to specify a value D and then uses it to implement Equation 10 in several algorithms including VI_{SSP} and LRTDP.

6 The Case of an Infinite Penalty

In contrast to fSSPUDE MDPs, no existing algorithm can solve iSSPUDE problems either implicitly or explicitly, so all algorithms for tackling these MDPs that we present in this section are completely novel.

6.1 Value Iteration for iSSPUDE MDPs

As for the finite-penalty case, we begin by deriving a Value Iteration-like algorithm for solving iSSPUDE. Finding a policy satisfying Eq. 9 may seem hard, since we are effectively dealing with a multicriterion optimization problem. Note, however, the optimization criteria are, to a certain degree, independent — we can *first* find the set of policies whose probability of reaching the goal from s_0 is optimal, and *then* select from them the policy minimizing the expected cost of goal trajectories. This amounts to finding the optimal goal-probability function P^* first, then computing the optimal cost function $[J^*|P^*]$ conditional on P^*, and finally deriving an optimal policy from $[J^*|P^*]$. We consider these subproblems in order.

Finding P^*. The task of finding, for every state, the highest probability with which the goal can be reached by any policy in a given goal-oriented MDP has been studied before — it is the MAXPROB problem mentioned in the Background section. Solving a goal-oriented MDP according to the MAXPROB criterion means finding P^* that satisfies

$$P^*(s) = 1 \; \forall s \in \mathcal{G} \quad (11)$$
$$P^*(s) = \max_{a \in \mathcal{A}} \sum_{s' \in \mathcal{S}} T(s,a,s') P^*(s') \; \forall s \notin \mathcal{G}$$

As already discussed, this P^* can be found by the VI_{MP} algorithm with an arbitrary initializing heuristic.

Finding $[J^*|P^*]$. We could derive optimality equations for calculating $[J^*|P^*]$ from first principles and then develop an algorithm for solving them. However, instead we present a more intuitive approach. Essentially, given P^*, we will build a modification M^{P^*} of the original MDP whose solution is exactly the cost function $[J^*|P^*]$. M^{P^*} will have no dead ends, have only actions greedy w.r.t. P^*, and have a transition function favoring transitions to states with higher probabilities of successfully reaching the goal. Crucially, M^{P^*} will turn out to be an SSP MDP, so we will be able to find $[J^*|P^*]$ with SSPs' familiar machinery.

To construct M^{P^*}, observe that an optimal policy π^* for an iSSPUDE MDP, one whose cost function is $[J^*|P^*]$, must necessarily use only actions greedy w.r.t. P^*, i.e., those maximizing the right-hand side of Eq. 11. For each state s, denote the set of such actions as $\mathcal{A}_s^{P^*}$. We focus on non-dead ends, because for dead ends $[J^*|P^*](s) = 0$, and they will not be part of M^{P^*}. By Eq. 11, for each such s, each $a^* \in \mathcal{A}_s^{P^*}$ satisfies $P^*(s) = \sum_{s' \in \mathcal{S}} T(s,a^*,s') P^*(s')$. Note that this equality expresses the following relationship between event probabilities:

$$P\left(\begin{array}{c}\text{Goal was reached}\\ \text{from } s \text{ via optimal policy}\end{array}\right)$$
$$= \sum_{s' \in \mathcal{S}} P\left(\begin{array}{c}a^* \text{ caused}\\ s \to s' \text{ transition}\end{array} \bigwedge \begin{array}{c}\text{Goal was reached}\\ \text{from } s \text{ via optimal policy}\end{array}\right),$$

or, in a slightly rewritten form,

$$\sum_{s' \in \mathcal{S}} P\left(\begin{array}{c}a^* \text{ caused}\\ s \to s' \text{ transition}\end{array} \;\middle|\; \begin{array}{c}\text{Goal was reached}\\ \text{from } s \text{ via optimal policy}\end{array}\right) = 1,$$

where $P\left(\begin{array}{c} a^* \text{ caused} \\ s \to s' \text{ transition} \end{array} \middle| \begin{array}{c} \text{Goal was reached} \\ \text{from } s \text{ via optimal policy} \end{array}\right) = \frac{T(s,a^*,s')P^*(s')}{P^*(s)}$.

These equations essentially say that if a^* was executed in s and, as a result of following an optimal policy π^* the goal was reached, then with probability $\frac{T(s,a^*,s_1)P^*(s_1)}{P^*(s)}$ action a^* must have caused a transition from s to s_1, with probability $\frac{T(s,a^*,s_2)P^*(s_2)}{P^*(s)}$ it must have caused a transition to s_2, and so on. This means that if we want to find the vector $[J^*|P^*]$ of expected costs of goal-reaching trajectories under π^*, then it is enough to find the optimal cost function of MDP $M^{P^*} = \langle \mathcal{S}^{P^*}, \mathcal{A}^{P^*}, \mathcal{T}^{P^*}, \mathcal{C}^{P^*}, \mathcal{G}^{P^*}, s_0^{P^*} \rangle$, where $\mathcal{G}^{P^*}$ and $s_0^{P^*}$ (if known) are the same as $\mathcal{G}$ and s_0 for the iSSPUDE M that we are trying to solve; $\mathcal{S}^{P^*}$ is the same as $\mathcal{S}$ for M but does not include dead ends, i.e., states s for which $P^*(s) = 0$; $\mathcal{A}^{P^*} = \cup_{s \in \mathcal{S}} \mathcal{A}_s^{P^*}$, i.e., the set of actions consists of all P^*-greedy actions in each state; for each $a^* \in \mathcal{A}_s^{P^*}$, $\mathcal{T}^{P^*}(s, a^*, s') = \frac{\mathcal{T}(s,a^*,s')P^*(s')}{P^*(s)}$, as above, and a^* is "applicable" only in s; and $\mathcal{C}^{P^*}(s, a)$ is the same as $\mathcal{C}$ for M, except it is defined only for $a \in \mathcal{A}^{P^*}$.

As it turns out, we already know how to solve MDPs such as M^{P^*}:

Theorem 4. *For an iSSPUDE MDP M with $P^*(s_0) > 0$, MDP M^{P^*} constructed from M as above is an SSP MDP.*

Proof sketch. Indeed, M^{P^*} is "almost" like the original iSSPUDE MDP, but has at least one proper policy because, by construction, it has no dead ends. □

Now, as we know [Bertsekas, 1995], J^* for the SSP M^{P^*} satisfies $J^*(s) = \min_{a \in \mathcal{A}^{P^*}} \mathcal{C}^{P^*}(s, a) + \sum_{s' \in \mathcal{S}} \mathcal{T}^{P^*}(s, a, s') J^*(s')$. Therefore, by plugging in $\frac{\mathcal{T}(s,a,s')P^*(s')}{P^*(s)}$ in place of $\mathcal{T}^{P^*}(s, a, s')$ and $[J^*|P^*]$ in place of J^*, we can state the following theorem for the original iSSPUDE MDP M:

Theorem 5. *For an iSSPUDE MDP with the optimal goal-probability function P^*, the optimal cost function $[J^*|P^*]$ characterizing the minimum expected cost of trajectories that reach the goal satisfies*

$$[J^*|P^*](s) = 0 \ \forall s \ \textbf{s.t.} \ P^*(s) = 0 \tag{12}$$

$$[J^*|P^*](s) = \min_{a \in \mathcal{A}^{P^*}} \left\{ \mathcal{C}(s, a) + \sum_{s' \in \mathcal{S}} \frac{\mathcal{T}(s, a, s')P^*(s')}{P^*(s)} [J^*|P^*](s') \right\}$$

Putting It All Together. Our construction not only let us derive the optimality equation for $[J^*|P^*]$, but also implies that $[J^*|P^*]$ can be found via VI, as in the case of SSP MDPs [Bertsekas, 1995], over P^*-optimal actions and non-dead-end states. Moreover, since the optimal policy for an SSP MDP is greedy w.r.t. the optimal cost function and solving an iSSPUDE MDP ultimately reduces to solving an SSP, the following important result holds:

Theorem 6. *For every iSSPUDE MDP, there exists a Markovian deterministic policy π^* that can be derived from P^* and $[J^*|P^*]$ for non-dead-end states using*

$$\pi^*(s) = arg \min_{a \in \mathcal{A}^{P^*}} \left\{ \mathcal{C}(s, a) + \sum_{s' \in \mathcal{S}} \frac{\mathcal{T}(s, a, s')P^*(s')}{P^*(s)} [J^*|P^*](s') \right\} \tag{13}$$

Combining optimality equations 11 and 12 for P^* and $[J^*|P^*]$ respectively with Equation 13, we present a VI-based algorithm for solving iSSPUDE MDPs, called IVI (Infinite-penalty Value Iteration) in Algorithm 1.

Input: iSSPUDE MDP M
Output: Optimal policy π^* for non-dead-end states of M

1. Find P^* using arbitrarily initialized VI_{MP}.
2. Find $[J^*|P^*]$ using arbitrarily initialized VI_{SSP} over M^{P^*} with update equations 12

Return π^* derived from P^* and $[J^*|P^*]$ via Equation 13

Algorithm 1: IVI

6.2 Heuristic Search for iSSPUDE MDPs

Input: iSSPUDE MDP M
Output: Optimal policy $\pi^*_{s_0}$ for non-dead-end states of M rooted at s_0

1. Find $P^*_{s_0}$ using FRET initialized with an admissible heuristic $\hat{P} \geq P^*$
2. Find $[J^*|P^*]_{s_0}$ using FIND-AND-REVISE over M^{P^*} with optimality equations 12, initialized with an admissible heuristic $\hat{J} \leq [J^*|P^*]$.

Return $\pi^*_{s_0}$ derived from $P^*_{s_0}$ and $[J^*|P^*]_{s_0}$ via Equation 13

Algorithm 2: SHS

As we established, solving an iSSPUDE MDP with VI is a two-stage process, whose first stage solves a MAXPROB MDP and whose second stage solves an SSP MDP. In the Background section we mentioned that both of these kinds of MDPs can be solved with heuristic search; MAXPROB — with the FRET framework, and SSP — with the FIND-AND-REVISE framework. This allows us to construct a heuristic search schema called SHS (Staged Heuristic Search) for iSSPUDE MDPs, presented in Algorithm 2.

There are two major differences between Algorithms 1 and 2. The first one is that SHS produces functions $P^*_{s_0}$ and $[J^*|P^*]_{s_0}$ that are guaranteed to be optimal only over the states visited by some optimal policy $\pi^*_{s_0}$ starting from the initial state s_0. Accordingly, the SHS-produced policy $\pi^*_{s_0}$ specifies actions only for these states and does not prescribe any for other states. Second, SHS requires two admissible heuristics to find an optimal (partial) policy, one ($\hat{P}$) being an *upper* bound on P^* and the other ($\hat{J}$) being a *lower* bound on $[J^*|P^*]$.

7 Equivalences of Optimization Criteria

The presented algorithms for MDPs with unavoidable dead ends are significantly more complicated than those for MDPs with unavoidable ones. Nonetheless, intuition tells us that for a given tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{C}, \mathcal{G}, D, s_0 \rangle$, solving it under the infinite-penalty criterion (i.e., as an iSSPUDE) should yield the same policy as solving it under the finite-penalty criterion (i.e., as an fSSPUDE) if in the latter case the penalty D is very large. This can be stated as a theorem:

Theorem 7. *For iSSPUDE and fSSPUDE MDPs over the same domain, there exists the smallest finite penalty D_{thres} s.t. for all $D > D_{thres}$ the set of optimal policies of fSSPUDE (with penalty D) is identical to the set of optimal policies of iSSPUDE.*

Proof sketch. Although the full proof is technical, its main observation is simple — as D increases, it becomes such a large deterrent against hitting a dead end that any policy with a probability of reaching the goal lower than the optimal P^* starts having a higher expected cost of reaching the goal than policies optimal according to iSSPUDE's criterion. □

As a corollary, if we choose $D > D_{thres}$, we can be sure that at any given state s, all optimal (JF*-greedy) policies of the resulting fSSPUDE will have the same probability of reaching the goal, and this probability is $P^*(s)$ according to the infinite-penalty optimization criterion (and therefore will also have the same conditional expected cost $[J^*|P^*]$)

This prompts a question: what can we say about the probability of reaching the goal of JF*-greedy policies if we pick $D \leq D_{thres}$? Unfortunately, in this case different greedy policies may not only be suboptimal in terms of this probability, but even for a fixed D each may have a different, arbitrarily low chance of reaching the goal. For example, consider an MDP with three states, s_0 (the initial state), d (a dead end), and g (a goal). Action a_d leads from s_0 to d with probability 0.5 and to g with probability 0.5 and costs 1 unit. Action a_g leads from s_0 to g also with probability 1, and costs 3 units. Finally, suppose we solve this MDP as an fSSPUDE with $D = 4$. It is easy to see that both policies, $\pi(s_0) = a_d$ and $\pi(s_0) = a_g$, have the same expected cost, 3. However, the former reaches the goal with probability 0.5, while the latter always reaches it. The ultimate reason for this discrepancy is that the policy evaluation criterion of fSSPUDE is oblivious to policy's probability of reaching the goal, and optimizes for this parameter only indirectly, via policy's expected cost.

To summarize, we have two ways of finding an optimal policy in the infinite-penalty case, either by directly solving the corresponding iSSPUDE instance, or by choosing a sufficiently large D and solving the finite-penalty fSSPUDE MDP. We do not know of a principled way to choose D, but it is typically easy to guess by inspecting the MDP. Thus, although the latter method gives no a-priori guarantees, it often yields a correct answer in practice.

8 Experimental Results

The objective of our experiments was to find out the most practically efficient way of finding the optimal policy in the presence of unavoidable dead ends and infinite penalty for visiting them, by solving an iSSPUDE MDP or an fSSPUDE MDP with a large D. To make a fair comparison between these methods, we employ very similar algorithms to handle them. For both classes, the most efficient optimal solution methods are heuristic search techniques, so in our experiments we assume knowledge of the initial state and use only algorithms of this type.

To solve an fSSPUDE, we use the implementation of the LRTDP algorithm, an instance of the FIND-AND-REVISE heuristic search framework for SSPs, available in the miniGPT package [Bonet and Geffner, 2005]. As a source of admissible heuristic state costs/goal-probability values, we choose the maximum of atom-min-forward heuristic [Haslum and Geffner, 2000] and SixthSense [Kolobov et al., 2011]. The sole purpose of the latter is to soundly identify many of the dead ends and assign the value of D to them. (Identifying a state as a dead end may be nontrivial if the state has actions leading to other states.)

Since solving iSSPUDE involves tackling two MDPs, a MAXPROB and an SSP, to instantiate the SHS schema (Algorithm 2) we use two heuristic search algorithms. For the MAXPROB component, we use a specially adapted version [Kolobov et al., 2011] of miniGPT's LRTDP, equipped with SixthSense (note that the atom-min-forward heuristic is cost-based and does not apply to MAXPROB MDPs). For the SSP component, we use miniGTP's LRTDP, as for fSSPUDE, with atom-min-forward; SixthSense is unnecessary because SSP has no dead ends.

Our benchmarks were problems 1 through 6 of the Exploding Blocks World domain from IPPC-2008 [Bryce and Buffet, 2008] and problems 1 through 15 of the Drive domain from IPPC-06 [Buffet and Aberdeen, 2006]. Most problems in both domains have unavoidable dead ends. To set the D penalty for the fSSPUDE model, we examined each problem and tried to come up with an intuitive, easily justifiable value for it. For all problems, $D = 500$ yielded a policy that was optimal under both the finite-penalty and infinite-penalty criterion.

Solving the fSSPUDE with $D = 500$ and iSSPUDE versions of each problem with the above implementations yielded the same qualitative outcome on all benchmarks. In terms of speed, solving fSSPUDE was at least an order of magnitude faster than solving iSSPUDE. The difference in used memory was occasionally smaller, but only because both algorithms visited nearly the entire state space reachable from s_0 on some problems. Moreover, in terms of memory as well as speed the difference between solving fSSPUDE and iSSPUDE was the largest (that is, solving iSSPUDE was comparatively the *least* efficient) when the given MDP had $P^*_{s_0}(s) = 1$, i.e. the MDP had no dead ends at all or had only avoidable ones.

Although seemingly surprising, these performance patterns have a fundamental reason. Recall that FRET algorithms, used for solving the MAXPROB part of an iSSPUDE, use the BET operator. BET, for every encountered fixed point $P^\times$ of the Bellman backup operator needs to traverse the transition graph involving all actions greedy w.r.t. $P^\times$, starting from s_0. Also, FRET needs to be initialized with an admissible heuristic, in our experiments – SixthSense, which assigns the value of 0 to states it believes to be dead ends and 1 to the rest.

Now, consider how FRET operates on a MAXPROB corresponding to an iSSPUDE instance that does not have any dead ends, i.e. on the kind of iSSPUDE MDPs that, as our experiments show, is most problematic. For such a MAXPROB, there exists only one admissible heuristic function, $\hat{P}(s) = 1$ for all s, because $P^*(s) = 1$ for all s and an admissible $\hat{P}$ needs to satisfy $\hat{P}(s) \geq P^*(s)$ everywhere. Thus, the heuristic FRET starts with is actually the optimal goal-probability function, and as a consequence, is a fixed point of the Bellman backup operator. Therefore, to conclude that $\hat{P}$ is optimal, FRET needs to build its greedy transition graph. Observe, however, that since $\hat{P}$ is 1 everywhere, this transition graph includes every state reachable from s_0, and uses every action in the MDP! Building and traversing it is very expensive.

The same performance bottleneck, although to a lesser extent, can also be observed on iSSPUDE instances that do have unavoidable dead ends. Building large transition graphs significantly slows down FRET (and hence, SHS) even when P^* is far from being 1 everywhere.

The above reasoning may explain why solving iSSPUDE is slow, but by itself does not explain why solving fSSPUDE is fast in comparison. For instance, we might expect the performance of FIND-AND-REVISE algorithms on fSSPUDE to suffer in the following situations. Suppose state s is a dead end not avoidable from s_0 by any policy. This means that $J^*(s) = D$ under the finite-penalty optimization criterion, and that s is reachable from s_0 by any optimal policy. Thus, FIND-AND-REVISE will halt no earlier than the cost of s under the current cost function reaches D. Moreover, suppose that the heuristic $\hat{J}$ initializes the cost of s to 0 — this is one of the possible admissible costs for s. Finally, assume that all actions in s lead back to s with probability 1 and cost 1 unit. In such a situation, an FIND-AND-REVISE algorithm will need to update the cost of s D times before convergence. Clearly, this will make the performance of FIND-AND-REVISE very bad if the chosen value of D is very large. This raises the question: was solving fSSPUDE in the above experiments so much more efficient than solving iSSPUDE due to our choice of (a rather small) value for D?

To dispel these concerns, we solved fSSPUDE instances of the aforementioned benchmarks with $D = 5 \cdot 10^8$ instead of 500. On all of the 21 problems, the increase in speed compared to the case of fSSPUDE with $D = 500$ was no more than a factor of 1.5. The reason for such a small discrepancy is the fact that, at least on our benchmarks, FIND-AND-REVISE almost never runs into the pathological case described above thanks to the atom-min-forward and SixthSense heuristics. They identify the majority of dead ends encountered by LRTDP and immediately set their costs to D. Thus, instead of spending many updates on such states, LRTDP gets their optimal costs in just one step. To test this explanation, we disabled these heuristics and assigned the cost of 0 to all states at initialization. As predicted, the solution time of the fSSPUDE instances skyrocketed by orders of magnitude.

The presented results appear to imply an unsatisfying fact — on iSSPUDE MDPs that are SSPs, the presented algorithms for solving iSSPUDE are not nearly as efficient as algorithmic schema for SSPs, such as FIND-AND-REVISE. The caveat, however, is that the price SSP algorithms pay for efficiency is *assuming* the existence of proper solutions. iSSPUDE algorithms, on the other hand, implicitly *prove* the existence of such a solution, and are therefore theoretically more robust.

9 Conclusion

A significant limitation of SSP MDPs is their inability to model dead-end states, consequences of catastrophic action outcomes that make reaching the goal impossible. While attempts to incorporate dead ends into SSP have been made before, a principled theory of goal-oriented MDPs with dead-end states has been lacking.

In this paper, we present new general MDP classes that subsume SSP and make increasingly weaker assumptions about the presence of dead ends. SSPADE assumes that dead ends are present but an agent can avoid them if it acts optimally from the initial state. fSSPUDE admits unavoidable dead ends but expects that an agent can put a finite price on running into a dead end. iSSPUDE MDPs model scenarios in which entering a dead end carries an infinite penalty and is to be avoided at all costs.

For these MDP classes, we present VI-based and heuristic search algorithms. We also study the conditions under which they have equivalent solutions. Our empirical results show that, in practice, solving fSSPUDE is much more efficient and yields the same optimal policies as iSSPUDE.

In the future, we hope to answer the question: are iSSPUDE MDPs fundamentally harder than fSSPUDE, or can we invent more efficient heuristic search algorithms for them? Besides, as we found out after submitting this article, a more general class of MDPs than iSSPUDE, called S^3P, has been proposed in the literature but not completely solved [Teichteil-Königsbuch, 2012]. Deriving algorithms for it will be our next research objective.

Abstract

Orienteering problems (OPs) are a variant of the well-known prize-collecting traveling salesman problem, where the salesman needs to choose a subset of cities to visit within a given deadline. OPs and their extensions with stochastic travel times (SOPs) have been used to model vehicle routing problems and tourist trip design problems. However, they suffer from two limitations – travel times between cities are assumed to be time independent and the route provided is independent of the risk preference (with respect to violating the deadline) of the user. To address these issues, we make the following contributions: We introduce (1) a dynamic SOP (DSOP) model, which is an extension of SOPs with dynamic (time-dependent) travel times; (2) a risk-sensitive criterion to allow for different risk preferences; and (3) a local search algorithm to solve DSOPs with this risk-sensitive criterion. We evaluated our algorithms on a real-world dataset for a theme park navigation problem as well as synthetic datasets employed in the literature.

1 Introduction

An orienteering problem (OP) is a planning problem where the goal is to find a sequence of vertices in a graph that maximizes the sum of rewards from those vertices subject to the constraint that the sum of edge lengths along that sequence is no larger than a threshold [34]. It was motivated by competitive orienteering sports where competitors start and end at specified locations and try to accumulate as much reward as possible from visiting checkpoints within a given deadline. Aside from this problem, researchers have also used OPs to model other problems like vehicle routing [11], production scheduling [2] and, more recently, tourist trip design problems [35].

One of the limitations of OPs is that it assumes that edge lengths are deterministic, which can be an inaccurate assumption in applications with uncertainty. Using vehicle routing problems as an example, the travel time between cities, which are modeled with edge lengths, depends on road congestion and is thus not deterministic. Thus, researchers have extended OPs to Stochastic OPs (SOPs), where edge lengths are now random variables that follow a given distribution and the goal is now to find a sequence that maximizes the sum of expected utilities from vertices in the sequence [6].

Although SOPs more accurately model applications with uncertainty, there are two assumptions that limit its applicability. Firstly, the assumption that the distribution of the random variables is time independent can still be inaccurate. Using the vehicle routing problem again as an example, the level of congestion of a road can change throughout the day – roads are more likely to be congested during commuting hours and less likely to be congested in the middle of the night. Thus, the distribution of travel times on the road should also change throughout the day. Therefore, in this paper, we extend SOPs to Dynamic SOPs (DSOPs).

Secondly, the expected utilities do not capture the risk preference of the user (with respect to violating the deadline) who will be employing the solution. In other words, the solution returned for a user with a hard deadline is the same as the one for a user with a soft deadline. Intuitively, the solution for the user with a soft deadline should be longer, and thus more rewarding, but riskier than the solution for the user with a hard deadline. To address this issue, we intro-

duce a risk-sensitive criterion that captures this risk preference. To illustrate the applicability of DSOPs, we evaluated our algorithms on a real-world dataset for a theme park navigation problem as well as synthetic datasets employed in the literature.

2 Motivating Domain

Ubiquitous computing has made substantial progress in recent years, particularly fueled by the increased prevalence of "smart" devices like smart phones. The widespread use of such devices presents a unique opportunity for the delivery of real-time contextualized and personalized information to users. For instance, operators of theme parks have now deployed smart phone applications that allow users to access real-time information like current queueing times at various attractions so that they can better plan their itinerary in the park.[1] Unfortunately, access to current queueing times only allows users to plan myopically, that is, to choose which attraction to go to next. If users also had access to predicted future queueing times, which park operators should be able to provide based on historical data, then the users might be able to make longer term plans that take that information into account. Our research is motivated by this exact problem, where a visitor to a theme park likes to choose (or be recommended) a sequence of attractions that optimizes his/her visitor experience subject to the constraint that the total travel and queueing time in the park is no larger than a threshold. In this paper, we conduct experiments on a real-world dataset for this problem.

3 Background

We now provide a brief description of OPs and SOPs.

3.1 OPs

The *orienteering problem* (OP) [34] is defined by a tuple $\langle G, T, R, v_1, v_n, H\rangle$. $G = \langle V, E\rangle$ is a graph with sets of vertices V and edges E; $T : v_i \times v_j \to \mathbb{R}^+ \cup \{0, \infty\}$ specifies a finite non-negative travel time between vertices v_i and v_j if $e_{ij} \in E$ and ∞ otherwise; and $R : v_i \to \mathbb{R}^+ \cup \{0\}$ specifies a finite non-negative reward for each vertex $v_i \in V$. A solution in an OP is a Hamiltonian path over a subset of vertices including start vertex v_1 and end vertex v_n and whose total travel time is no larger than H. Solving OPs optimally means finding a solution that maximizes the sum of rewards of vertices in its path. Researchers have shown that solving OPs optimally is NP-hard [11]. In this paper, we assume that the end vertex can be any arbitrary vertex.

A simplified version of our motivating theme park navigation problem, where travel and queueing times are deterministic and static, can be modeled as an OP: v_1 corresponds to the entrance of the park, v_n corresponds to the exit of the park, other vertices v_i correspond to attractions in the park, and travel times $T(v_i, v_j)$ correspond to the sum of the travel time between attractions v_i and v_j and the queueing time at attraction v_j.

The start and end vertices in OPs are typically distinct vertices. In the special case where they are the same vertex, the problem is called a *orienteering tour problem* (OTP) [27]. The difference between both formulations is small. It is always possible to add a dummy edge with zero travel time between the start and end vertices to convert an OP to an OTP.

Researchers have proposed several exact branch-and-bound methods to solve OPs [18] including optimizations with cutting plane methods [20, 9]. However, since OPs are NP-hard, exact algorithms often suffer from scalability issues. Thus, constant-factor approximation algorithms [4] are necessary for scalability. Researchers also proposed a wide variety of heuristics to address this issue including sampling-based algorithms [34], local search algorithms [11, 7], neural network-based algorithms [38] and genetic algorithms [32]. More recently, Schilde et al. developed an ant colony optimization algorithm to solve a bi-objective variant of OPs [29].

3.2 Stochastic OPs

The assumption of deterministic travel times is unrealistic in many real-world settings. Using our motivating theme park navigation problem as an example, the travel time of a patron depends on factors like fatigue. Thus, researchers have extended OPs to *Stochastic OPs* (SOPs) [6], where travel times are now random variables that follow a given distribution, and the goal is to find a path that maximizes the sum of expected utilities from vertices in the path. The random variables are assumed to be independent of each other. The expected utility of a vertex is the difference between the expected reward and expected penalty of the vertex. The expected reward (or penalty) of a vertex is the reward (or penalty) of the vertex times the probability that the travel time along the path thus far is no larger (or larger) than H. More formally, the expected utility $U(v_i)$ of a vertex v_i is

$$U(v_i) = P(a_i \leq H)\, R(v_i) - P(a_i > H)\, C(v_i)$$

where the random variable a_i is the arrival time at vertex v_i (that is, the travel time from v_1 to v_i), $R(v_i)$

[1] http://disneyparksmobile.com/ is one such example.

is the reward of arriving at vertex v_i before or at H and $C(v_i)$ is the penalty of arriving at vertex v_i after H. Campbell et al. have extended OP algorithms to solve SOPs including an exact branch-and-bound method and a local search method based on variable neighborhood search [6]. Gupta et al. introduced a constant-factor approximation algorithm for a special case of SOPs, where there is no penalty for arriving at a vertex after H [12].

4 Dynamic Stochastic OPs

Stochastic OPs (SOPs) assume independence of travel time distributions across different edges. However, in many problems, there is a considerable dependence of travel times on the arrival time at a vertex. Using our motivating theme park navigation problem again as an example, the travel time of a user depends on factors like fatigue, and the level of fatigue of a patron increases as they spend more time in the park.

To capture dependencies between travel time distributions, we introduce an extension to SOPs called *Dynamic SOPs* (DSOPs). The key difference from SOPs is that the travel time distribution in DSOPs for moving from vertex v_i to v_j is dependent on the arrival time a_i at vertex v_i. In this paper, we will assume $T_{i,j}$ to be a discrete set of distributions, where each element of the set corresponds to a range of values for a_i. Therefore, the travel time distribution for an arrival time of a_i is represented as $T_{i,j}^{a_i}$ and hence the probability that travel time is m is given by $T_{i,j}^{a_i}(m)$.

4.1 Risk-Sensitive Criterion

While expected utility is a good metric in general, the approach by [6] suffers from many limitations. Firstly, it is a point estimate solution which does not consider the "risk" profile of the user. By "risk", we do not refer to the term used in a financial sense, but rather the level of conservativeness measured in terms of the probability of completing the path within the deadline. In other words, a risk-seeking user will be prepared to choose a sequence of attractions that have a large utility, but with a higher probability of not completing the path within the deadline, compared to a risk-averse user who might choose a more "relaxed" path with lower utility. Secondly, the underlying measurement of expected utility is not intuitive in the sense that a utility value accrued at each attraction does not usually depend on the probability that the user arrives at the attraction by a certain time; but rather, the utility is accrued when the attraction is visited, and the user is concerned with visiting all the attractions (i.e. sum of utilities) within a certain time threshold.

Given the above consideration, we are interested in the problem that allows the user to tradeoff between the level of conservativeness (or risk) against the total utility. More precisely, given a value $0 \leq \epsilon \leq 1$, we are interested in obtaining a path, where the probability of completing the entire path within a deadline H is at least $1 - \epsilon$. Or more precisely,

$$P(a_n \leq H) \geq 1 - \epsilon \tag{1}$$

where a_n is the arrival time at the last vertex of the path. The objective value is therefore inversely proportional to the value of ϵ.

5 Completion Probability Approximations

In this section, we describe two ways of approximating the completion probability $P(a_n \leq H)$, which is used in Equation 1. Given the order $\pi = \langle v_1, v_2, \ldots, v_k, v_n \rangle$, we can use the following expression to compute the completion probability:

$$\begin{aligned} P(a_n \leq H) = & \\ & \int_{a_n=0}^{a_n \leq H} \int_{a_k=0}^{a_k=a_n} \int_{a_{k-1}=0}^{a_{k-1}=a_k} \cdots \int_{a_1=0}^{a_1=a_2} \\ & T_{k,n}^{a_k}(a_n - a_k)\, T_{k-1,k}^{a_{k-1}}(a_k - a_{k-1}) \cdots T_{1,2}^{a_1}(a_2 - a_1) \\ & d(a_1)\, d(a_2) \ldots d(a_k)\, d(a_n) \end{aligned} \tag{2}$$

where a_n is the arrival time at the exit node, and we capture the dependencies on arrival times at each of the vertices by reducing the range of feasible arrival times (for the integrals) based on the previous activities in the order of vertices. Unfortunately, the computation of the expression is expensive since the integrals have to be computed sequentially. To provide an intuition for the time complexity, computing triple integrals take around 30 minutes with an exponential distribution (most scalable of all distributions with integration) on our machine using the Matlab software. To address this issue of scalability, we introduce two approximation approaches, a sampling-based approach and a matrix-based approach.

5.1 Sampling-based Approach

One can approximate the completion probability $P(a_n \leq H)$ of a path by randomly sampling the travel time distributions for each edge along the path, and checking if the arrival time a_n at the last vertex exceeds H. For example, assume that we want to compute $P(a_n \leq H)$ for the path $\pi = \langle v_1, v_2, \ldots, v_k, v_n \rangle$. Using the starting time a_1, we generate a travel time sample from the distribution $T_{1,2}^{a_1}$ to represent the travel time from vertex v_1 to vertex v_2, which is also the arrival time a_2 at vertex v_2. We then generate a

travel time sample from the distribution $T_{2,3}^{a_2}$ to represent the travel time from vertex v_2 to vertex v_3. The arrival time a_3 at vertex v_3 is thus the sum of both travel times. We continue this process until we generate a travel time sample to represent the travel time from vertex v_k to vertex v_n, and the arrival time a_n is thus the sum of all travel times. We count this entire process as a single sample. We can then approximate

$$P(a_n \leq H) \approx \hat{P}(a_n \leq H) = \frac{N^+}{N} \tag{3}$$

where N^+ is the number of samples whose arrival time $a_n \leq H$ is no larger than the deadline H and N is the total number of samples. Unfortunately, this approach does not provide any theoretical guarantees on whether Equation 1 is truly satisfied. However, as we increase the number of samples, the approximation for the actual distribution becomes tighter.

5.2 Matrix-based Approach

Alternatively, one can exploit the fact that the dependencies are primarily due to arrival time at a vertex and not on the entire order of vertices before the current vertex. At a higher level, it implies that the underlying problem is Markovian and hence we can decompose the expression of Equation 2. We also make conservative estimates of the probability such that we can provide theoretical guarantees on whether Equation 1 is truly satisfied.

The key ideas here are (1) to divide the possible arrival times a_i at vertex v_i into a finite number of ranges $\mathbf{r}_{i,1}, \mathbf{r}_{i,2}, \ldots, \mathbf{r}_{i,k}$, where $\mathbf{r}_{i,j}$ is the j-th range of arrival time at vertex v_i and (2) to pre-compute for all pairs of vertices v_i and v_j a conservative estimate $\hat{P}(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p})$ of the probability $P(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p})$ of transitioning between ranges of arrival times $\mathbf{r}_{i,p}$ and $\mathbf{r}_{j,q}$. Thus, we can now decompose the expression of Equation 2 to an expression that exploits the Markovian property along with ranges of arrival times:

$$\begin{aligned} P(a_n \leq H) = & \\ & \sum_i P(a_1 \in \mathbf{r}_{1,i}) \cdot \sum_j P(a_2 \in \mathbf{r}_{2,j} | a_1 \in \mathbf{r}_{1,i}) \\ & \cdots \sum_y P(a_k \in \mathbf{r}_{k,y} | a_{k-1} \in \mathbf{r}_{k-1,x}) \\ & \cdot \sum_z P(a_n \in \mathbf{r}_{n,z} | a_k \in \mathbf{r}_{k,y}) \end{aligned}$$

and conservatively approximate it by

$$\begin{aligned} \hat{P}(a_n \leq H) = & \\ & \sum_i \hat{P}(a_1 \in \mathbf{r}_{1,i}) \cdot \sum_j \hat{P}(a_2 \in \mathbf{r}_{2,j} | a_1 \in \mathbf{r}_{1,i}) \\ & \cdots \sum_y \hat{P}(a_k \in \mathbf{r}_{k,y} | a_{k-1} \in \mathbf{r}_{k-1,x}) \\ & \cdot \sum_z \hat{P}(a_n \in \mathbf{r}_{n,z} | a_k \in \mathbf{r}_{k,y}) \end{aligned}$$

It is clear that $\hat{P}(a_n \leq H) \leq P(a_n \leq H)$ is a conservative estimate if $\hat{P}(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p}) \leq P(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p})$ are all conservative estimates. $\hat{P}(a_1 \in \mathbf{r}_{1,i})$ depends on the starting time at vertex v_1, which is provided as an input. We now describe how to compute the other probabilities $\hat{P}(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p})$. If the range $\mathbf{r}_{i,p}$ contains only a single point a_i, then

$$\begin{aligned} P(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p}) =& P(a_j \in \mathbf{r}_{j,q} | a_i) \\ =& \int_{a_j \in \mathbf{r}_{j,q}} T_{i,j}^{a_i}(a_j - a_i)\ d(a_j) \end{aligned} \tag{4}$$

However, the realization of the random variable a_i only occurs at runtime, and computing the integral in Equation 4 at runtime is expensive. Thus, we would like to compute a conservative estimate $\hat{P}(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p})$ of probability $P(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p})$ for all possible realizations of $a_i \in \mathbf{r}_{i,p}$. We thus compute them as follows:

$$\begin{aligned} \hat{P}(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p}) = & \\ & \min_{a_i \in \mathbf{r}_{i,p}} \int_{a_j \in \mathbf{r}_{j,q}} T_{i,j}^{a_i}(a_j - a_i)\ d(a_j) \end{aligned} \tag{5}$$

The value in the integral is the probability of the arrival time a_j to be in the range $\mathbf{r}_{j,q}$ for a given value of a_i. Thus, by taking the minimum of these probabilities over all possible values of a_i in the range $\mathbf{r}_{i,p}$, the conditional probability $\hat{P}(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p}) \leq P(a_j \in \mathbf{r}_{j,q} | a_i \in \mathbf{r}_{i,p})$ is a conservative estimate of the true probability.

Once all the probabilities are pre-computed, they form transition matrices

$$\mathbf{P}_{i,j} = \begin{pmatrix} \hat{P}(a_j \in \mathbf{r}_{j,1}) | a_i \in \mathbf{r}_{i,1}) & \hat{P}(a_j \in \mathbf{r}_{j,2}) | a_i \in \mathbf{r}_{i,1}) & \cdots \\ \hat{P}(a_j \in \mathbf{r}_{j,1}) | a_i \in \mathbf{r}_{i,2}) & \hat{P}(a_j \in \mathbf{r}_{j,2}) | a_i \in \mathbf{r}_{i,2}) & \cdots \\ \cdots & \cdots & \cdots \end{pmatrix} \tag{6}$$

which represent the transition probabilities from vertices v_i to v_j. Finally, to compute $\hat{P}(a_n \leq H)$, we compute the multiplication of matrices $\mathbf{P}_1 \cdot \mathbf{P}_{1,2} \cdot \mathbf{P}_{2,3} \cdots \mathbf{P}_{k-1,k} \cdot \mathbf{P}_{k,n}$ and in the resultant matrix, sum up all the probabilities for ranges of arrival times a_n that are less than or equal to the deadline H.

6 DSOP Algorithms

In this section, we describe a branch-and-bound algorithm and a local search algorithm that solves DSOPs.

6.1 Branch-and-Bound Algorithm

We provide a depth-first branch-and-bound algorithm, where the root of the search tree is the start vertex and the children of a vertex are all the unvisited vertices minus the exit vertex. The branch of an arbitrary vertex thus represents the path from the start vertex to that vertex. The value of a vertex is the sum of rewards of all vertices along its branch. The algorithm prunes the subtree of a vertex if it fails to satisfy our risk-sensitive criterion. For example, assume that a vertex v_k is on the branch $\pi = \langle v_1, v_2, \ldots, v_k \rangle$, where vertex v_i is on the i-th position on the branch. The algorithm prunes the subtree rooted at vertex v_k if the condition in Equation 1 is not satisfied if one appends the exit vertex to the end of the path. The algorithm returns the vertex with the largest value and the branch of that vertex with the exit vertex appended at the end of the path as the best solution that satisfies the risk-sensitive criterion.

6.2 Local Search Algorithm

Unfortunately, the branch-and-bound algorithm suffers from scalability issues as the size of the search tree is exponential in the number of vertices in the graph. We thus introduce a local search algorithm that is based on the standard two-phase approach – a construction heuristic to generate an initial solution followed by local improvements on that solution.

6.2.1 Construction Heuristic

The construction heuristic is a greedy insertion algorithm that greedily inserts the best unvisited vertex at the best position in the current path according to a given metric. The algorithm begins with the path that starts at the start vertex and immediately exits at exit vertex, and it terminates when it can no longer insert any attraction at any position without violating the condition in Equation 1.

In this paper, we use the following metric to evaluate the value of inserting vertex v_i at position p: $\frac{\Delta R}{1+\Delta P}$, where ΔR and ΔP is the gain in reward and probability, respectively, for inserting vertex v_i at position p. Thus, $\Delta R = R(v_i)$, which is the reward of vertex v_i, and $\Delta P = \hat{P}(a_n \leq H) - \hat{P}'(a_n \leq H)$, where $\hat{P}'(a_n \leq H)$ and $\hat{P}(a_n \leq H)$ is the probability of arriving at the exit vertex before and after insertion, respectively. We use the same approach of multiplying transition matrices described in Section 6.1 to speed up the computation of the probabilities. Finally, we add 1 to the gain in probabilities such that the denominator is greater than 0.

This metric is motivated by similar metrics in knapsack problems, namely the utility of an item is the ratio between the reward and size of that item [23]. We have also tried 4 other variants of the above metric, namely (1) $\frac{1}{1+\Delta P}$, (2) ΔR, (3) $\frac{(\Delta R)^2}{1+\Delta P}$, (4) $\frac{\Delta R}{\sqrt{1+\Delta P}}$, where we ignored the effects of rewards in (1) and probabilities in (2), and we amplified the effects of rewards in (3) and probabilities in (4). However, our chosen metric was shown to outperform these 4 variants empirically.

6.2.2 Local Improvements

We use a hybrid approach that consists of a variable neighborhood search combined with simulated annealing to locally improve our initial solution found by the construction heuristic. Algorithm 1 shows the pseudocode of this algorithm. After constructing the ini-

tial solution (line 1), the algorithm iteratively runs the following four phases until the maximum number of iterations is reached (line 6):

Phase 1: If the path contains at least two vertices (not including the start and end vertices), then the algorithm performs a 2-Opt operation, that is, it randomly swaps two of these vertices (line 9).

Phase 2: If the path is not feasible, that is, it does not satisfy Equation 1, then the algorithm repeatedly removes the second last vertex until the path is feasible. (The algorithm does not remove the last vertex because it is the exit vertex.) Once the path is feasible, the algorithm repeatedly removes the second last vertex probabilistically (lines 10-12).[2]

Phase 3: The algorithm repeatedly inserts unvisited vertices greedily similar to the construction heuristic (line 13). The difference here is that the metric used can be one of five different metrics, either the metric chosen for the construction heuristics or one of its four variants described above. The algorithm starts by choosing one of the five metrics randomly (line 4). If there are no improvements in *maxIterNoImprove* iterations, the algorithm chooses a new different metric randomly (lines 25-26). These different metrics correspond to the different "neighborhoods" in our variable neighborhood search.

Phase 4: The algorithm then updates the current path to the new neighboring path, which is a result from inserting unvisited vertices in Phase 3, if the new path is a better path or with a probability that depends on the simulated annealing temperature (lines 14-17).

Reusing Matrix Computations: We re-compute the completion probability $\hat{P}(a_n \leq H)$ whenever we make a local move during the search, that is, when (a) two vertices are swapped, (b) a vertex is removed, and/or (c) a vertex is inserted. To compute these probabilities efficiently, we store the results of the products of transition matrices for subsets of vertices. For example, in a path $\pi = \langle v_1, v_2, \ldots, v_i, \ldots, v_j, \ldots \rangle$, if we swap vertices v_i and v_j, then the product of transition matrices for the vertices before v_i, the product of matrices for the vertices between v_{i+1} and v_{j-1}, and the product of matrices for the vertices after v_{j+1} remain unchanged. By storing all of these intermediate results, it is possible to make the computation of probabilities very efficient. However, it requires a significant amount memory for larger problems. In this paper, we store only the products of matrices for the vertices between the start vertex and every subsequent vertex in the path except for the exit vertex. For example, for a path $\pi = \langle v_1, v_2, v_3, v_n \rangle$, we store the product of matrices for vertices v_1 and v_2, which is $\hat{P}(a_2 \leq H)$, and the product of matrices for vertices v_1, v_2 and v_3, which is $\hat{P}(a_3 \leq H)$. While this is not the most efficient approach, it provides a good tradeoff between memory requirement and efficiency.

[2]The rand() function returns a random number in [0,1].

7 Experimental Results

We now empirically demonstrate the scalability of our approaches on synthetic datasets employed in the literature as well as a real-world dataset for a theme park navigation problem. We run our experiments on a 3.2GHz Intel i5 dual-core CPU with 12GB memory, and we set the parameters for the local search algorithm as follows: we set *maxIterNoImprove* to 50, *maxIterations* to 1500, T to 0.1 and ΔT to 0.99. We divide each travel time distribution to 100 ranges for the matrix-based computations and use 1000 samples for the sampling-based computations.

7.1 Synthetic Dataset Results

Our synthetic dataset is based on the dataset provided in [34] with 32 vertices. We assume that the total travel time of each edge is the sum of the travel time between the two vertices connected by that edge and the queueing time at the target vertex of that edge. As in [6], we assume that the total travel time of each edge is a gamma distribution, whose mean is the Euclidean distance between the vertices connected by that edge. We vary the shape parameter $2 \leq k \leq 9$ and scale parameter $1 \leq \theta \leq 4$ such that the mean of the values $\mu \approx k\theta$ is approximately equal to the product of the shape parameter k and the scale parameter θ. A gamma distribution with $k = 1$ is an exponential distribution. As we wanted a more normal-like distribution, we did not include this value of k in our experiments. We also bound the possible values of k such that shape of the distributions across time ranges do not vary significantly, and we use the same bound on the possible values of θ as in [6]. Lastly, we set rewards for each vertex to a random number between 1 and 100.

Table 1 shows our results for the construction heuristic algorithm (labeled CH) and local search algorithm (labeled LS), where we calculate the completion probability of a path (see Equation 1) using both the matrix-based approach (see Equations 5 and 6) and the sampling-based approach (see Equation 3). We report the completion probability of the best path found by the local search algorithm using the matrix-based approach (labeled P_M) and the sampling-based approach (labeled P_S). We also report the the percentage of improvement in the reward of the path found by the local search algorithm compared to the path found by the construction heuristic algorithm (denoted

Table 1: Experimental Results for Simpler Synthetic Datasets

in parentheses beside the local search rewards). The branch-and-bound algorithm successfully terminated for problems with small deadlines H and risk parameters ϵ only. Therefore, we did not tabulate its results as it is unfair to only consider successful runs in computing them. (We do not know the rewards and completion probabilities for unsuccessful runs.) We make the following observations:

- Table 1(a) shows that for the matrix-based approach, the solution rewards increase between $\theta = 1$ and $\theta = 2$, and remain relatively unchanged for larger values of θ. As θ increases, the variance of the gamma distributions increases as well. When $\theta = 1$, only very few ranges have non-zero transition probabilities computed with Equation 5. As a result, adding an additional edge to a solution can result in a significant decrease in completion probability. With larger values of θ, more ranges have non-zero transition probabilities, but the number of ranges and transition probabilities do not change much with increasing values of θ. Thus, the path length and, consequently, reward and runtime, typically increases as θ increases from 1 to 2, but remains relatively unchanged for larger values of θ. The runtime depends on the path length because the number of positions to check to find the best position to insert a vertex, which is done by the construction heuristic algorithm and phase 3 in the local improvement phase, depends on the path length.

  On the other hand, for the sampling-based approach, the solution rewards decrease as θ increases. Since the sampling probabilities are relatively accurate representations of the true probabilities, as the variance increases, adding an additional edge to a solution can result in a significant decrease in completion probability. Thus, the path length and, consequently, reward and runtime, typically decreases as θ increases.

- Table 1(a) also shows that as θ increases, for the sampling-based approach, the improvement of the local search algorithm over the construction heuristic algorithm decreases. The reason is that as the variance of the gamma distributions increases, there is less distinction between the different gamma distributions. Thus, many of the neighboring solutions are very similar to the solution found by the construction heuristic algorithm. For the matrix-based approach, the improvements are all negligible. The path lengths are short (with 1-3 vertices excluding the start and end vertices), and thus there is no much room

Table 3: Experimental Results for Real-World Theme Park Dataset

for improvement. We confirm this result with the branch-and-bound algorithm, where it found similar paths to those found by the local search algorithm for problems where it successfully terminated.

- Tables 1(b) and 1(c) show that as H or ϵ increases, the solution reward increases for both matrix- and sampling-based approaches, which is to be expected. Similarly, the runtime also increases since the number of positions to check to find the best position to insert a vertex also increases.

- Table 1(c) shows that the completion probabilities P_M and P_S are all no less than $1 - \epsilon$ for the matrix- and sampling-based approaches, respectively, which is to be expected.

We observe that the problems in this dataset are relatively easy as all gamma distributions have the same scale parameter and their means satisfy the triangle inequality. Thus, we modified the dataset to increase its difficulties in the following ways: (a) we choose the scale parameter θ of the gamma distributions for each edge randomly between 1 and 4 such that not all edges have distributions with the same scale parameter, and (b) we change the shape parameter k of the gamma distributions for some subset of edges such that their means no longer satisfy the triangle inequality. Table 2 shows our results for this more difficult synthetic dataset. We make the same observations here as in the simpler dataset with the exception that the improvements of the local search algorithm over the construction heuristic algorithm is now up to 30% as opposed to 18% earlier.

Overall, using the sampling-based approach, the local search algorithm provides reasonably better solutions compared to the construction heuristic algorithm. However, it is not guaranteed that these solutions are feasible, that is, they satisfy Equation 1. However, the feasibility likelihood increases with the number of samples. Thus, this approach is better suited for users without strict feasibility requirements. On the other hand, solution feasibility is guaranteed for algorithms using the matrix-based approach. Unfortunately, the local search algorithm fails to reasonably improve on the solutions found by the construction heuristic algorithm. Thus, the construction heuristic algorithm using the matrix-based approach is better suited for users with strict feasibility requirements.

7.2 Real-World Dataset Results

For our real-world theme park dataset, the total travel time of each edge is also a gamma distribution. We choose the scale parameter θ and shape parameter k such $\mu \approx k\theta$ and $\sigma^2 \approx k\theta^2$, where μ and σ^2 is the mean and variance, respectively, of our data points (across several months) for the sum of travel time and queueing time. Similar to the synthetic datasets, we also set rewards for each vertex to a random number between 1 and 100. However, we do not bound the possible values of the scale and shape parameters θ and k such that the gamma distributions approximate the data points as accurately as possible. Lastly, we segment our data points into two categories, peak days and non-peak days,[3] and present results for both categories.

Table 3 shows our results for the local search algorithm using the sampling-based approach to compute the completion probabilities; the deadline H is measured in hours. We only show the solution rewards as the other trends are similar to those observed for the synthetic datasets. Similar to the synthetic datasets, as H and ϵ increase, the solution reward also typically increases. Additionally, the solution rewards for non-peak days are larger than those for peak days. The reason is that the queueing time at an attraction is smaller on non-peak days than on peak days. Thus, it is possible to visit more attractions, and thus accrue more rewards, on non-peak days than on peak days.

8 Related Work

OPs have a long history and has been known by a variety of other names including selective TSPs [18], maximum collection problems [16] and bank robber problems [1]. Vansteenwegen et al. recently presented a broad overview of the problem, its variants and associated solution methods [36]. In contrast, to the best of our knowledge, there has not been much work in stochastic variants of OP thus far. Aside from the work on SOPs [6], two closely related problems with stochastic travel times are time-constrained TSPs with stochastic travel and service times [33] and stochastic selective TSPs [31]. These problems assume that the traveling time distributions are time independent, unlike our dynamic SOPs. Lastly, aside from travel time, researchers have also investigated stochasticity in the reward values of vertices [15].

SOPs also bear some similarity with Markov random fields (MRFs) [37] and Bayesian networks [28]. They are both graphical models, where nodes in a graph correspond to random variables and edges in a graph correspond to potential functions between pairs of random variables. While MRF graphs can be cyclic, Bayesian network graphs are strictly acyclic. The goal in these two models is to compute the maximum a posteriori (MAP) assignment, which is the most probable assignment to all the random variables of the underlying graph in MRFs [37, 17, 30] and Bayesian networks [24, 14, 39]. Thus, the main difference between MAP assignment problems and SOPs is that MAP assignment problems are *inference* problems while SOPs are *planning* problems. DSOPs can potentially be represented using the TiMDP model [5]. However, the objective in TiMDPs is to maximize expected reward, which is unlike in DSOPs, where we also consider the robustness criterion.

With respect to modeling and accounting for different risk preferences, there are generally the following three approaches: (1) Stochastic dominance, whose theory was developed in statistics and economics [19, 13]. Stochastic dominance defines partial orders on the space of random variables and allow for pairwise comparison of different random variables. (2) Mean-risk analysis, whose models originate from finance. They include the well known mean-variance optimization model in portfolio optimization, where the variance of the return is used as the risk functional [21]. (3) Chance constraints or percentile optimization, whose models were initiated and developed in operations research [22, 25]. Recently, researchers have provided a thorough overview of the state-of-the-art of the optimization theory with chance constraints [26]. Our approach of defining a risk-sensitive measure that allows the user to specify a level of risk (failure tolerance) is along the lines of using chance constraints to model and account for different risk preferences. While it has been applied to solve planning and scheduling problems [3, 8, 10], to the best of our knowledge, it has yet to be applied to solve OPs.

9 Conclusions

Researchers have used OPs to model vehicle routing and tourist trip design problems. However, OPs assume that the travel times are independent of the time of day and the route returned is independent of the risk preference of the user. Therefore, we make the following contributions in this paper: (1) we introduce a dynamic and stochastic OP (DSOP) model that allow for time-dependent travel times; (2) we propose a risk-sensitive criterion that allow for different risk preferences; and (3) we develop a local search algorithm to solve DSOPs with this risk-sensitive criterion. We also empirically show that this approach is applicable on a real-world theme park navigation problem. We anticipate that such user-centric route guidance will be more widely used as users carry smart devices and use mobile applications with increasing intensity.

[3] Peak days are Fridays, Sundays and Mondays according to our theme park operator.

Abstract

We introduce a novel framework for computing optimal randomized security policies in networked domains which extends previous approaches in several ways. First, we extend previous linear programming techniques for Stackelberg security games to incorporate benefits and costs of arbitrary security configurations on individual assets. Second, we offer a principled model of failure cascades that allows us to capture both the direct and indirect value of assets, and extend this model to capture uncertainty about the structure of the interdependency network. Third, we extend the linear programming formulation to account for exogenous (random) failures in addition to targeted attacks. The goal of our work is two-fold. First, we aim to develop techniques for computing optimal security strategies in realistic settings involving interdependent security. To this end, we evaluate the value of our technical contributions in comparison with previous approaches, and show that our approach yields much better defense policies and scales to realistic graphs. Second, our computational framework enables us to attain theoretical insights about security on networks. As an example, we study how allowing security to be endogenous impacts the relative resilience of different network topologies.

1 Introduction

Game theoretic approaches to security have received much attention in recent years. There have been numerous attempts to distill various aspects of the problem into a model that could be solved in closed form, particularly accounting for interdependencies of security decisions (e.g., Kunreuther and Heal [2003], Grossklags et al. [2008]). Numerous others offer techniques based on mathematical programming to solve actual instances of security problems. One important such class of problems is network interdiction [Cormican et al., 1998], which models zero-sum encounters between an interdictor, who attempts to destroy a portion of a network, and a smuggler, whose goal typically involves some variant of a network flow problem (e.g., maximizing flow or computing a shortest path).

Our point of departure is another class of optimization-based approaches in security settings: Stackelberg security games [Paruchuri et al., 2008]. These are two-player games in which a *defender* aims to protect a set of targets using a fixed set of limited defense resources, while an *attacker* aims to assail a target that maximizes his expected utility. A central assumption in the literature on Stackelberg security games is that the defender can commit to a probabilistic defense (equivalently, the attacker observes the probabilities with which each target is covered by the defender, but not the actual defense realization).

Much of the work on Stackelberg security games focuses on building fast, scalable algorithms, often in restricted settings [Kiekintveld et al., 2009, Jain et al., 2010, Shieh et al., 2012]. One important such restriction is to assume that targets exhibit *independence*: that is, the defender's utility only depends on which target is attacked and the security configuration at that target. Short of that restriction, one must, in principle, consider all possible combinations of security decisions jointly for all targets, making scalable computation elusive. Many important settings, how-

ever, exhibit interdependencies between potential targets of attack. These may be explicit, as in IT and supply chain network security, or implicit, as in defending critical infrastructure (where, for example, successful delivery of transportation services depends on a highly functional energy sector, and vice versa), or in securing complex software systems (with failures at some modules having potential to adversely affect other modules). While in such settings the assumption of independence seems superficially violated, we demonstrate below that under realistic assumptions about the nature of interdependencies, we can nevertheless leverage the highly scalable optimization techniques which assume independence.

In all, we offer the following contributions. (1) We modify and extend the previous linear programming techniques for Stackelberg security games to allow for an arbitrary set of security configurations (rather than merely to cover a target, or not), as well as to account for both random and targeted failures, and replace hard constraints on defense resources with costs associated with specific security configurations (Section 3). (2) We present and justify a crucial assumption on the nature of interdependencies that allows us to use our LP formulations which fundamentally assume independence between targets (Section 4.1). We then offer a simple model of interdependencies based on probabilistic failure cascades satisfying this assumption. Our model makes an explicit distinction between an intrinsic and indirect value of assets, the latter being due entirely to interdependencies. This allows an economically meaningful extension of a well-known independent cascade approach to modeling the spread of infectious diseases or ideas (Section 4). (3) We demonstrate that for trees we can compute expected utilities for all targets in linear time (Section 4). (4) We extend our model to capture uncertainty about network structure, and experimentally study the impact of such uncertainty (Sections 4.5 and 6.1). (5) We show that our approach is both scalable to realistic security settings and offers much better solutions than state-of-the-art alternatives (Sections 5.2 and 5.2). (6) We experimentally study the properties of optimal defense configurations in real and generated networks (Section 6).

2 Stackelberg Security Games

A Stackelberg security game consists of two players, the leader (defender) and the follower (attacker), and a set of possible targets. The leader can decide upon a randomized policy of defending the targets, possibly with limited defense resources. The follower (attacker) is assumed to observe the randomized policy of the leader, but not the realized defense actions. Upon observing the leader's strategy, the follower chooses a target so as to maximize its expected utility.

In past work, Stackelberg security game formulations focused on defense policies that were costless, but resource bounded. Specifically, it had been assumed that the defender has K fixed resources available with which to cover targets. Additionally, security decisions amounted to covering a set of targets, or not. While in numerous settings to which such work has been applied (e.g., airport security, federal air marshal scheduling) this formulation is very reasonable, in other settings one may choose among many *security configurations* for each valued asset, and, additionally, security resources are only available at some cost. For example, in cybersecurity, protecting computing nodes could involve configuring anti-virus and/or firewall settings, with stronger settings carrying a benefit of better protection, but at a cost of added inconvenience, lost productivity, as well as possible licensing costs. Indeed, costs on resources may usefully replace resource constraints, since such constraints are often not hard, but rather channel an implicit cost of adding further resources.

While security games as described above naturally entail an attacker, most systems exhibit failures that are not at all a deliberate act of sabotage, but are due entirely to inadvertent errors. Even though such failures are generally far more common than attacks, the vast majority of work in security games posits an attacker, but ignores such failures entirely; essentially the lone exception is a paper by Zhuang and Bier [2007] which offers an analytic treatment of a simple model making explicit the distinction between attacks and natural disasters. Our formulation below is, to our knowledge, the first to explicitly model both attacks and random failures in the Stackelberg security game literature.

To formalize, suppose that the defender can choose from a finite set O of security configurations for each target $t \in T$, with $|T| = n$. A configuration $o \in O$ for target $t \in T$ incurs a cost $c_{o,t}$ to the defender. If the attacker happens to attack t while configuration o is in place, the expected value to the defender is denoted by $U_{o,t}$, while the attacker's value is $V_{o,t}$. A key assumption in Stackelberg security games is that the targets are completely independent: that is, player utilities only depend on the target attacked and its security configuration [Kiekintveld et al., 2009]. We revisit this assumption below when we turn to networked (interdependent) settings. We denote by $q_{o,t}$ the probability that the defender chooses o at target t. Finally, let r be the prior probability of the defender that a failure will happen due to a deliberate attack. If no attack is involved, any target can fail; the defender's belief that target t randomly fails (conditional on the event that no attack is involved) is g_t, with $\sum_t g_t = 1$.

3 Computing Optimal Randomized Security Configurations

Previous formulations of Stackelberg security games involved a fixed collection of defender resources, and in most cases a binary decision to be made for each target: to cover it, or not. To adapt these to our domains of interest, we first modify the well-known multiple linear program (henceforth, multiple-LP) formulation that assumes target independence to incorporate an arbitrary set of security configurations, together with their corresponding costs of deployment. In the multiple-LP formulation, each linear program solves for an optimal randomized defense strategy *given that the attacker attacks a fixed target* $\hat{t}$, with the constraint that $\hat{t}$ is an optimal choice for the attacker. The defender then chooses the best solution from all feasible LPs as his optimal randomized defense configuration. The independence assumption becomes operational here because we treat defense configurations $q_{o,t}$ for each target in isolation, as this assumption obviates the need to randomize over joint defense schedules for all targets. The LP formulation for a representative target $\hat{t}$ is shown in Equations 1a-1d.

$$\max r\left(\sum_o U_{o,\hat{t}} q_{o,\hat{t}}^{\hat{t}}\right) + (1-r)\left(\sum_{t,o} g_t U_{o,t} q_{o,t}^{\hat{t}}\right) - \sum_t \sum_o c_{o,t} q_{o,t}^{\hat{t}}. \quad (1a)$$

s.t.

$$\forall_{o,t}\ q_{o,t}^{\hat{t}} \in [0,1] \quad (1b)$$

$$\forall_t \sum_o q_{o,t}^{\hat{t}} = 1 \quad (1c)$$

$$\forall_t \sum_o V_{o,t} q_{o,t}^{\hat{t}} \leq \sum_o V_{o,\hat{t}} q_{o,\hat{t}}^{\hat{t}} \quad (1d)$$

The intuition behind the multiple-LP formulation is that in an optimal defense configuration, the attacker must (weakly) prefer to attack *some* target, and, consequently, one of these LPs must correspond to an optimal defense policy.

Notice that we can easily incorporate additional linear constraints. For example, it is often useful to add a budget constraint of the form:

$$\forall_{\hat{t},t} \quad \sum_o c_{o,t} q_{o,t}^{\hat{t}} \leq B.$$

4 Incorporating Network Structure

4.1 A General Model of Interdependencies

Thus far, a key assumption has been that the utility of the defender and the attacker for each target depends only on the defense configuration for that target, as well as whether it is attacked or not. In many domains, such as cybersecurity and supply chain security, assets are fundamentally interdependent, with an attack on one target having potential consequences for others. In this section, we show how to transform certain important classes of problems with interdependent assets into a formulation in which targets become effectively independent, for the purposes of our solution techniques.

Below we focus on the defender's utilities; attacker is treated identically. Let w_t be an *intrinsic worth* of a target to the defender, that is, how much loss the defender would suffer if this target were to be compromised with no other target affected (i.e., not accounting for indirect effects). In doing so, we assume that these worths are independent for different targets. Let $s = \{o_1, \ldots, o_n\}$ be the security configuration on all nodes. The probability that a given t' is affected depends on s and the target t chosen by the attacker. Let $z_{s,t'}(t)$ be the marginal probability that target t' is affected when the attacker attacks target t. Assuming that the utility function is additive in target-specific worths and the attacker can only attack a single target, the defender's expected utility from choosing s when t is attacked is

$$U_t(s) = E\left[\sum_{t'} w_{t'} 1(\mathrm{t}' \text{ affected} \mid \mathrm{s}, \mathrm{t})\right] = \sum_{t'} w_{t'} z_{s,t'}(t),$$

where $1(\cdot)$ is an indicator function. This expression makes apparent that in general $U_t(s)$ depends on defense configurations at all targets, making the problem intractable. We now make the crucial assumption that enables fast computation of defender policies by recovering inter-target independence.

Assumption 1. *For all t and t', $z_{s,t'}(t) = z_{o_t,t'}(t)$.*

In words, the probability that a target t' is affected when t is attacked only depends on the security configuration at the attacked target t. Below, we use o instead of o_t where t is clear from context.

A way to interpret our assumption is that security against external threats is not very efficacious once an attack has found a way into the system. Alternatively, if the utility of nodes is derived from their contribution to overall connectivity (e.g., in communication networks, where removing a node can, for example, increase latency), it is quite natural to assume that removal of a node impacts global connectivity *regardless of security policies on other nodes.* Our assumption was also operational in other work on interdependent security [Kunreuther and Heal, 2003], where a justification is through a story about airline baggage screening: baggage that is transferred between

airlines is rarely thoroughly screened, perhaps due to the expense. Thus, even while an airline may have very strong screening policies, it is poorly protected from luggage entering its planes via transfers. Cybersecurity has similar shortcomings: defense is often focused on external threats, with little attention paid to threats coming from computers internal to the network. Thus, once a computer on a network is compromised, the attacker may find it much easier to compromise others on the same network.

Under the above assumption, the defender utility when t is attacked under security configuration o is:

$$U_{o,t} = z_{o,t}(t)w_t + \sum_{t' \neq t} z_{o,t'}(t)w_{t'}.$$

By a similar argument and an analogous assumption for the attacker's utility, we thereby recover target independence required by the linear programming formulations above.

4.2 Cascading Failures Model

In general, one may use an arbitrary model to compute or estimate $z_{o,t'}(t)$. Here, we offer a specific model of interdependence between targets that is simple, natural, and applies across a wide variety of settings.

Suppose that dependencies between targets are represented by a graph (T, E), with T the set of targets (nodes) as above, and E the set of edges (t, t'), where an edge from t to t' (or an undirected edge between them) means that target t' depends on target t (and, thus, a successful attack on t may have impact on t'). Each target has associated with it a worth, w_t as above, although in this context this worth is incurred only if t is affected (e.g., compromised, broken). The security configuration determines the probability $z_{o,t}(t)$ that target t is affected if the attacker attacks it *directly* and the defense configuration is o. We model the interdependencies between the nodes as independent cascade contagion, which has previously been used primarily to model diffusion of product adoption and infectious disease [Kempe et al., 2003, Dodds and Watts, 2005]; Mounzer et al. [2010] is a rare exception (a similar model was also proposed by Tsai et al. [2012], but involves both a defender and an attacker maximizing impact of information diffusion through cascades). The contagion proceeds starting at an attacked node t, affecting its network neighbors t' each with probability $p_{t,t'}$; the contagion then spreads from the newly affected nodes t' to their neighbors, and so on. The contagion can only occur once along any network edge, and once a node is affected, it stays affected through the diffusion process. An equivalent way to model this process is to start with the network (T, E) and remove each edge (t, t') with probability $(1-p_{t,t'})$. The entire connected component of an attacked node is then deemed affected.

4.3 Computing Expected Utilities

Given the independent cascade model of interdependencies between targets, we must compute expected utilities, $U_{o,t}$ and $V_{o,t}$, of the defender and the attacker respectively (note that these are expectations only over the cascades, but not the defender's mixed strategy). In general, we can do so by simulating cascades starting at every node t (using breadth-first search), with expected utility of defender/attacker estimated as a sample average over K simulated cascades (expectation in this case is with respect to random realizations of attack success for specific targets as well as edges that become a part of the failure contagion). In several special cases, however, we can either compute these exactly and efficiently, or speed up utility estimation. We now address these special cases.

4.3.1 Cascades on Trees

It is intuitive that when the dependency graph is a tree, expected utilities can be computed efficiently. A naive algorithm can do it in linear time *for each target* t, yielding quadratic time in total (since we must repeat the process for all targets). In fact, we can do it in linear time *for all targets*, as the following theorem asserts.

Theorem 1. *If (T, E) is an undirected tree we can compute expected utilities for at targets in $O(|T|)$ time.*

The proofs of this and other results can be found in the online supplement.

4.3.2 Cascades on Undirected Graphs

In general undirected graphs, we can apply a very simple optimization in the way we sample cascades to obtain substantial speedups when the graph is dense. First, observe that rather than determining live edges as the cascade unfolds, we can instead flip the biased coin for each edge to determine whether it is live or not during a particular cascade *prior* to propagating the failure. The resulting graph contains a subset of edges from the original graph. At this point, observe that each potential target in a given connected component will result in the same defender/attacker utility. We therefore only need to compute the expected loss once for each connected component. When the size of the largest connected component is $O(|T|)$, a likely scenario in dense graphs, this optimization results in an $O(|T|)$ speedup.

4.4 The Significance of Capturing Interdependence

An obvious question that may arise upon pondering the complexities of our framework is whether they are worthwhile: it may well be that previous approaches which assume target independence offer satisfactory approximation. We now show theoretically, and later experimentally, that our approach improves dramatically as compared to one which assumes independence.

Proposition 1. *There exists a family of problem instances for which the independence assumption yields a solution that is a factor of $O(n)$ worse than optimal.*

4.5 Incorporating Uncertainty about the Network

Applying our framework in real-world networked security settings requires an accurate understanding of the interdependencies. Thus far, we assumed that the actual network over which cascading failures would spread is perfectly known. A natural question is: what if our network model is inaccurate?

Formally, we model the uncertainty about the network as a parameter ϵ which represents the probability of incorrectly estimating the relationship between a pair of targets. Thus, if there is an edge between t and t', we now let this edge be present with probability $1-\epsilon$. On the other hand, if t and t' are not connected in the graph given to us, we propose that they are, in fact, connected with probability ϵ. Thus, when the graph is large, even a small amount noise will cause us to err about a substantial number of edges.[1]

Note that there is a natural way to incorporate this model of uncertainty into our framework. Let us interpret $p_{t,t'}$ as the probability of a cascade from t to t' *conditional on an edge from t to t'*. Then, if t and t' are connected, we modify cascade probabilities to be $\hat{p}_{t,t'} = p_{t,t'}(1-\epsilon)$, whereas if they are not connected, the cascade probability is $\hat{p}_{t,t'} = p_{t,t'}\epsilon$.

5 Experiments

The goal of this section is to illustrate the value of our framework as a computational tool for designing security in interdependent settings. Specifically, we aim to demonstrate that our approach clearly improves on state-of-the-art alternatives, and offers a scalable solution for realistic security problems. We pursue this aim by randomly constructing dependency graphs using Erdos-Renyi (ER) and Preferential Attachment (PA) generative models [Newman, 2010], as well as using a graph representing a snapshot of Autonomous System (AS) interconnections generated using Oregon route-views [of Oregon Route Views Project]; this graph contains 6474 targets and 13233 edges and thus offers a reasonable test of scalability. In the ER model every directed link is made with a specified and fixed probability p; we refer to it as ER(p). The PA model adds nodes in a fixed sequence, starting from an arbitrary seed graph with at least two vertices. Each node i is attached to m others stochastically (unless $i \leq m$, in which case it is connected to all preceding nodes), with probability of connecting to a node j proportional to the degree of j, d_j.

For the randomly generated networks, all data presented is averaged over 100 graph samples. Since we generate graphs that may include undirected cycles, we obtain expected utilities for all nodes on a given graph using 10,000 simulated cascades (below we show that this is more than sufficient). Intrinsic worths w_t are generated uniformly randomly on $[0, 1]$. Cascade probabilities $p_{t,t'}$ were set to 0.5 unless otherwise specified. In the sequel, we restrict the defender to two security configurations at every target, one with a cost of 0 which stops attacks with probability 0 and one with a cost of c which prevents attacks with probability 1.

5.1 Sampling Efficiency

Throughout our experiments we use 10,000 samples to evaluate the expected utilities of players. A natural question is: are we taking enough samples? To answer this, we systematically varied the number of samples between 0 (i.e., letting $U_{o,t} = -w_t$) and 100,000. Our results offer strong evidence that 10,000 samples is more than enough: the expected utility (evaluated using 100,000 samples) of the resulting defense configurations becomes flat already when the number of samples is 1000.

5.2 Scalability

An important question given the complexity of our framework is whether it can scale to realistic defense scenarios. To test this, we ran our framework on the AS graph consisting of 6474 targets and 13233 edges. Since this is a large undirected graph containing cycles, a sampling approach was required, but the total running time (including both sampling and solving linear programs) amounted to less than 1 hour. Given the importance of security, and the fact that *distributions* of security settings are computed once (or at least infrequently, as long as significant changes to the

[1] We assume here that both the defender and attacker share the same uncertainty about the network. An alternative model could consider an attacker that has more (or exact) information about the network. The resulting defender problem would become a Bayesian Stackelberg game.

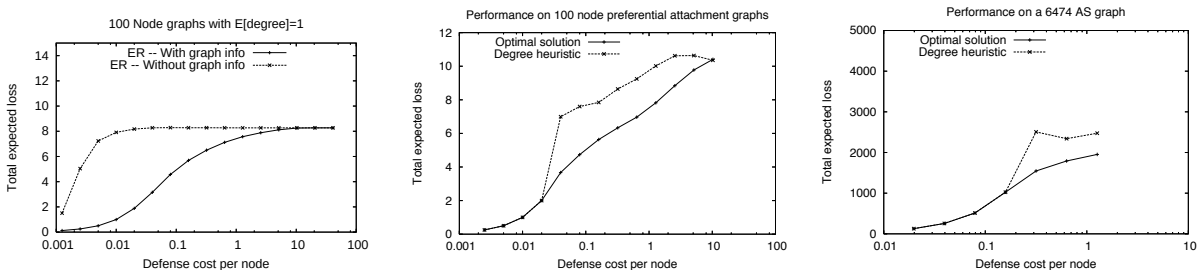

Figure 1: Left: Comparison between our approach ("with graph info") and one assuming independence ("without graph info") using the ER(0.1) generative model. Middle: Comparison to the degree-based heuristic on PA graphs. Right: Comparison to the degree-based heuristic on the AS graph.

interdependency structure are not very frequent), this seems a relatively small computational burden.

5.3 Comparison to State-of-the-Art Alternatives

There are two prime computational alternatives to our framework. The first is to assume that targets are independent. While we showed above that in the worst case this can be quite a poor approximation, we offer empirical support to the added value of our approach below. The second is to use a well-known heuristic developed in the context of vaccination strategies on networks. This latter heuristic would in our case defend nodes in order of their connectivity (degree), until the defense budget is exhausted. Figure 1 compares our approach first to the former (left) and then to the latter (right). In both cases, computing optimal defense strategies using our framework yields much higher utility to the defender than the alternatives.

Aside from interdependencies, two other important aspects of our model are the fact that it allows an arbitrary number of security configurations, instead of simply allowing the defender to defend, or not, each target, and its ability to optimize with respect to both intelligent attackers and inadvertent failures. We now show that both of these can add substantial value. Figure 2 (top) shows a comparison between a solution which only allows two configurations (defend and do not defend) and two solutions which also allow for a third configuration, which is less effective than full defense, but also less costly. We consider two potential third options, one providing 50% defense at 12.5% of the cost of full defense (1/2 – 1/8) and one providing 75% defense at 12.5% cost (3/4 – 1/8). It is clear from this graph that considering the third configuration adds considerable value. Figure 2 (bottom) assumes that all (or nearly all) failures arise randomly, and compares a solution which posits an attacker to an optimal solution. Again, the value of solving the problem optimally is clear. This plot actually shows an interesting pattern, as the expected utility of the defender is non-monotonic in cost when the solution is suboptimal. This is because the differences between the two solutions are most important when costs are intermediate; with low costs, nearly everything is fully defended, while high costs imply almost no defense.

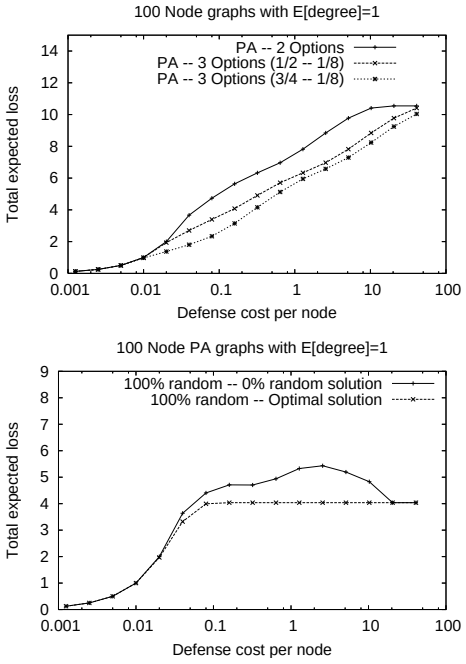

Figure 2: Top: Comparison between assuming only two configurations, and allowing the defender to consider three alternatives. Bottom: Comparison between a solution which assumes that failures are only due to attacks, and an optimal solution, when failures are actually random. Comparisons use PA graphs.

6 Applications to Interdependent Security Analysis

In this section we apply our framework to several network security domains. For simplicity, we restrict at-

tention to zero-sum security games, unless otherwise specified. As above, we consider ER and PA generative models, although we utilize a generalized version of PA. In a generalized PA model, connection probabilities are $\frac{(d_i)^\mu}{\sum_j (d_j)^\mu}$, such that when $\mu = 0$ the degree distribution is relatively homogeneous, just as in ER, $\mu = 1$ recovers the "standard" PA model, and large values of μ correspond to highly inhomogeneous degree distributions. Throughout, we use $\mu = 1$ unless otherwise specified. All parameters are set as in the experiments section, unless otherwise specified.

In addition to generative models of networks, we explore two networks derived from real security settings: one with 18 nodes that models dependencies among critical infrastructure and key resource sectors (CIKR), as inferred from the DHS and FEMA websites, and the second with 66 nodes that captures payments between banks in the core of the Fedwire network [Soramaki et al., 2007].

For the CIKR network, each node was assigned a low, medium, or high worth of 0.2, 0.5, or 1, respectively, based on perceived importance (for example, the energy sector was assigned a high worth, while the national monuments and icons sector a low worth). Each edge was categorized based on the importance of the dependency (gleaned from the DHS and FEMA websites) as "highly" or "moderately" significant, with cascade probabilities of 0.5 or 0.1 respectively. For the Fedwire network, all nodes were assigned an equal worth of 0.5, and cascade probabilities were discretely chosen between 0.05 and 0.5 in 0.05 increments depending on the weight of the corresponding edges shown in Soramaki et al. [2007].

6.1 The Impact of Uncertainty

Our framework offers a natural way to incorporate uncertainty about the network into the analysis. An important question is: how much impact on defender decision does uncertainty about the network have? Figure 3 quantifies the impact of uncertainty on the quality of defense if the observed graph is the PA network with average degree of 2. When cascade probabilities are relatively high ($p_{t,t'} = 0.5$ for all edges, top plot), even if the amount of noise is relatively small ($\epsilon = 0.01$), the resulting increase in the number of possible cascade paths in the network makes the defender much more vulnerable. With smaller cascade probabilities ($p_{t,t'} = 0.1$, bottom plot), however, noise has relatively little impact. It can thus be vital for the defender to obtain an accurate portrait of the true network over which failures may cascade when the interdependencies among the components are strong.

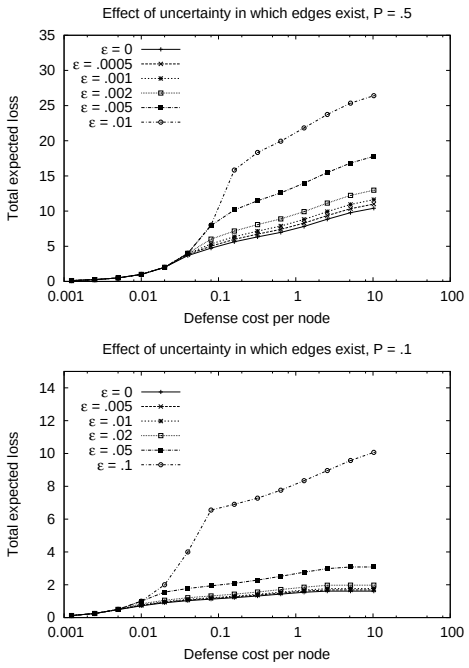

Figure 3: The impact of noise on PA networks. Top: when $p_{t,t'} = 0.5$; Bottom: when $p_{t,t'} = 0.1$.

6.2 The Impact of Marginal Defense Cost

Our next analysis deals with the impact of marginal defense cost c on defender expected losses, his total costs, and the sum of these (i.e., negative expected utility). The results for ER and BA (both with 100 nodes and average degree of 2), as well as CIKR and Fedwire networks are shown in Figure 4. All the plots feature a clear pattern: expected loss and (negative) utility are monotonically increasing, as expected, while total costs start at zero, initially rise, and ultimately fall (back to zero in 3 of the 4 cases). It may at first be surprising that total costs eventually fall even as marginal costs continue to increase, but this clearly must be the case: when c is high enough, the defender will not wish to invest in security at all, and total costs will be zero. What is much more surprising is the presence of two peaks in PA and Fedwire networks. Both of these networks share the property that there is a non-negligible fraction of nodes with very high connectivity [Newman, 2010, Soramaki et al., 2007]. When the initial peak is reached, the network is fully defended, and as marginal costs rise further, the defender begins to reduce the defense resources expended on the less important targets. At a certain point, only the most connected targets are protected, and since these are so vital to protect, total costs begin increasing again. After the second peak is reached, c is finally large enough to discourage the defender from fully protecting even the most important targets, and the subsequent fall of

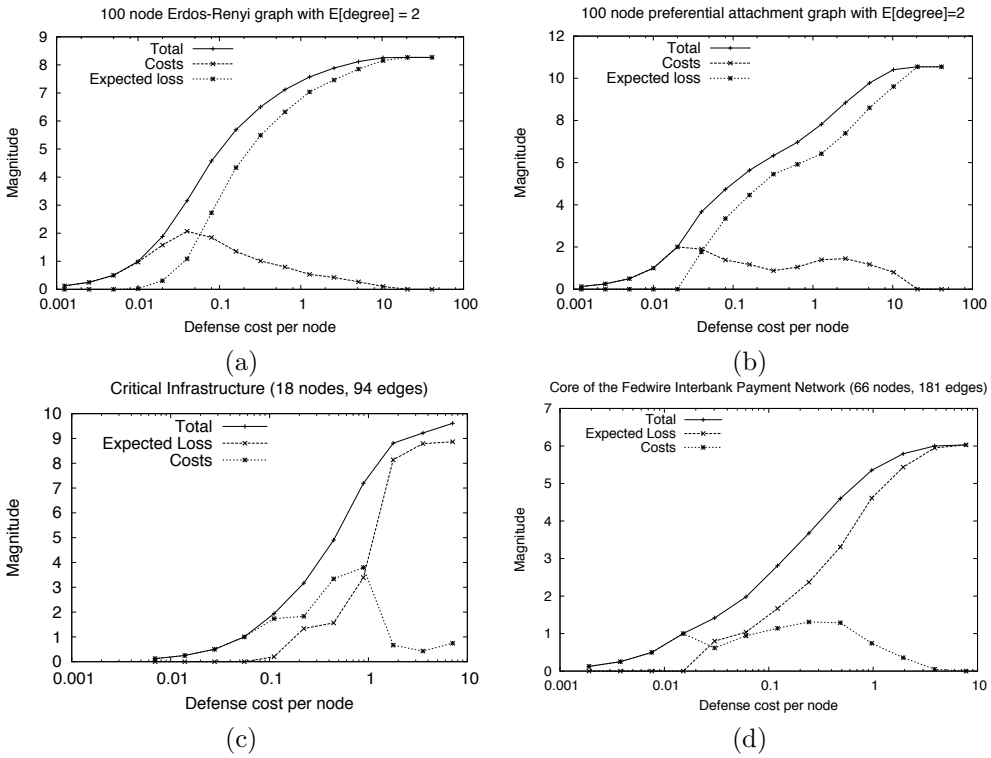

Figure 4: Expected loss, cost, and their sum in (a) 100-node ER(0.2), (b) 100-node PA, (c) 18-node critical infrastructure, and (d) 66-node core of the Fedwire networks as defense cost increases. The results for ER and PA are averages over 100 stochastic realizations of these networks.

total costs is no longer reversed.

6.3 Resilience to Targeted Attacks: Impact of Network Structure

One of the important streams in the network science literature is the question of relative resilience of different network topologies to failures, random or targeted. A central result, replicated in a number of contexts, is that network topology is a vital factor in determining resilience [Albert et al., 2000, Newman, 2010]. Of particular interest to us is the observation that scale-free networks such as PA exhibit poor tolerance to targeted attacks as compared to ER [Albert et al., 2000], which is precisely the context that we consider.

In Figure 5 (top) we show the defender's utility for three different network topologies, PA, ER, and Fedwire as a function of cost c. Remarkably, there is essentially no difference between PA and ER (and not much between these and Fedwire) until c is quite high, at which point they begin to diverge. This seems to contradict essentially all the previous findings in that network topology seems to play little role in resilience in our case! A superficial difference here is that we consider a cascading failure model, while most of the previous work on the subject focused on diminished connectivity due to attacks. We contend that the most important distinction, however, is that previous work studying resilience did not account for a simple observation that most important targets are also most heavily defended; indeed, there was no notion of endogenous defense at all. In scale-free graphs, there are well connected nodes whose failure has global consequences. These are the nodes which are most important, and are heavily defended in optimal decisions prescribed by our framework. Once the defense decision becomes endogenous, differences in network topology disappear. Naturally, once c is high enough, defense of important targets weakens, and eventually we recover the standard result: for high c, PA is considerably more vulnerable than ER.

To investigate the impact of network topology on resilience further, we consider the generalized PA model in which we systematically vary the homogeneity of the degree distribution by way of the parameter μ. The results are shown in Figure 5 (bottom). In this graph, we do observe clear variation in resilience as a function of network topology, but the operational factor in this variation is homogeneity in the distribution of expected utilities, rather than degrees: increasing *homogeneity* of the utility distribution *lowers network resilience*. This seems precisely the opposite

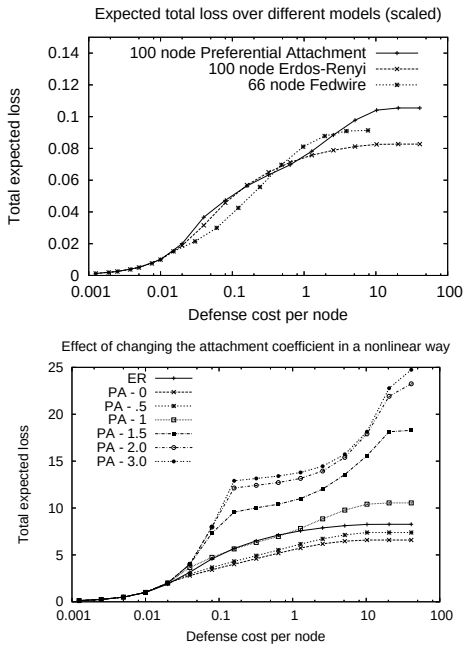

Figure 5: Top: Expected total loss: comparison across different network structures. Bottom: Expected defender disutility in the generalized PA model as we vary μ (keeping average degree fixed at 2). ER is also shown for comparison.

of the standard results in network resilience, but the two are in fact closely related, as we now demonstrate. Superficially, the trend in the figure seems to follow the common intuition in the resilience literature: as the degree distribution becomes more inhomogeneous (more star-like), it becomes more difficult to defend. Observe, however, that ER is actually more difficult to defend than PA with $\mu = 0$. The lone difference of the latter from ER is the fact that nodes that enter earlier are more connected and, therefore, the degree distribution in the PA variant should actually be more *inhomogeneous* than ER! The answer is that random connectivity combined with inhomogeneity of degrees actually makes the distribution of *utilities* less homogeneous in PA with $\mu = 0$, and, as a result, fewer nodes on which defense can focus as compared to ER. On the other hand, as the graph becomes more star-like, the utilities of all nodes become quite similar; in the limiting case, all nodes are only two hops apart, and attacking any one of them yields a loss of many as a result of cascades.

There is another aspect of network topology that has an important impact on resilience: network density. Figure 6 shows a plot of an Erdos-Renyi network with the probability of an edge varying between 0.0025 to 0.08 (average degree between .25 and 8) and cost c fixed at 0.04. Clearly, expected utility and loss of the defender are increasing in density, but it is rather sur-

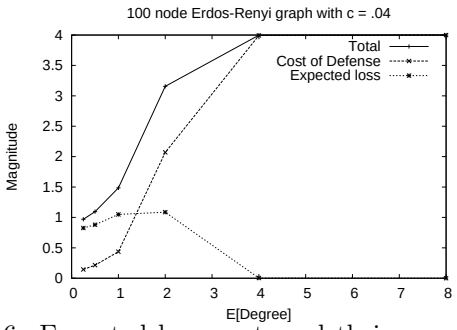

Figure 6: Expected loss, cost, and their sum in 100-node Erdos-Renyi networks as a function of network density (equivalently, expected degree).

prising to observe how sharply they jump once average degree exceeds 1 (the ER network threshold for a large connected component); in any case, network density has an unmistakable impact. The reason is intuitive: increased density means more paths between targets, and, consequently, greater likelihood of large cascades in the event that a target is compromised. Total cost initially increases in response to increased density, in part to compensate for the increased vulnerability to attacks, but eventually falls, since it is too expensive to protect everything, and anything short of that is largely ineffective.

7 Conclusion

We presented a framework for computing optimal randomized security policies in network domains, extending previous linear programming approaches to Stackelberg security games in several ways. First, we extended previous linear programming techniques to incorporate benefits and costs of arbitrary security configurations on individual assets. Second, we offered a principled model of failure cascades that allows us to capture both the direct and indirect value of assets, and showed how to extend this model to capture uncertainty about the structure of the interdependency network. Third, we allowed the defender to account for failures due to actual attacks, as well as those that are a result of exogenous failures. Our results demonstrate the value of our approach as compared to alternatives, and show that it is scalable to realistic security settings. Furthermore, we used our framework to analyze four models of interdependencies: two based on random graph generation models, a simple model of interdependence between critical infrastructure and key resource sectors, and a model of the Fedwire interbank payment network.

Abstract

A tree-based dictionary learning model is developed for joint analysis of imagery and associated text. The dictionary learning may be applied directly to the imagery from patches, or to general feature vectors extracted from patches or superpixels (using any existing method for image feature extraction). Each image is associated with a path through the tree (from root to a leaf), and each of the multiple patches in a given image is associated with one node in that path. Nodes near the tree root are shared between multiple paths, representing image characteristics that are common among different types of images. Moving toward the leaves, nodes become specialized, representing details in image classes. If available, words (text) are also jointly modeled, with a path-dependent probability over words. The tree structure is inferred via a nested Dirichlet process, and a retrospective stick-breaking sampler is used to infer the tree depth and width.

1 Introduction

Statistical topic models, such as latent Dirichlet allocation (LDA) (Blei et al., 2003b), were originally developed for text analysis, but they have been recently transitioned successfully for the analysis of imagery. In most such topic models, each image is associated with a distribution over topics, and each topic is characterized by a distribution over observed features in the image. In this setting researchers typically represent an image as a bag of visual words (Fei-Fei & Perona, 2005; Li & Fei-Fei, 2007). These methods have been applied to perform unsupervised clustering, classification and annotation of images, using image features as well as auxiliary data such as image annotations (Barnard et al., 2003; Blei & Jordan, 2003; Blei & MaAuliffe, 2007; Wang et al., 2009; Li et al., 2009).

In such work feature extraction is performed as a pre-processing step, and local image descriptors, *e.g.*, scale-invariant feature transform (SIFT) (Lowe, 1999), and other types of features (Arbelaez & Cohen, 2008), are commonly used to extract features from local patches (Fei-Fei & Perona, 2005; Li & Fei-Fei, 2007; Bart et al., 2008; Sivic et al., 2008; Wang et al., 2009), segments (Li et al., 2009; Yang et al., 2010), or superpixels (Du et al., 2009). Different images are related to one another by their corresponding distributions over topics.

There are several limitations with most of this previous work. First, vector quantization (VQ) is typically applied to the image features (Fei-Fei & Perona, 2005), and the codes play the role of "words" in traditional topic modeling. There is a loss of information in this quantization step, and one must tune the number of codes (the proper codebook may change with different types of images, and as new imagery are observed). Secondly, feature design is typically performed separately from the subsequent image topic modeling. Finally, most of the image-based topic modeling is performed at a single scale or level (Wang et al., 2009; Li et al., 2009; Du et al., 2009), thereby not accounting for the hierarchical characteristics of most natural imagery.

In recent work, there have been papers that have addressed particular aspects of the above limitations, but none that has addressed all. For example, in Li et al. (2011) the authors employed a dictionary-learning framework, eliminating the need to perform VQ. This dictionary learning could be applied to traditional features pre-computed from the image, or it could be applied directly to patches of raw imagery, thereby ameliorating the requirement of separating the feature-design and topic-modeling steps. However, Li et al. (2011) did not consider the hierarchical charac-

ter of imagery. Recently Li et al. (2010) employed a nested Chinese restaurant process (nCRP) to infer a hierarchical tree representation for a corpus of images and (if available) accompanying text; however, in that work the VQ step was still employed, and therefore a precomputation of features was as well. Further, in Li et al. (2010), while the tree width was inferred, the depth was set. Finally, the nCRP construction in Li et al. (2010) has the disadvantage of only updating parent-child-transition parameters from one node of the tree at a time, in a sampler, yielding poor mixing relative to a stick-breaking Dirichlet process (DP) implementation (Ishwaran & James, 2001). Related but distinct dictionary learning with the nCRP was considered in Zhang et al. (2011).

Motivated by these recent contributions, and the limitations of most existing topic models of imagery and text, this paper makes the following contributions:

- A nested DP (nDP) model is developed to learn a hierarchical tree structure for a corpus of imagery and text, with a stick-breaking construction employed; we infer both the tree depth and width, using a retrospective stick-breaking construction (Papaspiliopoulos & Roberts, 2008).
- A beta-Bernoulli dictionary learning framework (Zhou et al., 2011b) is adapted to such a hierarchical model, removing the VQ step, and allowing one to perform topic modeling directly on image patches, thereby integrating feature design and topic modeling. However, if desired, the dictionary learning may also be applied to features pre-computed from the image, using *any* existing method for feature design, and again removing the limitations of VQ.

2 Modeling Image Patches

We wish to build a hierarchical model to arrange M images and their associated annotations (when available); the vocabulary of such annotations is assumed to be of dimension N_v. The vector $\boldsymbol{x}_{mi}$ represents the pixels or features associated with the ith patch in image m, and $\boldsymbol{y}_m = (y_{m1}, \ldots, y_{mN_v})^T$ represents a vector of word counts associated with that image, when available (y_{mn} represents the number of times word $n \in \{1, \ldots, N_v\}$ is present in the annotation).

The mth image is divided into N_m patches (or superpixels (Li et al., 2010)), and the data for the ith patch is denoted $\boldsymbol{x}_{mi} \in \mathbb{R}^P$ with $i = 1, \ldots, N_m$. The vector $\boldsymbol{x}_{mi}$ may represent raw pixel values, or a feature vector extracted from the pixels (using any available method of image feature extraction, *e.g.*, SIFT (Lowe, 1999)). Each $\boldsymbol{x}_{mi}$ is represented as a sparse linear combination of learned dictionary atoms. Further, each patch is assumed associated with a "topic"; the probability of which dictionary atoms are employed for a given patch is dictated by the topic it is associated with.

Specifically, each patch is represented as $\boldsymbol{x}_{mi} = \mathbf{D}(\boldsymbol{z}_{mi} \odot \boldsymbol{s}_{mi}) + \boldsymbol{e}_{mi}$, where $\odot$ represents the element-wise/Hadamard product, $\mathbf{D} = [\boldsymbol{d}_1, \cdots, \boldsymbol{d}_K] \in \mathbb{R}^{P \times K}$, K is the truncation level on the possible number of dictionary atoms, $\boldsymbol{z}_{mi} = [z_{mi1}, \cdots, z_{miK}]^T$, $\boldsymbol{s}_{mi} = [s_{mi1}, \cdots, s_{miK}]^T$, $z_{mik} \in \{0, 1\}$ indicates whether the kth atom is *active* within patch i in image m, $s_{mik} \in \mathbb{R}^+$, and $\boldsymbol{e}_{mi}$ is the residual. Note that $\boldsymbol{z}_{mi}$ represents the specific sparseness pattern of dictionary usage for $\boldsymbol{x}_{mi}$. The hierarchical form of the model is

$$\begin{aligned} \boldsymbol{x}_{mi} &\sim \mathcal{N}(\mathbf{D}(\boldsymbol{z}_{mi} \odot \boldsymbol{s}_{mi}), \gamma_e^{-1}\mathbf{I}_P) \\ \boldsymbol{d}_k &\sim \mathcal{N}(0, \frac{1}{P}\mathbf{I}_P) \\ \boldsymbol{s}_{mi} &\sim \mathcal{N}_+(0, \gamma_s^{-1}\mathbf{I}_K) \\ \boldsymbol{z}_{mi} &\sim \prod_{k=1}^{K} \text{Bernoulli}(\pi_{h_{mi}k}) \end{aligned} \quad (1)$$

where gamma priors are placed on both γ_e and γ_s. Positive weights $\boldsymbol{s}_{mi}$ (truncated normal, $\mathcal{N}_+(\cdot)$) are imposed, which we have found to yield improved results.

The indicator variable h_{mi} defines the topic associated with $\boldsymbol{x}_{mi}$. The K-dimensional vector $\boldsymbol{\pi}_h$ defines the probability that each of the K columns of $\mathbf{D}$ is employed to represent topic h, where the kth component of $\boldsymbol{\pi}_h$ is π_{hk}. These probability vectors are drawn

$$\boldsymbol{\pi}_h \sim G_0, \quad G_0 = \prod_{k=1}^{K} \text{Beta}(a_0/K, b_0(K-1)/K) \quad (2)$$

where π_{hk} represents the probability of using $\boldsymbol{d}_k$ for object type h, and the introduction of G_0 is for discussions below. This representation for $\boldsymbol{\pi}_h$ corresponds to an approximation to the beta-Bernoulli process (Thibaux & Jordan, 2007; Paisley & Carin, 2009; Zhou et al., 2011a,b), which also yields an approximation to the Indian buffet process (IBP) (Griffiths & Ghahramani, 2005; Teh et al., 2007).

3 Tree Structure via nDP

The nested Dirichlet process (nDP) tree construction developed below is an alternative means of constituting the same type of tree manifested by the nested Chinese restaurant process (Blei et al., 2003a; Li et al., 2010). We emphasize the nDP construction because of the stick-breaking implementation we employ, which

allows block updates, and therefore often manifests better mixing than the nCRP-type implementation (Ishwaran & James, 2001). Related work was considered in Wang & Blei (2009), but VB inference was employed and the tree size was therefore not inferred (a fixed truncation was imposed). The retrospective sampler developed below allows inference of both the tree depth and width (Papaspiliopoulos & Roberts, 2008).

Consider a draw from a DP, $G \sim \mathrm{DP}(\gamma, G_0)$, where $\gamma > 0$ is an "innovation" parameter, with G_0 defined in (2). Then the DP draw (Ishwaran & James, 2001) may be expressed as $G = \sum_{n=1}^{\infty} \lambda_n \delta_{\phi_n}$, where $\lambda_n = \nu_n \prod_{l<n}(1-\nu_l)$, $\nu_l \sim \mathrm{Beta}(1,\gamma)$, and $\phi_n \sim G_0$; each ϕ_n corresponds to a topic, as in (2). Letting $\boldsymbol{\lambda} = (\lambda_1, \lambda_2, \dots)^T$, we denote the draw of $\boldsymbol{\lambda}$ as $\boldsymbol{\lambda} \sim \mathrm{Stick}(\gamma)$.

3.1 Tree width

Using notation from Adams et al. (2010), let $\boldsymbol{\epsilon}$ represent a path through the tree, characterized by a sequence of parent-child nodes, and let $|\boldsymbol{\epsilon}|$ be the length of this path (total number of layers traversed). In addition to representing a path through the tree, $\boldsymbol{\epsilon}$ identifies a node at layer $|\boldsymbol{\epsilon}|$, *i.e.*, the node at the end of path $\boldsymbol{\epsilon}$. For node $\boldsymbol{\epsilon}$, let $\boldsymbol{\epsilon}\epsilon_i$, $i = 1, 2, \dots$, denote the *children* of $\boldsymbol{\epsilon}$, at level $|\boldsymbol{\epsilon}| + 1$. To constitute a distribution over the children nodes, we draw $G_{\boldsymbol{\epsilon}} \sim \mathrm{DP}(\gamma, G_0)$, yielding $G_{\boldsymbol{\epsilon}} = \sum_{i=1}^{\infty} \lambda_{\boldsymbol{\epsilon}\epsilon_i} \delta_{\phi_{\boldsymbol{\epsilon}\epsilon_i}}$, where $\lambda_{\boldsymbol{\epsilon}\epsilon_i} = \nu_{\boldsymbol{\epsilon}\epsilon_i} \prod_{j=1}^{i-1}(1-\nu_{\boldsymbol{\epsilon}\epsilon_j})$, $\nu_{\boldsymbol{\epsilon}\epsilon_j} \sim \mathrm{Beta}(1,\gamma)$, and $\phi_{\boldsymbol{\epsilon}\epsilon_i} \sim G_0$, with G_0 defined in (2); $\boldsymbol{\lambda}_{\boldsymbol{\epsilon}} = (\lambda_{\boldsymbol{\epsilon}\epsilon_1}, \lambda_{\boldsymbol{\epsilon}\epsilon_2}, \dots)^T$ is denoted as drawn $\boldsymbol{\lambda}_{\boldsymbol{\epsilon}} \sim \mathrm{Stick}(\gamma)$. The probability measure $G_{\boldsymbol{\epsilon}}$ constitutes in principle an infinite set of children nodes, with $\lambda_{\boldsymbol{\epsilon}\epsilon_i}$ defining the probability of transiting from node $\boldsymbol{\epsilon}$ to child ϵ_i; $\phi_{\boldsymbol{\epsilon}\epsilon_i}$ constitutes the topic-dependent probability of dictionary usage at that child node.

The process continues *in principle* to an infinite number of levels, with each child node spawning an infinite set of subsequent children nodes, manifesting a tree of infinite depth and width. However, note that a draw $\boldsymbol{\lambda}_{\boldsymbol{\epsilon}}$ will typically only have a relatively small number of components with appreciable amplitude. This means that while $G_{\boldsymbol{\epsilon}}$ constitutes in principle an infinite number of children nodes, only a small fraction will be visited with appreciable probability.

Let $\boldsymbol{c}_m = (c_m^1, c_m^2, \dots)^T$ represent the path associated with image m, where c_m^l corresponds to the node selected at level l. For conciseness we write $\boldsymbol{c}_m \sim \mathrm{nCRP}(\gamma)$ (Blei et al., 2003a), emphasizing that the underlying transition probabilities $\boldsymbol{\lambda}_{\boldsymbol{\epsilon}}$, controlling the probabilistic path through the tree, are a function of parameter γ.

3.2 Tree depth

We also draw an associated probability vector $\boldsymbol{\theta}_m \sim \mathrm{Stick}(\alpha)$. Patch $\boldsymbol{x}_{mi}$ is associated with level l_{mi} in path $\boldsymbol{c}_m$, where $l_{mi} \sim \sum_{l=1}^{\infty} \theta_{ml} \delta_l$. Since $\boldsymbol{\theta}_m$ typically only has a small number of components with appreciable amplitude, the tree depth is also constrained.

3.3 Modeling words

In Section 2 we developed topic (node) dependent probabilities of atom usage; we now extend this to words (annotations), when available. A distribution over words may be associated with each topic (tree node) h. For topic h we may draw (Blei et al., 2003b)

$$\boldsymbol{\psi}_h \sim \mathrm{Dir}(\frac{\eta}{N_v}, \dots, \frac{\eta}{N_v}) \tag{3}$$

where $\boldsymbol{\psi}_h$ is the distribution over words for topic h.

Recall that each image/annotation is associated with a path $\boldsymbol{c}_m$ through a tree, and $\boldsymbol{\theta}_m$ controls the probability of employing each node (topic) on that path. Let θ_{mh} represent the probability that node h is utilized, with $h \in \boldsymbol{c}_m$. Then the "collapsed" probability of word usage on this path, marginalizing out the probability of node selection, may be expressed as

$$\boldsymbol{\psi}_{\boldsymbol{c}_m} = \sum_{h \in \boldsymbol{c}_m} \theta_{mh} \boldsymbol{\psi}_h \tag{4}$$

A probability over words $\boldsymbol{\psi}_{\boldsymbol{c}_m}$ is therefore associated with each path $\boldsymbol{c}_m$. One may argue that the $\boldsymbol{\theta}_m$ used to control node usage for image patches should be different from that used to represent words; this is irrelevant in the final model, as a path-dependent $\boldsymbol{\psi}_{\boldsymbol{c}_m}$ is drawn directly from a Dirichlet distribution (discussed below), and therefore (4) is only illustrative/motivating.

3.4 Retrospective sampling

The above discussion indicated that while the width and depth of the tree is infinite in principle, a finite tree is manifested given finite data, which motivates adaptive inference of the tree size. In a retrospective implementation of a stick-breaking process, we constitute a *truncated* stick-breaking process, denoted $\boldsymbol{w} \sim \mathrm{Stick}_L(\gamma)$, with $w_n = V_n \prod_{l<n}(1-V_l)$, $V_n \sim \mathrm{Beta}(1,\gamma)$ for $n < L$, and $V_L = 1$; here there is an L-stick truncation, yielding $\boldsymbol{w} = (w_1, \dots, w_L)^T$, with w_L representing the probability of selecting a stick *other* than sticks 1 through $L-1$.

In a retrospective sampler (Papaspiliopoulos & Roberts, 2008), each of the aforementioned sticks is truncated as above. When drawing children nodes and levels, if the last stick (the Lth above) is selected, this

implies that a new child/level must be added, since the first $L-1$ sticks are not enough to capture how the data are clustered. If stick L is selected, then a new node/level is constituted (a new child is added), by drawing a new $V_L \sim \text{Beta}(1,\gamma)$, and then $V_{L+1}=1$, thereby now constituting an $(L+1)$-dimensional stick representation; the associated node-dependent statistics are constituted as discussed in Section 2 (drawing new probabilities over dictionary elements). The model therefore infers "in retrospect" that the L-level truncation was too small, and expands adaptively. The model also has the ability to shrink the number of sticks used at any component of the model, if less than the associated truncated level is needed to define the number of children/levels are actually utilized.

3.5 Generative Process

The generative process for the model is summarized as follows:

1. Draw dictionary $\mathbf{D} \sim \prod_{k=1}^{K} \mathcal{N}(0, \frac{1}{P}\mathbf{I}_P)$
2. Draw γ, α, γ_e and γ_s from respective gamma distributions
3. For each image $m \in \{1,2,...,M\}$
   (a) Draw $\boldsymbol{c}_m \sim \text{nCRP}(\gamma)$
   (b) For each *newly utilized* node $\boldsymbol{\epsilon}$ in the tree, draw dictionary usage probabilities $\boldsymbol{\pi}_{\boldsymbol{\epsilon}} \sim \prod_{k=1}^{K} \text{Beta}(a_0/K, b_0(K-1)/K)$
   (c) Draw $\boldsymbol{\theta}_m \sim \text{Stick}(\alpha)$
   (d) For the ith patch or feature vector
      i. Draw level index $l_{mi} \sim \sum_{l=1}^{\infty} \theta_{ml}\delta_l$, which along with $\boldsymbol{c}_{mi}$ defines node h_{mi}
      ii. Draw $\boldsymbol{z}_{mi} \sim \prod_{k=1}^{K} \text{Bernoulli}(\pi_{h_{mi}k})$, and $\boldsymbol{s}_{mi} \sim \mathcal{N}_+(0, \gamma_s^{-1}\mathbf{I}_K)$
      iii. Draw $\boldsymbol{x}_{mi} \sim \mathcal{N}(\mathbf{D}(\boldsymbol{z}_{mi} \odot \boldsymbol{s}_{mi}), \gamma_e^{-1}\mathbf{I}_P)$
4. For each unique tree path p, draw $\boldsymbol{\psi}_p \sim \text{Dir}(\frac{\beta}{N_V}, \ldots, \frac{\beta}{N_V})$
5. If annotations are available for image m, $\boldsymbol{y}_m \sim \text{Mult}(|\boldsymbol{y}_m|, \boldsymbol{\psi}_{\boldsymbol{c}_m})$, where $|\boldsymbol{y}_m|$ is the total number of words in $\boldsymbol{y}_m$

In Step 3(b), new nodes (topics) are added "in retrospect", as discussed in the previous subsection (nodes may also be pruned with this sampler). After completing Step 3, the tree size is constituted, which allows Step 4, imposition of a distribution over words for each path.

Algorithm 1 Retrospective Sampling for l_{mi}

Input: L_m, $\boldsymbol{z}$, $\boldsymbol{l}$, a_0, b_0
Output: l_{mi}, L_m
for $m=1$ **to** M and $i=1$ **to** N_m **do**
  Sample $\mu_{m|\boldsymbol{\epsilon}|}$, $\boldsymbol{\pi}_{\boldsymbol{\epsilon}}$ from the conditional posterior for $|\boldsymbol{\epsilon}| \leq L_m$, and from the prior for $|\boldsymbol{\epsilon}| > L_m$; $\theta_{m|\boldsymbol{\epsilon}|} = \mu_{m|\boldsymbol{\epsilon}|}\prod_{s=1}^{|\boldsymbol{\epsilon}|-1}(1-\mu_{ms})$
  Sample $U_{mi} \sim \text{Uniform}[0,1]$

    Set $l_{mi}=j$ with probability $\kappa_{mi}(j)$, otherwise, leave l_{mi} unchanged
  else
    $L_m = L_m+1$, set $l_{mi}=L_m$ with probability $\kappa_{mi}(L_m)$, otherwise, leave l_{mi} unchanged
  end if
end for

4 Model Inference

A contribution of this paper concerns use of retrospective sampling to infer the tree width and depth. To save space for an extensive set of experimental results, we here only discuss updates associated with inferring the tree depth. A complete set of update equations are provided in Supplementary Material, where one may also find a summary of all notation.

To sample l_{mi} from the conditional posterior, we first need to specify the likelihood that $\{\boldsymbol{\epsilon} \in \boldsymbol{c}_m\}$:

$$p(\boldsymbol{z}_{mi}|\boldsymbol{\pi}_{\boldsymbol{\epsilon}}, \boldsymbol{c}_m) = \prod_{k=1}^{K} \pi_{\boldsymbol{\epsilon}k}^{z_{mik}}(1-\pi_{\boldsymbol{\epsilon}k})^{1-z_{mik}}$$

and the prior distribution, which is specified by a stick-breaking draw $\boldsymbol{\theta}_m$ for each image m. Although l_{mi} can be sampled from a closed form posterior for a fixed L_m, here to learn L_m adaptively we instead use an Metropolis-Hastings step, where the proposal distribution is defined as

$$q(l_{mi}=j) \propto \begin{cases} \theta_{mj}p(\boldsymbol{z}_{mi}|\boldsymbol{\pi}_j, \boldsymbol{c}_m), & j \leq L_m \\ \theta_{mj}\mathcal{M}_{mi}(L_m), & j > L_m \end{cases}$$

where $\mathcal{M}_{mi}(L_m) = \max_{1\leq|\boldsymbol{\epsilon}|\leq L_m}\{p(\boldsymbol{z}_{mi}|\boldsymbol{\pi}_{\boldsymbol{\epsilon}}, \boldsymbol{c}_m)\}$. Note that the sampled value of l_{mi} is allowed to be larger than the truncation level L_m, consequently L_m and the depth of the tree is learned adaptively. The acceptance probability $\kappa_{mi}(j)$ for $l_{mi}=j$ is

$$\begin{cases} 1, & j \leq L_m \;\&\; L'_m = L_m \\ \min\{1, \frac{\tilde{c}_{mi}(L_m)\mathcal{M}_{mi}(L'_m)}{\tilde{c}_{mi}(L'_m)p(\boldsymbol{z}_{mi}|\boldsymbol{\pi}_{h_{mi}}, \boldsymbol{c}_m)}\}, & j \leq L_m \;\&\; L'_m < L_m \\ \min\{1, \frac{\tilde{c}_{mi}(L_m)p(\boldsymbol{z}_{mi}|\boldsymbol{\pi}_j, \boldsymbol{c}_m)}{\tilde{c}_{mi}(L'_m)\mathcal{M}_{mi}(L_m)}\}, & j > L_m \end{cases}$$

where the normalizing constant is defined as $\tilde{c}_{mi}(L_m) = \sum_{|\boldsymbol{\epsilon}|=1}^{L_m}\theta_{m|\boldsymbol{\epsilon}|}p(\boldsymbol{z}_{mi}|\boldsymbol{\pi}_{\boldsymbol{\epsilon}}, \boldsymbol{c}_m) + \mathcal{M}_{mi}(L_m)(1-$

$\sum_{|\boldsymbol{\epsilon}|=1}^{L_m} \theta_{m|\boldsymbol{\epsilon}|}$). The retrospective sampling procedure for l_{mi} is summarized in Algorithm 1.

5 Experiments

We test the proposed model with five datasets: (i) a simulated, illustrative example that examines the ability to learn the tree structure; (ii) a subset of the MNIST digits data, (iii) face data (Tenenbaum et al., 2000); (iv) the Microsoft (MSRC) image database; and (v) the LabelMe data. In the case of (iv) and (v), the images are supplemented by annotations. For (ii)-(v), we process patches from each image. For the MNIST and face data, we randomly select 50 partially overlapping patches in each image, with 15×15 and 40×40 patch sizes, respectively (placement of patches was not tuned, selected uniformly at random, with partial overlap). For the MSRC and LabelMe data, we collect all $32 \times 32 \times 3$ non-overlapping patches from the *color* images (we also consider overlapping patches in this case, but it was found unnecessary). Recall that $\boldsymbol{x}_{mi} \in \mathbb{R}^P$, with P the number of pixels in each patch ($P = 225$ for MNIST, $P = 1600$ for the face data, and $P = 3072$ for MSRC and LabelMe data).

We have examined different methods for initializing the dictionary, including random draws from the prior and various fixed redundant bases, such as the over-complete DCT. Alternatively, we may use existing dictionary-learning methods (independent of the topic model); for this purpose, we use the covariate-dependent hierarchical beta process (with the covariates linked to the relative locations between patches) to learn an initial set of dictionary atoms (Zhou et al., 2011b). Additionally, in examples (ii)-(v), we initialize the tree with 4 levels. In this initialization, four nodes are present beneath the root node, and each subsequent node has two children, down four levels; nested K-means clustering is used to initialize the data among the clusters (nodes) at the respective levels.

In all experiments, the hyperparameters were set $a_0 = b_0 = 1$, $c_0 = d_0 = e_0 = f_0 = 10^{-6}$, $\alpha = 1$ and $\gamma = 1$, and the truncation level (upper bound) on the number of dictionary elements was $K = 400$; many related settings of these parameters yield similar results, and no tuning was performed.

5.1 Inferring the tree: simulated data

We first illustrate that the proposed model is able to infer both the depth and width of the tree, using synthesized data for which the tree that generates the data is known; the data are like (but distinct from) that considered in Figure 2 of Blei et al. (2003a). In this simple example we wish to isolate the component

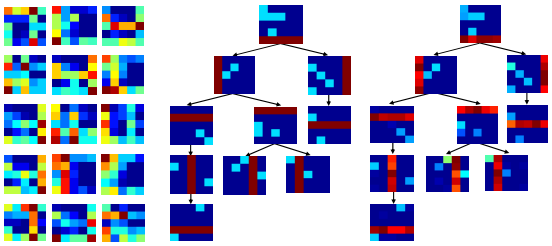

Figure 1: Example with synthesized images. Left: Example images. Middle: The ground truth for the underlying model. Right: The inferred model from the maximum-likelihood collection sample.

of the model that infers the tree, so there is no dictionary learning. The data consists of a 25-element alphabet, arranged as 5×5 blocks on a grid; each topic is characterized by the probability of using each of the 25 elements (there is a probability π_{hk} for using element $k \in \{1, \ldots, 25\}$, for each topic/node h). For each topic h the "truth" (middle in Figure 1) has probabilities 0 (blue), 0.1 (cyan blue), and 0.5 (red). The generative process for image m corresponds to first drawing a path $\boldsymbol{c}_m$ through the tree, and then 1000 times a node on this patch is drawn from $\boldsymbol{\theta}_m$, and finally each of the 25 alphabet members are drawn Bernoulli, with the associated topic-dependent probabilities (this is the proposed model, without dictionary learning). The final data ("image") consists of a count of the number of times each of the 25 elements was used, across the 1000 draws (example data at left in Figure 1). A total of 100 5×5 "images" were drawn in this manner to constitute the data. The right part of Figure 1 corresponds to the *recovered* tree, based upon the maximum-likelihood collection sample. Of course, the order of the branches and children is arbitrary; the inferred tree in Figure 1 (right) was arranged *a posteriori* to align with the "truth" (middle), to clarify presentation.

In this example the tree was initialized with 3 paths, each with three 3 layers (note in truth there are four paths, with variable number of layers). We also initialized the tree with 4 and 5 paths, under the same experimental setting, and similar recovery is achieved. If we initialized with less than 3 paths or more than 5, the recovered tree was still reasonable (close), but not as good. However, the inference of the topic-dependent usage probabilities $\boldsymbol{\pi}_h$ was very robust to numerous different settings. These results are based on 2000 samples, 1000 discarded as burn-in.

5.2 Model fit

For the MNIST handwritten digit database, we randomly choose 100 images per digit (digits 0 through

9), and therefore $M = 1000$ images are considered in total; the images are of size 28×28. The face dataset (Tenenbaum et al., 2000) contains $M = 698$ faces, each of size 64×64. Concerning the inferred trees, for the MNIST data, the maximum-likelihood collection sample had 168 paths and each path was typically 5 layers deep; for the face data 80 paths were inferred, and each was typically 5 layers. To quantitatively compare the ability of the hierarchical dictionary construction to fit the data, we consider reconstruction error for the data, comparing with the single-layer ("flat") model in Li et al. (2011); results are summarized in Table 1, corresponding to $\|\boldsymbol{x}_{mi} - \mathbf{D}(\boldsymbol{z}_{mi} \odot \boldsymbol{s}_{mi})\|_2^2$, averaged across all images m and patches i. In addition to results for MNIST and faces data, we show results for the MSRC and LabelMe data sets (analyzed in this case *without* annotations).

We also performed experiments to investigate how initialization affects the performance. In Table 1, instead of initializing the dictionary via the hierarchical beta process (hBP), they are initialized at random. While there is a slight degradation in performance with random initialization, it is not marked, and the results are still better than those produced by Li et al. (2011). Similar improvements in hBP initialization were observed for the classification task discussed below; hBP helps, but random initialization is still good.

Table 1: Reconstruction error comparison (mean square error multiplied by 10^3, and $\pm$ one standard deviation) on MNIST, Face, MSRC and LabelMe datasets. 'nDP+hBP' and 'nDP+random' correspond to the proposed model with the dictionary initialized by hBP and randomly, respectively, while the "flat" (single layer) model corresponds to Li et al. (2011).

	MNIST	Face	MSRC	LabelMe
flat model	11.10 ± 0.32	8.18 ± 0.17	10.27 ± 0.54	12.16 ± 0.30
nDP+hBP	10.42 ± 0.21	7.64 ± 0.12	8.64 ± 0.36	10.21 ± 0.27
nDP+random	10.85 ± 0.35	7.91 ± 0.20	9.25 ± 0.41	11.53 ± 0.50

The proposed model fits the data better than the "flat" model in Li et al. (2011); the gains are more evident when considering real and sophisticated imagery (the MSRC and LabelMe data). It is important to note that the proposed model is effectively no more complicated than the model in Li et al. (2011). Specifically, in Li et al. (2011) and in the proposed model, each image is put in a cluster, where in Li et al. (2011) a single-layer Dirichlet process was used to perform clustering, where here paths through the tree define clusters. In Li et al. (2011) and here each cluster/path is characterized by a distribution over topics, and in both models each topic is characterized by probabilities of atom usage (and each model has a truncation level on the dictionary of the same size). The difference is that in Li et al. (2011) the probabilities of topic usage for each cluster are drawn independently, where here the tree structure, and shared nodes between different paths, manifest statistical dependencies between the probability of topic usage in different paths with shared nodes.

In these examples a total of 250 Gibbs samples were run, with 150 discarded as burn-in. The results of the model correspond to averaging across the collection samples. In all examples useful results were found with a relatively small number of Gibbs samples.

5.3 Organizing MSRC data

We use the same settings of images and annotations from the MSRC data[1] as considered in Du et al. (2009), to allow a direct comparison. We choose 320 images from 10 categories of images with manual annotations available. The categories are "tree", "building", "cow", "face", "car", "sheep", "flower", "sign", "book" and "chair". The numbers of images are 45 and 35 in the "cow" and "sheep" classes, respectively, and 30 in all the other classes. Each image has size 213×320 or 320×213. For annotations, we remove all words that occur less than 8 times (approximately 1% of words), and obtain 15 unique annotation-words, thus $N_v = 15$.

The full tree structure inferred is shown in Figure 2, with its maximum depth inferred to be 6 (maximum-likelihood collection sample depicted, from 100 collection samples). On the second level, it is clearly observed that images are clustered in several main subgenres, *e.g.*, one with images containing grass, one with flowers, and another with urban construction, including cars and buildings, etc. For each path, we depict up to the 8 most-probable images assigned to it (fewer when less than 8 were assigned).

To further demonstrate the form of the model, two pairs of example images are shown in Figure 3. The pairs of images were assigned to two distinct paths, that shared nodes near the root (meaning the model infers shared types of patches between the images, assigned to these shared nodes). For each node, three example patches that are assigned to it are selected, from each of the two images. For the pair of example images from the "sheep" and "cow" classes, patches of grass and legs are shared on the top nodes, while distinct patches manifesting color and texture are separately assigned to nodes at bottom levels. The two images from the "building" class show the diversity of this category. It is anticipated that the "building" category will be diverse, with common patches shared at nodes near the root, and specialized patches near the leaves

[1] `http://research.microsoft.com/en-us/projects/objectclassrecognition/`

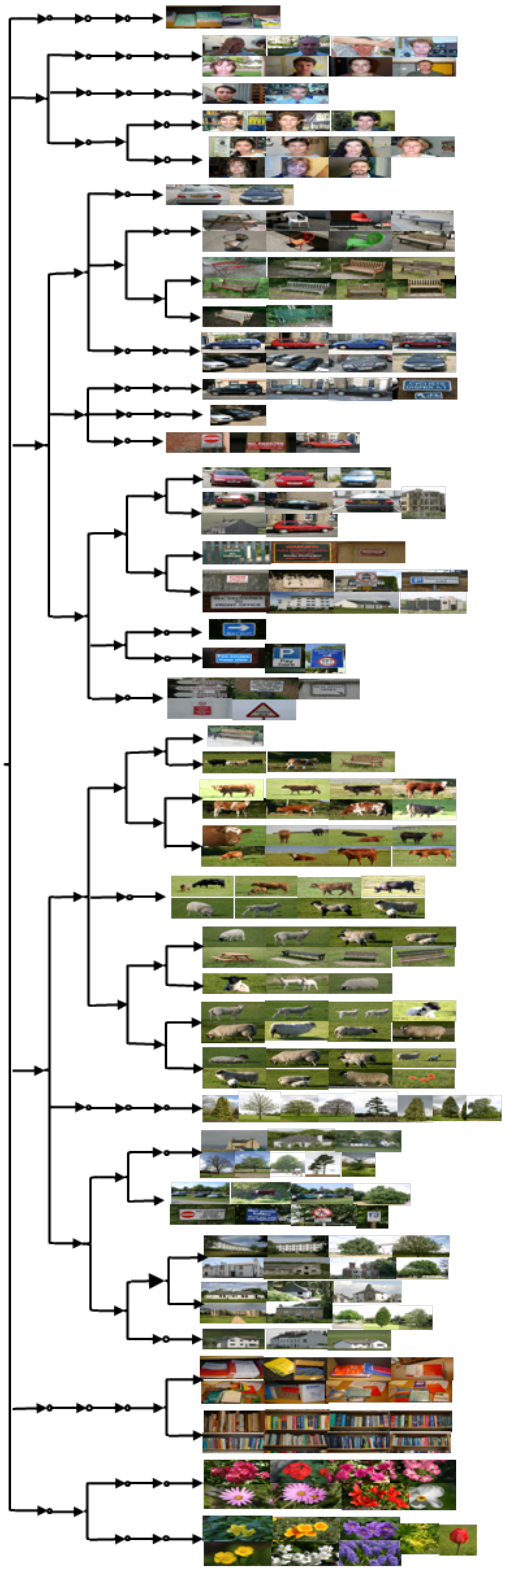

Figure 2: The full tree structure inferred from MSRC data. For each path, up to 8 images assigned to it are shown.

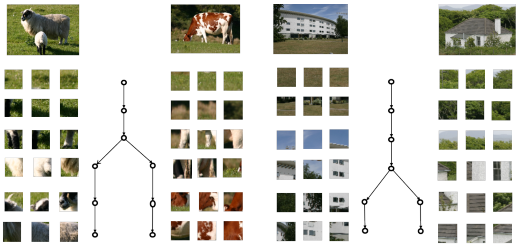

Figure 3: Two pairs of example images, and the paths they were assigned to. Between the images is shown the splitting paths. At top are the example images, and for each image we depict three example patches assigned to a respective node.

(for different types of buildings/structures). These typical examples illustrate that ubiquitous patches are shared at nodes near the root, with nodes toward the leaves describing details associated with specialized classes of images. It is this hierarchical structure that is missed by the model in Li et al. (2011), and that also apparently manifests the better model fit, as summarized in Table 1.

Another product of the model is a distribution over words for each path in the tree (not shown, for brevity). We illustrate this component of the model for the LabelMe data, considered next.

5.4 Organizing LabelMe data

The LabelMe data[2] contain 8 image classes: "coast", "forest", "highway", "inside city", "mountain", "open country", "street" and "tall building". We use the same settings of images and annotations as Wang et al. (2009): we randomly select 100 images for each class, thus the total number of images is 800. Each image is resized to be 256×256 pixels. For the annotations, we remove terms that occur less than 10 times, and obtain a vocabulary of 99 unique words, thus $N_v = 99$. There are 5 terms per annotation in the LabelMe data on average. Figure 6 visualizes 7 sub-trees of the inferred tree structure; there are 7 nodes inferred on the second level, and each node represents one sub-tree. Class "street" and class "insidecity" share the same root node, labeled 5 in Figure 6.

Based on the learned posterior word distribution $\boldsymbol{\psi}_p$ for the pth image class, we can further infer which words are most probable for each path. Figure 4 shows the $\boldsymbol{\psi}_p$ for 8 example paths (maximum-likelihood sample, from 100 collection samples), with the five largest-probability words displayed; the capital letters associated with each histogram in Figure 4 have associated paths through the tree as indicated in Figure 6. A good connection is manifested between the words and paths (examine the images and words associated with

[2] http://www.cs.princeton.edu/~chongw/

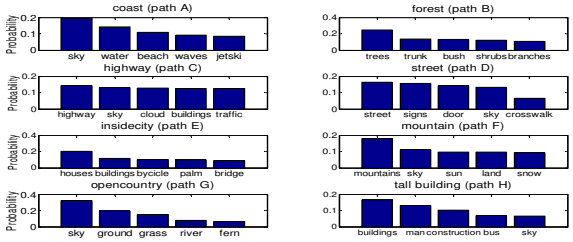

Figure 4: Inferred distributions over words for LabelMe data, as a function of inferred image category. The letters correspond to paths in Figure 6.

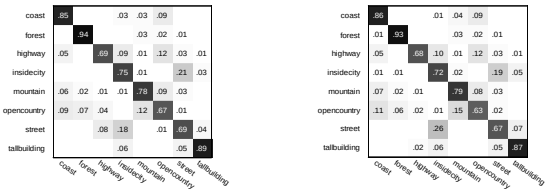

(a) (b)

Figure 5: For the 800 testing images from LabelMe data, (a): Confusion Matrix on original patches with the average accuracy of 78.3%. (b): Confusion Matrix on SIFT features with the average accuracy of 76.9%.

each path).

We evaluate the proposed model on the image-classification task, similar to as considered in Li et al. (2010). A set of 800 randomly selected images are held out as testing images from the 8 classes, each class with 100 testing images. Each image is represented by the estimated distribution over all the nodes in the entire hierarchy. Only nodes that are associated to the image have nonzero values in the distribution. We calculate the χ^2-distances between the node distribution of the testing images and those of the training images. The KNN algorithm (K is set to be 50) is then applied to obtain the class label.

Figure 5(a) shows the confusion matrix of classification, with an average classification accuracy of 78.3%, compared with 76% in Li et al. (2011). In all of the above examples the dictionary learning was applied directly to the observed pixel values within a given patch, with no *a priori* feature extraction. Alternatively, the patch-dependent data $\boldsymbol{x}_{mi}$ may correspond to features extracted using *any* image feature extraction algorithm. To illustrate this, we now let $\boldsymbol{x}_{mi}$ correspond to SIFT features (Lowe, 1999) on the same patches; in this experiment the dictionary learning replaces the VQ step in models like Wang et al. (2009). In Figure 5(b) we show the confusion matrix of the model based on SIFT features, with an average accuracy of 76.9%, slightly better than the results reported in Wang et al. (2009) (but here there is no need to tune the number of VQ codes). This also demonstrates that performing dictionary learning directly on the patches, rather than via a state-of-the-art feature extraction method, yields highly competitive results.

We now compare the proposed hierarchical model with the hierarchical model in Li et al. (2010), in which offline SIFT feature extraction and VQ are employed. Based on related work in Wang et al. (2009), we used a codebook of size 240, and achieved an average classification accuracy of 77.4%, compared with 79.6% reported above for our algorithm. Note, however, that we found the model in Li et al. (2010) to be very sensitive to the codebook size, with serious degradation in performance manifested with 150 or 400 codes, for example. To further test the proposed model, we considered the same classification experiment on MSRC data, which is characterized by 10 classes. Five images per class were randomly chosen as testing data, and the remaining images are treated as training data to learn a hierarchical structure. An average accuracy of 64% is obtained with the proposed model, compared with 60% using that in Li et al. (2010), where the codebook size is set to be 200. These experiments indicate that the proposed model typically does better than that in Li et al. (2010) for the classification task, even when we optimize the latter with respect to the number of codes.

The experiments above have been performed in 64-bit Matlab on a machine with 2.27 GHz CPU and 4 Gbyte RAM. One MCMC sample of the proposed model takes approximately 4, 2, 8 and 10 minutes respectively for the MNIST, Face, MSRC and LabelMe experiments (in which we simultaneously analyzed respectively 1000, 698, 320, and 800 total images). Note that while these model *learning* times are relatively expensive, model testing (after the tree and dictionary are learned) is very fast, this employed for the aforementioned classification task. To scale the model up to larger numbers of training images, we may perform variational Bayesian inference rather than sampling, and employ online-learning methods (Hoffman et al., 2010; Carvalho et al., 2010).

6 Conclusions

The nested Dirichlet process has been integrated with dictionary learning to constitute a new hierarchical topic model for imagery. The dictionary learning may be employed on the original image pixels, or on features from any image feature extractor. If words are available, they may be utilized as well, with word-dependent usage probabilities inferred for each path through the tree. The model infers both the tree depth and width. Encouraging qualitative and quantitative results have been demonstrated for analysis of many of the traditional datasets in this field, with comparisons provided to other related published methods.

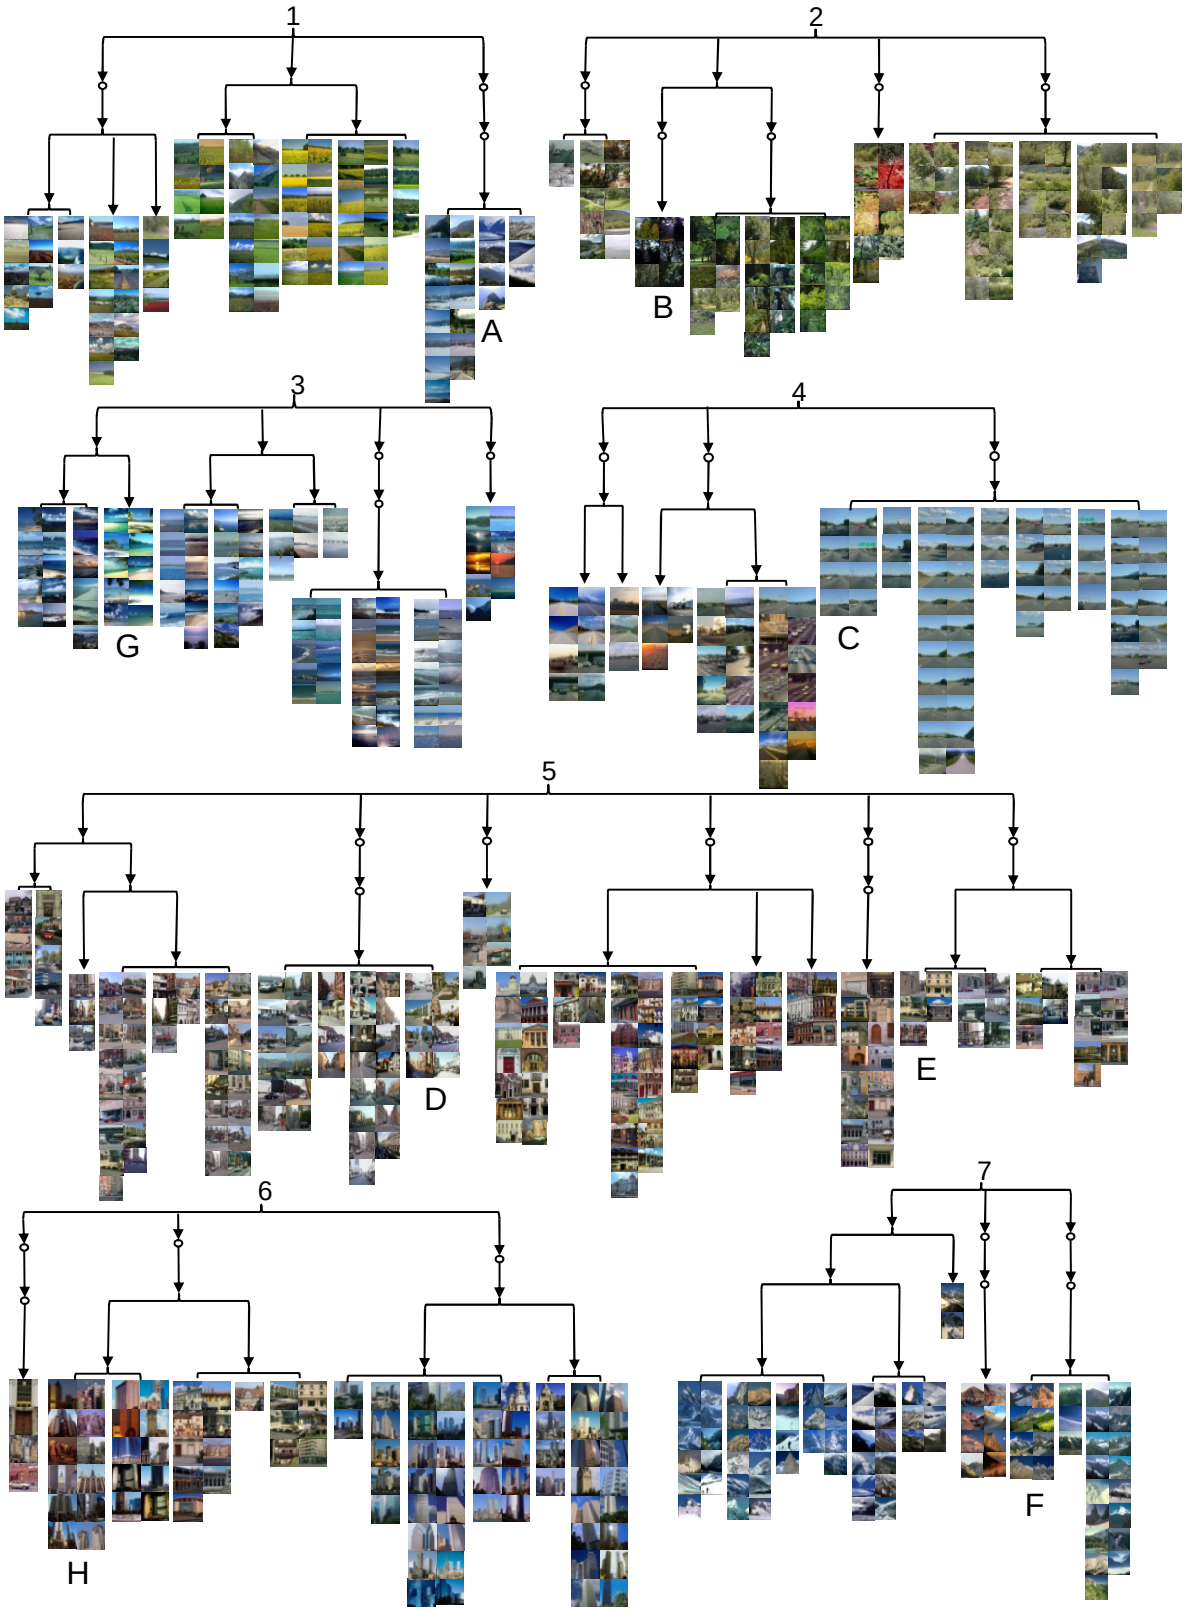

Figure 6: The structure of 7 sub-trees inferred from LabelMe data. The root of each sub-tree is one child node of the root for the entire tree structure. For each path, all images assigned to it are listed with no order importance. The letters refer to paths for which distributions over words are depicted in Figure 4.

Abstract

We introduce a method to learn a mixture of submodular "shells" in a large-margin setting. A submodular shell is an abstract submodular function that can be instantiated with a ground set and a set of parameters to produce a submodular function. A mixture of such shells can then also be so instantiated to produce a more complex submodular function. What our algorithm learns are the mixture weights over such shells. We provide a risk bound guarantee when learning in a large-margin structured-prediction setting using a projected subgradient method when only approximate submodular optimization is possible (such as with submodular function maximization). We apply this method to the problem of multi-document summarization and produce the best results reported so far on the widely used NIST DUC-05 through DUC-07 document summarization corpora.

1 Introduction

Submodular functions [10] are those that satisfy the property of *diminishing returns*: given a finite ground set V, for any $A \subseteq B \subseteq V \setminus v$, a submodular function f must satisfy $f(A \cup \{v\}) - f(A) \geq f(B \cup \{v\}) - f(B)$, i.e., the incremental "value" of v decreases as the context in which v is considered grows from A to B. Submodular functions share a number of properties in common with convex and concave functions [29], including their wide applicability, their generality, their multiple options for their representation, and their closure under a number of common operators (including mixtures, truncation, complementation, and certain convolutions). For example, the weighted sum of a collection of submodular functions $\{f_i\}_i$, $f = \sum_i w_i f_i$ where w_i are nonnegative weights, is also submodular. While they have a long history in operations research, game theory, econometrics, and electrical engineering, they are still beginning to be studied in machine learning for a variety of tasks including sensor placement [19, 20], structure learning of graphical models [34], document summarization [27, 28] and social networks [18].

The problem of learning submodular functions has also recently been addressed. For example, in [15], it is asked "can one make only polynomial number of queries to an unknown submodular function f and constructs a $\hat{f}$ such that $\hat{f}(S) \leq f(S) \leq g(n)\hat{f}(S)$ where n is the ground set size and for what function $g : \mathbb{N} \to \mathbb{R}$ is the possible?". Among many results, they show that even with adaptive queries and monotone functions, one cannot learn better than an $\Omega(\sqrt{n}/\log n)$ approximation of a given fixed submodular function. Similarly, [1] addressed the submodular function learning problem from a learning theory perspective, given a distribution on subsets. They provide strong negative results including that one can not approximate in this setting to within a constant factor. In general, therefore, learning submodular functions is hard.

While learning over all possible submodular functions may be hard, this does not preclude learning submodular functions with known forms with unknown parameters. For example, given a finite set of M fixed submodular components $\{f_i\}_{i=1}^M$ where $f_i : 2^V \to \mathbb{R}$ is submodular over V, then learning a conical mixture $\sum_{i=1}^M w_i f_i$, where $(w_1, w_2, \ldots, w_M) = \boldsymbol{w} \in \mathbb{R}_+^M$, has not in the above been ruled out to have approximate guarantees. Such mixtures might span a very large set of submodular functions, depending on the diversity of the component set. We call such a problem "learning submodular mixtures."

In this paper we extend this one step further, to an approach we call learning "submodular shells." An instantiated submodular shell is a function $f_{\alpha,(V,\beta)} : 2^V \to \mathbb{R}$ indexed by a pair of parameter vectors α, β and a

ground set V. The parameters β are associated with a particular ground set V but the parameters α of the shell apply to *any* ground-set vector pair (V,β). A *shell* has the form $f_{\bar{\alpha},(\cdot,\cdot)}$, which does not have (V,β) instantiated. We might learn, for example, that a particular value $\bar{\alpha}$ produces a good shell $f_{\bar{\alpha},(\cdot,\cdot)}$ for any instantiation of that shell with a particular (V,β). In this sense, a submodular shell might be seen as a form of "structured submodularity." Moreover, we might learn $\boldsymbol{w}$ in a mixture of such shells $\sum_i w_i f_{\alpha_i,(\cdot,\cdot)}$ based on data consisting only of training tuples of the form $\{((V^{(t)},\beta^{(t)}),S^{(t)})\}_t$ where $S^{(t)} \subseteq V^{(t)}$ and which can be used in an objective that involves the instantiated mixture of shells. Note that here, training tuples may consist of a sequence of different ground sets, and the goal is from these training tuples, and given a finite and fixed set of shells parameterized by $\{\alpha_i\}$, identify the conical weights $\boldsymbol{w}$ that optimize an objective. Of course, if all training ground sets are identical, then learning submodular shell mixtures reduces to learning submodular mixtures. In practice, however, the training ground sets are not usually identical. E.g., in extractive document summarization, the training data could be a set of documents and the corresponding human summaries, where the ground sets, those sentences that constitute the documents, are not identical between training samples. In particular, for a document t, the ground set $V^{(t)} = \{1,\cdots,n_t\}$ where n_t is the number of sentences in document t, and $\beta^{(t)}$ could be the term-frequency vectors for the sentences (see Section 5.2 for more instances of this).

We introduce a method whereby submodular shell mixtures may be learnt in a max-margin structured-prediction setting, and provide a risk-bound guarantee under approximate submodular maximization (Theorem 1). We apply our method to the extractive document summarization problem and, as mentioned in the abstract, this yields extremely good results.

2 Structured Prediction

A main goal of learning is to identify a function $h : \mathcal{X} \to \mathcal{Y}$, that maps from an input domain $\mathcal{X}$ to an output domain $\mathcal{Y}$. Structured prediction problems [51, 50, 14] are those where these domains may consist of combinatorial structures. Often, given an input $\boldsymbol{x} \in \mathcal{X}$, only a subset of $\mathcal{Y}$, say $\mathcal{Y}_{\boldsymbol{x}}$, is valid. For example, if $\boldsymbol{x}$ is a sentence, and $\mathcal{Y}$ is the set of all parse trees, than only a subset of possible parse trees $\mathcal{Y}_{\boldsymbol{x}}$ might be valid. This offers little solace, however, as $\mathcal{Y}_{\boldsymbol{x}}$ is typically still exponentially large. Usually, one forms a score function $s : \mathcal{X} \times \mathcal{Y}$ that measures how good an output $\boldsymbol{y}$ is for a given input $\boldsymbol{x}$. The decision problem is, given an $\boldsymbol{x}$, find one of the outputs with the highest score, i.e., $\boldsymbol{y}^* \in \operatorname{argmax}_{\boldsymbol{y}\in\mathcal{Y}_{\boldsymbol{x}}} s(\boldsymbol{x},\boldsymbol{y})$.

One of the primary challenges of structured prediction is that one needs to handle $\mathcal{Y}_{\boldsymbol{x}}$, whose cardinality is finite but exponentially large. A common way to address this issue is to make assumptions on both $\mathcal{Y}$ and s. For instance, if s decomposes over the parts of $\mathcal{Y}$ and moreover only depends on "local" parts, one could employ dynamic programming or integer programming algorithm to find the optimal solution. Another approach is to explore combinatorial structures upon which efficient algorithms are available. Examples of this sort include the Hungarian method [21] for maximum weighted bipartite matching and the Chu-Liu-Edmonds algorithm [6, 9] for optimal branchings. Alternatively, as we do in the sequel, one could resort to approximate solutions with approximation guarantees.

3 Submodular Shell Scores

In this paper, we propose to explore the structured prediction problem using submodular shell score functions. That is, given $\boldsymbol{x}$, $s(\boldsymbol{x},\cdot) : \mathcal{Y}_{\boldsymbol{x}} \to \mathbb{R}$ is a submodular function where $\mathcal{Y}_{\boldsymbol{x}}$ is considered to be the finite ground set associated with $\boldsymbol{x}$ — there is a finite ground set $V_{\boldsymbol{x}}$ associated with $\boldsymbol{x}$ where $\mathcal{Y}_{\boldsymbol{x}} \subseteq 2^{V_{\boldsymbol{x}}}$. There are at least two benefits of using such submodular score functions. First, submodular functions are natural and expressive with the capability of modeling decisions beyond local or linear interactions among parts. That is, submodular functions may allow for global direct interactions over a structured object unlike score functions that must decompose in some way. Second, this expressive power does require prohibitive computation as would an arbitrary score function. The reason is that the submodular maximization problem, even under many constrained settings, can be solved efficiently and near-optimally with rigorous performance guarantees [36, 13, 25, 2, 11].

The hypothesis function we consider takes the following linear discriminant form:

$$h(\boldsymbol{x};\boldsymbol{w}) = \operatorname*{argmax}_{\boldsymbol{y}\in\mathcal{Y}_{\boldsymbol{x}}} s(\boldsymbol{x},\boldsymbol{y}) = \operatorname*{argmax}_{Y\in\mathcal{Y}_{\boldsymbol{x}}} \boldsymbol{w}^\top \boldsymbol{f}_{\boldsymbol{x}}(Y)$$
$$= \operatorname*{argmax}_{Y\in\mathcal{Y}_{\boldsymbol{x}}} \sum_i w_i f_{\alpha_i,(V_{\boldsymbol{x}},\beta_{\boldsymbol{x}})}(Y)$$

where $\boldsymbol{w} \in \mathbb{R}_+$ is a non-negative weight vector, and $f_{\alpha,(V,\beta)} : 2^V \to \mathbb{R}$ is submodular over subsets of V for every valid value of α and (V,β). Since the weights are non-negative, the score function is also submodular. We call $f_{\alpha,(V,\beta)}$ a *submodular shell*, abstracting a set of submodular functions characterized by some α,β and a ground set V. The score function is called a *submodular shell mixture*, and each $f_{\alpha_i,(V,\beta)}$ is a *shell component* of the mixture. Note that the parameters β are associated with a particular ground set V but the parameters α of the shell apply to *any* pair of ground set V and β value.

While we discuss our learning process in Section 4, we introduce the learning problem here to improve clarity. We are given a set of training instances $S = \{(\boldsymbol{x}^{(t)}, \boldsymbol{y}^{(t)})\}_{t=1}^{T}$ drawn independently from a distribution D over pairs $(\boldsymbol{x}, \boldsymbol{y}) \in \mathcal{X} \times \mathcal{Y}$ restricted in such a way that $\boldsymbol{y} \in \mathcal{Y}_{\boldsymbol{x}}$ for any pair $(\boldsymbol{x}, \boldsymbol{y})$. $\boldsymbol{x}^{(t)}$ corresponds to a finite ground set $V_{\boldsymbol{x}^{(t)}}$ and a set of parameters $\beta_{\boldsymbol{x}^{(t)}}$ and so we say that $\boldsymbol{x}^{(t)} = (V_{\boldsymbol{x}^{(t)}}, \beta_{\boldsymbol{x}^{(t)}})$. We also have a finite collection of M submodular shells $\{f_{\alpha_i,(\cdot,\cdot)}\}_{i=1}^{M}$ each of which is instantiated into a submodular function for any $\boldsymbol{x} \in \mathcal{X}$. That is, $f_{\alpha_i,\boldsymbol{x}^{(t)}} : 2^{V_{\boldsymbol{x}^{(t)}}} \to \mathbb{R}$ is a submodular function. We are also given a loss function and $\ell_{\boldsymbol{x},\boldsymbol{y}}(\hat{\boldsymbol{y}})$ that measures the loss of predicting $\hat{\boldsymbol{y}} \in \mathcal{Y}_{\boldsymbol{x}}$ when the true label is $\boldsymbol{y} \in \mathcal{Y}_{\boldsymbol{x}}$. The empirical risk minimization problem then is to find a conical mixture $\boldsymbol{w} \in \mathbb{R}_{+}^{M}$ such that the risk $\mathbb{E}_{(\boldsymbol{x},\boldsymbol{y})\sim D}[\ell_{\boldsymbol{x},\boldsymbol{y}}(h(\boldsymbol{x};\boldsymbol{w}))]$ is minimized. It is important to realize that what is learnt is the mixture coefficients $\boldsymbol{w}$ over a set of shells that may be instantiated into a weighted sum of submodular functions.

Before we discuss learning in detail, we consider the expressive power of mixtures of such submodular shells.

3.1 Submodular Shell Mixtures

A fairly rich subclass of submodular functions can be instantiated from submodular shell mixtures with components being simpler submodular shells. Consider, for example, truncation functions, mixtures of which can represent many submodular functions of interest. Given a modular function[1] $c : 2^V \to \mathbb{R}$, define a truncation function $t_{\alpha,(V,c)} : 2^V \to \mathbb{R}$ as

$$t_{\alpha,(V,c)}(A) = \min \left\{ c(A), \alpha \max_{B \subseteq V} c(B) \right\},$$

which is submodular, where $\alpha \in \mathbb{R}$ is the truncation threshold. A modular function can also be written as a truncation function with $\alpha = \infty$. We note that (V, β) above takes the form (V, c) here, and we might have a collection of such functions $\{t_{\alpha_i,(V,c)}\}_i$, and learning a mixture $\boldsymbol{w}$ would mean that w_i indicates the importance of truncation threshold α_i.

In fact, many submodular functions can be written as mixtures of truncation functions. For example, coverage type functions, canonical examples of submodular functions, can be written as submodular mixtures. Precisely, let a collection of sets be $\{A_i\}_{i \in \{1,\cdots,|V|\}}$ on a ground set E. Then the set cover function becomes

$$f : 2^V \to \mathbb{R}_+, \quad f(B) = \left| \bigcup_{i \in B} A_i \right|.$$

We can define costs $c_{i,j} = 1$ if A_i contains $j \in E$ and $c_{i,j} = 0$ otherwise. We then have

$$f(B) = \left| \bigcup_{i \in B} A_i \right| = \sum_{j=1}^{|E|} \min \left\{ \sum_{i \in B} c_{i,j}, 1 \right\},$$

which is a mixture of truncation functions. Moreover sums of concave functions applied to cardinality functions [47] can be represented as mixtures of truncation functions — any sum of such functions can be expressed as a sum of a modular function and nonnegative linear combinations of truncation functions.

Another interesting class is weighted matroid rank functions [32]. Given matroids [56, 38] $\mathcal{M}_i = (V, \mathcal{I}_i)$, and modular functions $m_i : 2^V \to \mathbb{R}_+$, we get:

$$\sum_{i=1}^{M} w_i f^i_{m_i,(V,\mathcal{M}_i)} = \sum_{i=1}^{M} w_i \max\{m_i(I) : I \subseteq S, I \in \mathcal{I}_i\}$$

which includes cover-like functions and many others.

The submodular functions introduced in [28] for document summarization can also been seen as a mixture of submodular shells, with components being either the coverage or the diversity shell that can be instantiated for a particular document.

In general, by using rich enough families of shell components, a submodular shell mixture could be very expressive, representing a very large family of submodular functions. Moreover, another advantage of using submodular shell mixture representations is that, since we assume each component is given and only the component weights are unknown, the learning problem can be addressed by using well-established methods. And by learning shell mixtures, we can then apply the learnt mixture to structured problems even over different underlying ground sets.

4 Learning Submodular Shell Mixtures

While there might be many ways of learning shell mixtures, in this paper we take a large-margin approach, standard in structured prediction. In other words, we want to minimize the risk of making predictions (decisions) when using the submodular shell mixture as a score function. Of course, the standard maximization in learning structured prediction is only approximate in this case, since maximizing submodular functions in NP-hard (although constant-factor approximable). Moreover, we need to identify a valid loss function that dose not violate submodularity. We wish also to ensure that the learnt parameters have quality guarantees (e.g., a risk bound). All of this is done in the below.

[1] f is modular if both f and $-f$ are submodular.

4.1 Large Margin Learning

We consider the learning problem defined in Section 3. For concision, we denote

$$\mathcal{Y}_t \triangleq \mathcal{Y}_{\boldsymbol{x}^{(t)}}, \quad \boldsymbol{f}_t(\boldsymbol{y}) \triangleq \boldsymbol{f}_{\boldsymbol{x}^{(t)}}(\boldsymbol{y}), \text{ and } \ell_t(\boldsymbol{y}) \triangleq \ell_{\boldsymbol{x}^{(t)},\boldsymbol{y}^{(t)}}(\boldsymbol{y}).$$

We follow the maximum margin approach [51] to learn the component weights $\boldsymbol{w}$, where the goal is to find a score function that scores $\boldsymbol{y}^{(t)}$ higher than all other $\boldsymbol{y} \in \mathcal{Y} \setminus \boldsymbol{y}^{(t)}$ by some margin. Formally, the learning problem is as follows:

$$\min_{\boldsymbol{w} \geq 0} \frac{1}{T} \sum_{t=1}^{T} \hat{\ell}_t(\boldsymbol{w}) + \frac{\lambda}{2} \|\boldsymbol{w}\|^2, \tag{1}$$

where the generalized hinge loss

$$\hat{\ell}_t(\boldsymbol{w}) \triangleq \max_{\boldsymbol{y} \in \mathcal{Y}_t} \left(\boldsymbol{w}^\top \boldsymbol{f}_t(\boldsymbol{y}) + \ell_t(\boldsymbol{y}) \right) - \boldsymbol{w}^\top \boldsymbol{f}_t(\boldsymbol{y}^{(t)}) \tag{2}$$

and a quadratic regularizer is minimized.

Algorithm 1: Projected subgradient descent for learning submodular shell mixtures.

Input : $S = \{(\boldsymbol{x}^{(t)}, \boldsymbol{y}^{(t)})\}_{t=1}^{T}$ and a learning rate sequence $\{\eta_t\}_{t=1}^{T}$.

$\boldsymbol{w}_0 = 0$;

for $t = 1, \cdots, T$ **do**

  Approximate loss augmented inference:

  $\hat{\boldsymbol{y}}_t \approx \operatorname{argmax}_{\boldsymbol{y} \in \mathcal{Y}_t} \boldsymbol{w}_{t-1}^\top \boldsymbol{f}_t(\boldsymbol{y}) + \ell_t(\boldsymbol{y})$;

  Compute the subgradient:

  $\boldsymbol{g}_t = \lambda \boldsymbol{w}_{t-1} + \boldsymbol{f}_t(\hat{\boldsymbol{y}}_t) - \boldsymbol{f}_t(\boldsymbol{y}^{(t)})$;

  Update the weights with projection:

  $\boldsymbol{w}_t = \max(\boldsymbol{0}, \boldsymbol{w}_{t-1} - \eta_t \boldsymbol{g}_t)$;

Return : the averaged parameters $\frac{1}{T} \sum_t \boldsymbol{w}_t$.

Many algorithms have been proposed for the large margin learning problem, including those based on the exponentiated gradient method [7], the dual extragadient method [52], the cutting-plane algorithm [54], and the subgradient descent method [42, 43]. We adopt a subgradient descent algorithm to learn submodular shell mixtures, as illustrated in Algorithm 1, where max of two vectors takes dimension-wise maximum, i.e. $\max\{\boldsymbol{a}, \boldsymbol{b}\} = (\max(a_1, b_1), \cdots, \max(a_n, b_n))$ where $\boldsymbol{a}, \boldsymbol{b} \in \mathbb{R}^n$.

Note, to preserve submodularity, the component weights must be non-negative. We thus simply project the weights to the non-negative orthant whenever doing the updates, and it is easy to show that updates followed by projection onto a non-negative region do not affect the convergence or correctness of the algorithm as when a point is projected back into the convex set, it is moved closer to every point in the set including the optimal points.

Second, whether the learning can be done efficiently depends on whether the so called *loss augmented inference* (LAI) problem,

$$\max_{\boldsymbol{y} \in \mathcal{Y}_t} \boldsymbol{w}^\top \boldsymbol{f}_t(\boldsymbol{y}) + \ell_t(\boldsymbol{y}), \tag{3}$$

can be solved efficiently. The LAI problem has a term that precisely matches the prediction problem whose parameters we are trying to learn but also has an additional term corresponding to the loss. Tractability of LAI therefore not only depends on the tractability of the prediction problem but also on the form of loss functions. When using submodular shell mixtures as the score function, we use approximate inference with a performance guarantee. Therefore, we must perform approximate inference for the LAI problem as well. We thus in general refer to this as approximate learning.

4.2 Approximate learning

Since some form of inference is a dominant subroutine in many learning algorithms for structured prediction, it is natural to use good approximate inference techniques to make the learning problem tractable. When learning submodular shell mixtures, we inevitably must use approximate learning since, by using a more expressive class of score functions that need not decompose, the inference problem is intractable to do exactly. Using approximate inference as a drop-in replacement for exact inference in learning, however, could mislead the learning algorithm and result in poorly learnt models. This is analyzed in [24], where it is pointed out that approximate learning could fail even with an approximate inference method having approximation guarantees. In general, therefore, it is problematic to assume that an arbitrary choice of approximate inference method will lead to useful results when the learning method expects exact feedback. Choosing compatible inference and learning procedures is therefore crucial.

In the following, we aim to leverage the approximation guarantees of submodular optimization such that the performance of approximate learning of submodular shell mixtures can be bounded in some way. One possible way of bounding is to investigate the degree to which we can approximate the parameters $\boldsymbol{w}$ that would be obtained by exact learning, since the parameters themselves offer little utility if good prediction cannot be made from them. Alternatively, we can focus on the quality of prediction obtained from an approximately learned model. In particular, we seek to bound the risk gap. That is, the difference between the expected loss of predictions from an approximate (but efficient) scheme and from exact (but intractable) methods.

4.3 Analysis

Hence, we must further analyze whether using good approximate inference will lead us to good approximate learning in our case. Before doing so, we note that there are two types of approximation inference algorithms, namely undergenerating and overgenerating approximations.

Consider a maximization problem

$$\max_{\boldsymbol{y}\in\mathcal{Y}} f(\boldsymbol{y}) \triangleq f^*.$$

Undergenerating approximation algorithm always find a solution $\boldsymbol{y} \in \mathcal{Y}$ such that $f(\boldsymbol{y}) \leq f^*$, while overgenerating approximation algorithm always find a solution $\boldsymbol{y} \in \bar{\mathcal{Y}} \supseteq \mathcal{Y}$ such that $f(\boldsymbol{y}) \geq f^*$. A greedy algorithm or the loopy belief propagation [40] are instances of undergenerating approximation algorithms. Relaxation methods, e.g. linear programming relaxation, are overgenerating approximation algorithms. Note that undergenerating algorithms usually produce solutions that are within the feasible region of the problem. Overgenerating algorithms, on the other hand, generate solutions that might lie outside this feasible region. Therefore, solutions found by overgenerating algorithms sometimes need to be mapped back to the feasible region (e.g., rounding of linear programming produced solutions) in order to produce a feasible solution, during which the approximation guarantee no longer holds in some cases [44]. For learning submodular shell mixtures, we are particularly interested in undergenerating algorithms since the greedy algorithm, one of the undergenerating algorithms, offers near-optimal solutions for submodular maximization under certain (e.g., cardinality, budget, and matroid) constraints [36, 13].

Generalization bounds for approximate learning with cutting-plane algorithms, with either undergenerating or overgenerating inferences, have been shown in [12]. For subgradient descent methods, generalization analysis is available, but only for overgenerating cases, in [30, 22]. As far as we know, no generalization analyses are available for approximate learning with undergenerating subgradient methods. We fill this gap and offer risk bounds for approximate learning with undergenerating subgradient methods.

We need two definitions before moving on.

Definition 1 (ρ-approximate algorithm)**.** *Given $f : \mathcal{Y} \to \mathbb{R}^+$ and a maximization problem $\max_{\boldsymbol{y}\in\mathcal{Y}} f(\boldsymbol{y}) \triangleq f^*$, we call an (undergenerating) algorithm a ρ-approximate algorithm if it finds a solution $\boldsymbol{y} \in \mathcal{Y}$ such that $f(\boldsymbol{y}) \geq \rho f^*$, where $0 \leq \rho \leq 1$.*

Definition 2 (γ-approximate subgradient)**.** *Given $f : \mathbb{R}^M \to \mathbb{R}$, a vector $\boldsymbol{g} \in \mathbb{R}^M$ is called a γ-subgradient of f at $\boldsymbol{w}$ if for all $\boldsymbol{w}'$, $f(\boldsymbol{w}') \geq f(\boldsymbol{w}) + \boldsymbol{g}^\top(\boldsymbol{w}' - \boldsymbol{w}) - \gamma f(\boldsymbol{w})$ where $0 \leq \gamma \leq 1$ and $\boldsymbol{w}, \boldsymbol{w}' \in \mathbb{R}^M$.*

In Algorithm 1, one needs to solve the LAI in Eqn (3). Note that if ℓ is modular (e.g. hamming loss) or submodular (e.g. see Section 5.3), a ρ-approximate inference algorithm can also apply to this loss augmented inference to find a near-optimal solution efficiently. However, as mentioned above, when an approximate inference algorithm is used in a learning algorithm, a good approximation of the score might not be sufficient, and it is possible that the learning can fail even with rigorous approximate guarantees [24]. On the other hand, Ratliff et al. [43] show that the subgradient algorithm is robust under approximate settings, and the risk experienced during training with γ-approximate subgradients can be bounded.

Note that a ρ-approximate LAI does not necessary imply any γ-subgradient because the approximate ratio does not apply to the term $-\boldsymbol{w}^\top f_t(\boldsymbol{y}^{(t)})$. To analyze the actual impact of ρ-approximate LAI in the learning procedure when compared with the exact formulation, then, we provide risk bounds for the approximate learner in Theorem 1.

Theorem 1. *Assume $w_i, f_i, i = 1, \cdots, M$ are all upper-bounded by 1, $\hat{\ell}_t(\boldsymbol{w}) \leq B$, and $\|\boldsymbol{g}_t\| \leq G$. Let $\boldsymbol{w}^*$ and $\hat{\boldsymbol{w}}$ be the solutions returned by Algorithm 1 using exact and ρ-approximate LAI, respectively, with learning rate $\eta_t = \frac{2}{\lambda t}$ and $\lambda = \frac{G}{M}\sqrt{\frac{2(1+\log T)}{T}}$. Then for any $\delta > 0$ with probability at least $1 - \delta$,*

$$\mathbb{E}_{(\boldsymbol{x},\boldsymbol{y})\sim D}[\ell_{\boldsymbol{y}}(h(\boldsymbol{x};\hat{\boldsymbol{w}}))] \leq \frac{1}{\rho}\left(\frac{1}{T}\sum_{t=1}^{T}\hat{\ell}_t(\boldsymbol{w}^*)\right) + S(T),$$

where

$$S(T) = \frac{MG}{\rho}\sqrt{\frac{2(1+\log T)}{T}} + B\sqrt{\frac{2}{T}\log\frac{1}{\delta}} + \frac{1-\rho}{\rho}M.$$

The proof is given in the supplementary material. Note that there are three terms in $S(T)$. While the first two terms vanish as $T \to \infty$, the third term does not. Therefore, the additional risk incurred due to the use of ρ-approximate LAI for learning is $(R^* + (1-\rho)M)/\rho$, where $R^* = \lim_{T\to\infty}\frac{1}{T}\sum_{t=1}^{T}\hat{\ell}_t(\boldsymbol{w}^*)$ and can be seen as the risk of predictions using models learnt with exact inference. Thus, the better (larger ρ) the approximation, the less the additional risk there will be when using an approximate LAI. And when exact inference is used ($\rho = 1$), the additional risk shrinks to zero. Note that Theorem 1 applies to any loss function and any score function which is not necessary to be submodular. When addition assumptions are made (e.g., assumption that the loss function is linearly realizable as in [57]), a better bound might be possible where the additional risk shrinks to zero as T grows. On the other hand, when the LAI objective is monotone submodular, a

simple and efficient greedy algorithm performs near-optimally with approximation factor $1 - 1/e$ [36]. In practice, moreover, as the approximation factor of the greedy algorithm on submodular maximization is usually very close to 1 [27], one could expect very little additional risk when using Algorithm 1 with approximate inference on learning submodular shell mixtures.

To the best of our knowledge, Theorem 1 is the first approximate learning bound for subgradient algorithms with undergenerating (greedy) inference.

5 Application to Document Summarization

Submodular mixtures could be applied to many structured prediction problems of practical interest. In this paper, we apply submodular shell mixture learning to extractive document summarization as a case study.

5.1 Submodularity in Document Summarization

Extractive document summarization can be seen as a subset selection problem [27]. Given a ground set of sentences V, the task of extractive document summarization is selecting a subset of sentences, say S, that best represents the whole document. In other words, we want to find $A \subseteq V$ such that

$$A \in \operatorname*{argmax}_{B \subseteq V} f(B) \text{ subject to: } \sum_{i \in B} c_i \leq b, \qquad (4)$$

where $c_i \in \mathbb{R}^+$ is the cost of sentence i (e.g., it could be the number of words in the sentence), $b \in \mathbb{R}^+$ is the total budget (e.g., it could the largest number of words allowed in a summary), and $f : 2^V \to \mathbb{R}$ is a set function that models the quality of a summary. Eqn (4) is known as the problem of submodular maximization subject to knapsack constraints [31] which NP-complete [35]. However, when f is *monotone submodular*, Eqn (4) can be solved efficiently and near-optimally with a theoretical guarantee via greedy algorithms [48, 27].

One can always force f to be submodular, leading to an objective function that can be optimized well but might on the other hand poorly represent a given problem. One attractive property of submodularity, like convexity in continuous domain, is that it arises naturally in many applications. One such applications is document summarization. As pointed out in [28], many well-established methods, including the widely used maximum margin relevance method [3], actually correspond to submodular optimization. Moreover, it is shown that the commonly used ROUGE score [26] for automatic summarization evaluation is monotone submodular [28], giving further evidence that submodular functions are natural for document summarization.

In this paper, we further show that not only is the ROUGE score submodular, the score used in the Pyramid method [37], one of the manual evaluation metrics that has been used in recent TAC summarization track[2], is also monotone submodular.

Theorem 2. *The modified score in Pyramid method is monotone submodular.*

The proof is in Appendix C in the supplement.

The remaining question is how to design (or ideally learn) a good submodular function for summarization. Lin and Bilmes [28] proposed a class of submodular functions that models the coverage as well as the diversity of summary. In this paper, we further generalize their class of submodular functions and propose to use *submodular shell mixtures* for document summarization.

5.2 Submodular shells for summarization

Diversity shell components

We define a diversity shell component as

$$f^{\text{diversity}}_{(a,K,\mathcal{A}),(V,\boldsymbol{r})}(S) = \frac{\sum_{k=1}^{K} \left(\sum_{i \in S \cap P_k} r_i\right)^a}{\sum_{k=1}^{K} \left(\sum_{i \in P_k} r_i\right)^a}, \qquad (5)$$

where $0 \leq a \leq 1$ is the curvature, $K \in \mathbb{Z}^+$ is the number of clusters (partitions), $\mathcal{A}$ is a clustering algorithm, and $\{P_k\}_{k=1,\cdots,K}$ is a partition of the ground set V generated by $\mathcal{A}$, and $\boldsymbol{r} = \{r_i\}_{i=1}^{|V|}$ with $r_i \in [0, 1]$ is the vector of singleton reward of element $i \in V$. The diversity component models the diversity of a summary set S, by diminishing the benefit of choosing elements from the same cluster.

Note that the α parameter of a submodular shell here takes the form $(a, K, \mathcal{A})$. By using different values of a and K, and different clustering algorithms $\mathcal{A}$, we can produce a variety of submodular shells. The (V, β) parameter of a submodular shell takes the form of $(V, \boldsymbol{r})$. When a document (ground set) is given, rewards of each sentence (i.e., r_i) can be computed, and the diversity shell component is then instantiated into a submodular function that measures the diversity of a summary for this particular document.

Clustered facility location shell components

We define clustered facility-location like components as

$$f^{\text{c-facility}}_{(K,\mathcal{A}),(V,\boldsymbol{r})}(S) = \frac{1}{K} \sum_{k=1}^{K} \max_{i \in S \cap P_k} r_i, \qquad (6)$$

[2] http://www.nist.gov/tac/2011/Summarization/

where $K \in \mathbb{Z}^+$ is the number of clusters (partitions), $\mathcal{A}$ is a clustering algorithm, and $r_i \in [0,1]$ is the singleton reward of element $i \in V$. This function has a similar form to the well known submodular facility location function, but defined on a partition of the ground set. We thus call it clustered facility location. If a summary contains multiple elements from a same cluster, the element with largest singleton reward will be regarded as the "representative" of this cluster, and only the reward of this representative will be counted into the final score. This again diminishes returns of choosing elements from the same cluster and therefore $f^{\text{c-facility}}$ is submodular.

Fidelity shell components

Given a ground set V, we define fidelity components as

$$f^{\text{fidelity}}_{\alpha,\left(V,\{C_i\}_{i=1}^{|V|}\right)}(S) = \frac{1}{|V|}\sum_{i\in V}\min\left\{\frac{\mathcal{C}_i(S)}{\mathcal{C}_i(V)},\alpha\right\}, \quad (7)$$

where $0 < \alpha \leq 1$ is a saturation threshold and $\mathcal{C}_i : 2^V \to \mathbb{R}$ is a *monotone* submodular function modeling how S covers the information contained in i. This function is the normalized version of the coverage function defined in [28]. Basically, the saturation threshold controls how much of a given element $i \in V$ should be covered; once $\mathcal{C}_i(S)$ is large enough such that the ratio of it over its largest possible value ($\mathcal{C}_i(V)$) is above threshold, covering more of i does not further increase the function value. Therefore, a larger value of f^{fidelity} tends to have more $i \in V$ well covered. When a document is given, we can instantiate different submodular shells using a variety of C_i.

5.3 A Submodular Loss Function

The most widely used evaluation criteria for summarization is the ROUGE score, which is basically a submodular function that counts n-gram recall rate over human summaries. Let S be the candidate summary (a set of sentences extracted from the ground set V), $c_e : 2^V \to \mathbb{Z}_+$ be the number of times n-gram e occurs in summary S, and R_i be the set of n-grams contained in the reference summary i (suppose we have K reference summaries, i.e., $i = 1, \cdots, K$). Then ROUGE-N [26] can be written as the following set function:

$$f_{\text{ROUGE-N}}(S) \triangleq \frac{\sum_{i=1}^{K}\sum_{e\in R_i}\min(c_e(S), r_{e,i})}{\sum_{i=1}^{K}\sum_{e\in R_i} r_{e,i}},$$

where $r_{e,i}$ is the number of times n-gram e occurs in reference summary i. $f_{\text{ROUGE-N}}(S)$ is submodular, as shown in [28], but cannot be used as a loss function since it basically measures "accuracy" rather than loss.

An alternative is to use $1 - f_{\text{ROUGE-N}}(S)$ as a loss function, but this is supermodular. Note that in order to have the risk of the approximated learned model bounded, performance guarantees are required for the approximation algorithms used in loss augmented inference. When using $1 - f_{\text{ROUGE-N}}$, which is supermodular as a loss function, in the objective function for loss augmented inference (Eqn. (3)) along with a submodular shell mixture as the score function, the resulting objective function for LAI is then a submodular function plus a supermodular function. While an algorithm (e.g., submodular-supermodular procedure [33, 17]) is available to approximately optimize the sum of a submodular function and a supermodular function, performance guarantees usually do not exist for these algorithms (although this strategy might work well in practice and should ultimately be tested). Therefore, when using one-minus-ROUGE as the loss function, the greedy algorithm no longer provides a near-optimal solution when applied to the non-submodular objective, and the risk bound shown in Theorem 1 no longer holds.

To address this issue, we propose a ROUGE-like loss function that measures the "complement recall":

$$\ell_{\text{ROUGE}}(S) \triangleq \frac{\sum_{e\in\bar{R}}\omega_e c_e(S)}{\sum_{e\in\bar{R}}\omega_e r_e}, \quad (8)$$

where $\bar{R} = N \backslash \bigcup_i R_i$, and N is the set of all the n-grams occur in the set of documents, and $r_e = c_e(V)$ is the number of times n-gram e occurs in all the documents, ω_e is a non-negative weight for e, and $\bar{R}$ is the set of n-grams that are *not* covered by any human reference summary. Instead of counting with respect to a reference summary, ℓ_{ROUGE} counts the n-grams of a candidate summary S w.r.t. the *complement* of reference summaries.

Intuitively, we want a summary S to cover as many reference n-grams as possible so that it will get a high ROUGE-score; this is similar to having S be large and overlapping as little as possible with the n-grams that are *not* in human references. In this sense, ℓ_{ROUGE} measures the portion of how many n-grams in the complement of the reference n-grams set are covered, and when comparing summaries with the same size, the smaller ℓ_{ROUGE} is, the better. The best case, i.e., the human reference itself, will have ℓ_{ROUGE} equal to 0.

Obviously, a poor summary that would also have ℓ_{ROUGE} equal to 0 is an empty summary. It is worth noting that ℓ_{ROUGE} only makes sense when comparing summaries that are close to the same budget. Fortunately, most summarization algorithms try to consume every bit of the budget in order to consume as much information as possible under the budget constraint. For summaries produced in this way, ℓ_{ROUGE} offers a fair indicator of their quality: the smaller the loss value, the larger the number of reference n-gram overlaps there are, and therefore the better the summary. We

use the greedy algorithm for solving the summarization problems (Eqn. (4)). Due to its greedy nature, the algorithm always outputs summary candidates whose costs are close to the budget, and therefore ℓ_{ROUGE} can serve as a reasonable surrogate loss function for learning submodular shell mixtures for summarization tasks.

The major advantage of using ℓ_{ROUGE} as a loss function, of course, is algorithmic. The submodular learning analysis in Theorem 1 relies on the fact that a ρ-approximation algorithm is available for the loss augmented information. Since we use a submodular score function for summarization, the above objective will be submodular if the loss function is submodular. Fortunately, similar to $f_{\text{ROUGE-N}}$, the proposed loss for summarization, ℓ_{ROUGE}, is also monotone submodular (in fact modular). Therefore, the LAI in submodular shell mixture learning for summarization is exactly the budgeted submodular maximization problem (Eqn (4)), and efficient and near-optimal algorithms are then available. Consequently, all the theoretical analyses in Section 4.3 apply.

We will soon see (Section 7) that using the ROUGE-like loss function proposed here empirically outperforms using $1 - f_{\text{ROUGE}}$ as a loss functions.

6 Related work

Recently, Yue and Guestrin [57] studied a linear submodular bandits problem in an online learning setting for optimizing a general class of feature-rich submodular utility models in diversified retrieval, and their theoretical result is based on the assumption that the award function has a special (linear) form. Raman et al. [41] also propose an online learning model and algorithm for learning rankings that exploiting feedback to maximize any submodular utility measure. While our approach and analysis could also be applied to the online setting, the focus and analysis in this paper are more on the batch learning. The submodular utility models in [57, 41], however, can both be seen as special instances of submodular shell mixtures.

More closely related to our work is that of [46] where large-margin learning of submodular score functions for extractive document summarization is studied. The representation of a submodular score function in [46], again, turns out to be a special case of a submodular shell mixture. Moreover, our submodular shell mixture framework is more general and flexible than the framework proposed in [46]. Although the authors claim that their approach applies to all submodular summarization models, there are many submodular functions useful for summarization that are not linear on either pairwise similarity or singleton importance. For example, in the diversity reward function, we have a concave function over the sums of singleton rewards, and even if using linear model for singleton rewards, the score function is non-linear over parameters since the weights can not be linearly extracted, and thus the algorithms in [46] do not apply. Viewing each feature as input to a submodular component, on the other hand, preserves the linearity on the parameters, whereas Algorithm 1 applies. Moreover, representing a score function using a submodular shell mixture is expressive, as we have shown in Section 3.1.

In [46], a cutting plane algorithm with one-minus-ROUGE F-measure as loss function was used to learn model weights. When doing the loss augmented inference, they use the greedy algorithm introduced in [27] to approximately optimize the objective. Their objective function, however, is not submodular, due to the non-submodular loss function they use. Therefore, the LAI inference is no longer guaranteed to be near-optimal, and the performance of approximate learning with their cutting plane algorithm is no longer guaranteed [12]. Also, Sipos et al. [46] apparently neglect the fact that the learned similarity (or importance) should be non-negative, which is a necessary ingredient to preserve the submodularity of the learned score function. One simple way to ensure this is to constrain the weights to be non-negative, as we do for submodular shell mixtures by project the weights to the non-negative orthant (Algorithm 1).

7 Experiments

We evaluated our approach on NIST's DUC[3] data 2003-2007, and demonstrate results on both generic and query-focused summarization. DUC data were created by national institution of standard technology (NIST). The DUC evaluation is one of the standardized benchmark evaluations for document summarization and researchers continue to publish results on these data sets.

7.1 Query-independent summarization

Table 1: ROUGE-1 recall (R) and F-measure (F) results (%) on DUC-04. DUC-03 was used as development set.

DUC-04	R	F
Takamura and Okumura [49]	38.50	-
Wang et al. [55]	39.07	-
Lin and Bilmes [27]	-	38.39
Lin and Bilmes [28]	39.35	38.90
Kulesza and Taskar [23]	38.71	38.27
Best system in DUC-04 (peer 65)	38.28	37.94
Submodular Shell Mixture	**40.43**	**39.78**

The summarization tasks in DUC-03 and DUC-04 are

[3] http://duc.nist.gov/

generic summarization tasks. We used DUC-03 as the training set for submodular shell mixture learning. There are in total 60 document clusters in the DUC-03 task, therefore we have 60 training examples in total. We used a submodular shell mixture with 15 fidelity components for this task. In particular, the $\mathcal{C}_i$ function we used is $\mathcal{C}_i(S) = \sum_{j \in V} \delta_{i,j}$, where $\delta_{i,j}$ is the pairwise sentence similarity between sentence i and j. We used three types of sentence similarities. The first two are cosine similarities with unigram and bigram TF-IDF vectors respectively. The third similarity is again cosine similarity but on the vector generated by latent semantic analysis. For each of the similarity measures, we use five different saturation thresholds ($\alpha = 0.01, \cdots, 0.05$), and thus we have 15 fidelity components in total. We used Algorithm 1 with the ROUGE-like loss (Eqn. (8)) with $\omega_e = 1$ for all e to learn this submodular shell mixture. The ROUGE-1 results are shown in Table 1. As we can see, the result of the learned submodular shell mixture significantly outperforms all other previous reported results. Note that the experiment in [46] used a non-standard setup where DUC-04 data were divided into training, development, and test sets with only 5 documents in their test set. Therefore, results reported in [46] are not directly comparable to other results (e.g., our results) that follow standard DUC evaluation setup.

7.2 Query-focused summarization

Table 2: ROUGE-2 recall (R) and F-measure (F) results on DUC-05 (%). We used DUC-06 and DUC-07 as training sets.

DUC-05	R	F
Daumé III and Marcu [8]	6.98	-
Lin and Bilmes [28]	7.82	7.72
Best system in DUC-05 (peer 15)	7.44	7.43
Submodular Shell Mixture	**8.44**	**8.39**

Table 3: ROUGE-2 recall (R) and F-measure (F) results (%) on DUC-06, where DUC-05 and DUC-07 were used as training sets.

DUC-06	R	F
Celikyilmaz and Hakkani-tür [4]	9.10	-
Shen and Li [45]	9.30	-
Lin and Bilmes [28]	9.75	9.77
Best system in DUC-06 (peer 24)	9.51	9.51
Submodular Shell Mixture	**9.92**	**9.93**

Since 2004, DUC summarization evaluations have concentrated on query-focused summarization. We tested our approach for summarization on DUC-05, DUC-06 and DUC-07 data. In particular, we used DUC-06,07 as the training set for the DUC-05 task, DUC-05,07 as the training set for the DUC-06 task, and DUC-05,06 as the training set for the DUC-07 task.

Table 4: ROUGE-2 recall (R) and F-measure (F) results (%) on DUC-07. DUC-05 and DUC-06 were used as training sets. Note that the peer 15 system in DUC-07 used commercial web search engine to expand the queries.

DUC-07	R	F
Toutanova et al. [53]	11.89	11.89
Haghighi and Vanderwende [16]	11.80	-
Celikyilmaz and Hakkani-tür [4]	11.40	-
Lin and Bilmes [28]	12.38	12.33
Best system in DUC-07 (peer 15)	12.45	12.29
Submodular Shell Mixture	**12.51**	**12.40**

We used diversity components, clustered facility location components, and fidelity components to form the submodular shell mixture for query-focused summarization. Three clusterings with different numbers of clusters were created ($K = 0.1|V|, 0.2|V|, 0.3|V|$). As for the singleton rewards, we used both query-independent and query-dependent singleton rewards. The query-independent reward for i is simply the summation of the pairwise similarities of other elements in V to i. For the query-dependent reward, we simply used the number of terms (up to a bi-gram) that sentence j overlaps the query Q, where the IDF weighting is not used (i.e., every term in the query, after stop word removal, was treated as equally important). Therefore, in total, we have 6 clustered facility location components. We further used three curvatures in diversity components ($\alpha = 0.5, 0.6, 0.7$), which gives 18 diversity components in total. With one additional fidelity component, we have 25 components in total. Compared to other results reported in the literature (Table 2, Table 3 and Table 4), as far as we know, our approach achieves the best results reported so far on DUC-05, DUC-06, and DUC-07.

8 Conclusions

In this paper, we propose the notion of learning submodular shells, which abstract a set of submodular functions that can be instantiated into submodular functions given the input of a structured prediction task. Given a set of training instances, we use subgradient descent to learn the mixture coefficients over a set of submodular shells that may be instantiated into a weighted sum of submodular functions. We show that the submodular shell mixture is very expressive, and the risk of learning can be bounded when only approximate inference in possible. When applied to the task of document summarization, our approach achieves the best results reported so far on standardized benchmark takes for query-focused extractive summarization tasks.

{chrislin,mausam,weld}@cs.washington.edu

Abstract

To ensure quality results from crowdsourced tasks, requesters often aggregate worker responses and use one of a plethora of strategies to infer the correct answer from the set of noisy responses. However, all current models assume prior knowledge of all possible outcomes of the task. While not an unreasonable assumption for tasks that can be posited as multiple-choice questions (*e.g.* n-ary classification), we observe that many tasks do not naturally fit this paradigm, but instead demand a free-response formulation where the outcome space is of infinite size (*e.g.* audio transcription). We model such tasks with a novel probabilistic graphical model, and design and implement LazySusan, a decision-theoretic controller that dynamically requests responses as necessary in order to infer answers to these tasks. We also design an EM algorithm to jointly learn the parameters of our model while inferring the correct answers to multiple tasks at a time. Live experiments on Amazon Mechanical Turk demonstrate the superiority of LazySusan at solving SAT Math questions, eliminating 83.2% of the error and achieving greater net utility compared to the state-of-the-art strategy, majority-voting. We also show in live experiments that our EM algorithm outperforms majority-voting on a visualization task that we design.

1 Introduction

Crowdsourcing marketplaces (*e.g.*, Amazon Mechanical Turk) continue to rise in popularity. Hundreds of thousands of workers produce a steady stream of output for a wide range of jobs, such as product categorization, audio-video transcription and interlingual translation. Unfortunately, these workers also come with hugely varied skill sets and motivation levels. Ensuring high quality results is a serious challenge for all requesters.

Researchers have studied quality control extensively for the case of simple binary choice (or multiple choice) questions. A common practice is to ask multiple workers and aggregate responses by a majority vote [Snow et al., 2008]. Several extensions have been proposed that track the ability of individual workers while estimating the inherent difficulty of questions [Dai et al., 2010, Whitehill et al., 2009]. These methods typically outperform majority vote and achieve a much higher accuracy.

A key drawback of prior decision-theoretic approaches to quality control is the restriction to multiple choice questions, *i.e.*, jobs where every alternative answer is known in advance and the worker has to simply select one. While many tasks can be formulated in a multiple-choice fashion (*e.g.* n-ary classification), there a large number of tasks with an unbounded number of possible answers. A common example is completing a database with workers' help, *e.g.*, asking questions such as "Find the mobile phone number of Acme Corporation's CEO." Since the space of possible number of answers is huge (possibly infinite), the task interface cannot explicitly enumerate them for the worker. We call these tasks *open questions*.

Unfortunately, adapting multiple-choice models for open questions is not straightforward, because of the difficulty with reasoning about unknown answers. Requesters, therefore, must resort to using a majority-vote, a significant hindrance to achieving quality results from these more general open questions.

Our paper tackles this challenging problem of modeling tasks where workers are free to give any answer. As a first step, we restrict these tasks to those which have exactly one correct answer. We make the following contributions:

- We propose a novel, probabilistic model relating the accuracy of workers and task difficulty to worker responses, which are generated from a countably infinite set.
- We design a decision-theoretic controller, LazySusan, to dynamically infer the correct answer to a task by only soliciting more worker responses when necessary. We also design an Expectation-Maximization (EM) algorithm to jointly learn the parameters of our model while inferring the correct answers to multiple tasks at a time.
- We evaluate variations of our approach first in a simulated environment and then with live experiments on Amazon Mechanical Turk. We show that LazySusan outperforms majority-voting, achieving 83.2% error reduction and greater net utility for the task of solving SAT Math questions. We also show in live experiments that our EM algorithm outperforms majority-voting on a visualization task that we design.

2 Background

There exist many models that tackle the problem of inferring a correct answer for a task with a finite number of possible answers. Our work is based on the model of of Dai *et al.* [Dai et al., 2010], which we now review. Their model assumes that there are exactly 2 possible answers (binary classification). Let $d \in [0, 1]$ denote the inherent *difficulty* of completing a given task, and let $\gamma_w \in [0, \infty)$ be worker w's innate proneness to *error*. The accuracy of a worker on a task, $a(d, \gamma_w)$, is defined to be the probability that she produces the correct answer using the following model: $a(d, \gamma_w) = \frac{1}{2}\left(1 + (1 - d)^{\gamma_w}\right)$. As d and γ increase, the probability that the worker produces the correct answer approaches 0.5, suggesting that she is guessing randomly. On the other hand, as d and γ decrease, a approaches 1, when the worker will deterministically produce the correct answer.

Dai *et al.* couple this model with a utility function, which describes the worth of a correct answer, to define a Partially Observable Markov Decision Process (POMDP) that outputs a policy for TurKontrol, their decision-theoretic controller for crowdsourced tasks. A significant limitation of this model is its inability to handle tasks with an infinite number of possible answers.

In order to address this limitation, we use the Chinese Restaurant Process [Aldous, 1985], a discrete-time stochastic process that generates an infinite number of labels ("tables"). Intuitively, the process may be thought of as modeling sociable customers who, upon entering the restaurant, decide between joining other diners at a table or starting a new table. The greater the number of customers sitting at a table, the more likely new customers will join that table.

Formally, a Chinese Restaurant $R = (T, f, \theta)$ is a set of occupied tables $T = \{t_1, \ldots, t_n | t_i \in \mathbb{N}\}$, a function $f : T \to \mathbb{N}$ that denotes the number of customers at each table t_i, and a parameter $\theta \in \mathbb{R}^+$. Imagine that a customer arrives at the restaurant. He can either choose to sit at one of the occupied tables, or at a new empty table. The probability that he chooses to sit at an occupied table $t \in T$ is

$$C_R(t) \quad = \quad \frac{f(t)}{N + \theta}$$

where $N = \sum_{t \in T} f(t)$ is the total number of customers in the restaurant. The probability that he chooses to begin a new table, or, equivalently, the probability that he chooses not to sit at an occupied table is

$$NT_R \quad = \quad \frac{\theta}{N + \theta}$$

Note that this probability is not equivalent to the probability that the new customer chooses to sit at a *specific* unoccupied table $t \in \mathbb{N} \setminus T$. Since there are an infinite number of unoccupied tables, the total sum of these probabilities, should they be defined this way, would be unbounded.

θ is a parameter that defines how attractive unoccupied tables are at this restaurant. As θ grows, a new customer becomes more likely to sit by himself at a new empty table.

3 Probabilistic Model

We seek to develop a probabilistic model of workers on tasks that have a countably infinite solution space. As a first step, we focus on tasks that have exactly one correct answer (*e.g.* the examples mentioned in the introduction). We also assume that given the correct answer and problem difficulty, the worker's capability to produce the correct answer is independent of all the previous workers' responses. However, even when conditioning on v and d, wrong answers *are* dependent on previous workers' responses (because common mistakes are often repeated). Finally, we assume that workers are not adversarial and do not collaborate with each other.

Dai *et al.*'s model is unable to solve this problem. When one tries to extend their model to tasks with an infinite number of possible solutions, several issues arise from the difficulty of assigning an infinite number of probabilities. For instance, since their model assigns a probability to each possible solution, the naive extension of attempting to place a uniform distribution over the space of solutions is impossible.

Additionally, a good model must consider correlated errors [Grier, 2011]. For instance, consider a task that asks a worker to find the mobile phone number of a company's CEO. We can reasonably guess that the worker might Google the company name, and if one examined a histogram of worker responses, it would likely be correlated with the search results. A common error might be to return the company's main number rather than the CEO's mobile. Not all possible answers are equally likely, and a good model must address this fact.

The Chinese Restaurant Process meets our desiderata. Let tables correspond to possible incorrect solutions to the task (Chinese restaurant); a new worker (diner) is more likely to return a common solution (sit at a table with more people) than a less common solution. We now formally define our extension of Dai *et al.*'s model to the case of unbounded possible answers.

We redefine the accuracy of a worker for a given task, $a(d, \gamma_w)$, to be:

$$a(d, \gamma_w) \quad = \quad (1-d)^{\gamma_w}$$

As a worker's error parameter and/or the task's difficulty increases, the probability the worker produces the correct answer approaches 0. On the other hand, as the stated parameters decrease, a approaches 1, meaning the worker always produces the correct answer.

In addition to the difficulty d and the worker error γ_w, let $\theta \in \mathbb{R}^+$ denote the task's *bandwagon coefficient*. The parameter θ encodes the concept of the "tendency towards a common wrong answer." If θ is high, then workers who answer incorrectly will tend to provide new, unseen, incorrect answers, suggesting that the task does not have "common" wrong answers. Contrastingly, if θ is low, workers who answer incorrectly will tend toward the same incorrect answer, suggesting that the task lends itself to the same mistakes.

Figure 1 illustrates our generative model, which encodes a Bayes Net for responses made by W workers on a given task. x_i is a binary random variable that indicates whether or not the i^{th} worker answers correctly. It is influenced by the correct answer v, the difficulty parameter d, and the error parameter γ_i. b_i, the answer that is provided by the i^{th} worker, is determined by x_i and all previous responses $b_1, \ldots, b_{i-1}$. Only the responses are observable variables.

Let $\mathbf{B_i} = \{b_1, \ldots, b_i\}$ be the multiset of answers that workers $w_1, \ldots, w_i$ provide. Let $\mathbf{A_i} = \{a_1, \ldots, a_k\}$ be the set of unique answers in $\mathbf{B_i}$. The probability that the $i{+}1^{th}$ worker produces the correct answer is simply the worker's accuracy for the given task:

$$\begin{aligned} P(x_i = T|d, v) &= a(d, \gamma_{i+1}) \\ P(x_i = F|d, v) &= 1 - a(d, \gamma_{i+1}) \end{aligned}$$

Then, the probability that the worker's ballot is correct is defined as

$$P(b_{i+1} = v|d, v, \mathbf{B_i}) \quad = \quad P(x_i = T|d, v)$$

To define the probability space of wrong answers we use the Chinese Restaurant Process. Let $f(a) = |\{b \in \mathbf{B_i}|b = a\}|$, and let $R_{i,v} = (\mathbf{A_i} \setminus \{v\}, f, \theta)$ be a Chinese Restaurant Process. Then, the probability that the worker returns a previously seen incorrect answer, $y \in \mathbf{A_i} \setminus \{v\}$ is

$$P(b_{i+1} = y|d, v, \mathbf{B_i}) \quad = \quad P(x_i = F|d, v) C_{R_{i,v}}(y)$$

Finally, the probability that the worker returns an unseen answer is

$$P(b_{i+1} = u|d, v, \mathbf{B_i}) \quad = \quad P(x_i = F|d, v) N T_{R_{i,v}}$$

Here, u represents whatever the worker returns as long as $u \notin \mathbf{A_i}$. More formally, $u \in U$ where U is the singleton set $\{x|b_{i+1} = x \wedge b_{i+1} \notin \mathbf{A_i}\}$. We abuse notation to simplify and elucidate:

$$P(b_{i+1} \notin \mathbf{A_i}|d, v, \mathbf{B_i}) := P(b_{i+1} = u|d, v, \mathbf{B_i})$$

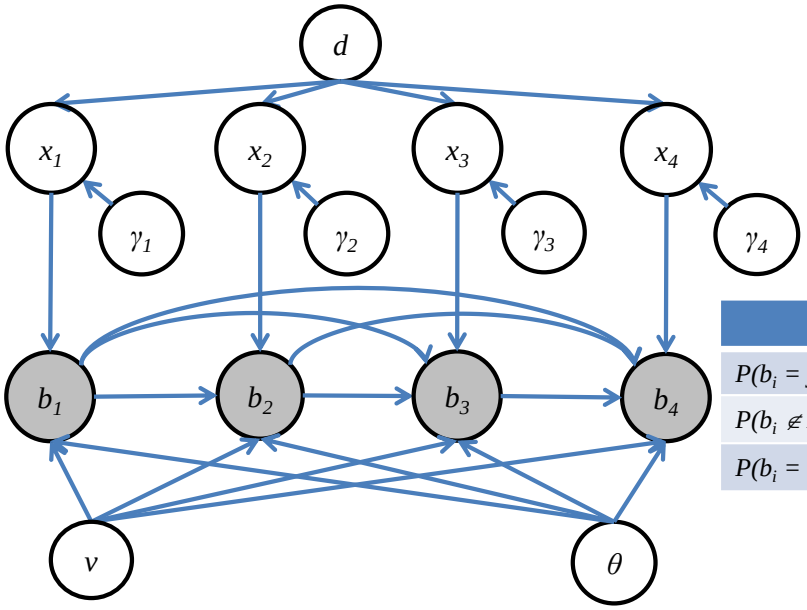
The model cares only about whether it has seen a worker's answer before, not what it actually turns out to be.

3.1 Model Discussion

We now make several subtle and important observations.

First, our model is dynamic in the following sense. As more workers provide answers, the probabilities that govern the generation of an incorrect answer change. In particular, the parameter θ becomes less and less significant as more and more workers provide answers. In other words, as i goes to infinity, the probability that a new worker provides an unseen answer, $\theta/(\theta{+}i)$, goes to 0. As workers provide answers, the probability mass that used to dictate the generation of a new unseen answer is slowly shifted to that which determines the generation of seen answers. See Section 5.4 for a consequence of this behavior. Although we do not believe these model dynamics completely reflect the real-world accurately, we believe our model is a good first approximation with several desirable aspects. In fact, the model dynamics we just described are able to capture the intuition that as more and more answers arrive, we should expect to see fewer and fewer new answers.

Second, certain areas of parameter space cause our model to produce adversarial behavior. In other words, there are settings of d and θ for a task such that the probability a worker produces a particular incorrect answer is greater than the probability a worker



x_i	$P(x_i)$
T	$a(d, \gamma_i)$
F	$1\text{-}a(d, \gamma_i)$

x_i	T	F
$P(b_i = y \in \mathbf{A_i} \mid x_i)$	0	$C_{R_{i,v}}(y)$
$P(b_i \notin \mathbf{A_i} \mid x_i)$	0	$NT_{R_{i,v}}$
$P(b_i = v \mid x_i)$	1	0

Figure 1: Whether or not worker i gets it right, x_i, depends on his error parameter γ_i and the difficulty of the task d. Worker i's answer b_i depends on x_i, the question's true answer v, and all the previous workers' answers $b_1, \ldots, b_{i-1}$. R_i is a Chinese Restaurant Process defined by $\mathbf{B_i}$. This figure shows 4 workers. The b_i are the only observed variables.

provides the correct answer, on average. The following theorem, proven in the supplementary materials, makes this observation.

Theorem. *Suppose the difficulty, d, is fixed and all workers' γ are equal. Then, $\theta < \frac{1-2(1-d)^\gamma}{(1-d)^\gamma}$ if and only if the expected probability the next worker returns the first-seen incorrect answer is greater than the probability the next worker returns the correct answer.*

We note that the theorem only considers the first-seen incorrect answer since the behavior of the Chinese Restaurant Process is such that the first-seen incorrect answer is generated with the highest expected probability. Thus, if the expected probability of generating the correct answer exceeds that of the first-seen incorrect answer, the model will not produce adversarial behavior.

Finally, while the purpose of this paper is to address open questions with infinite answer spaces, we note that Polya's Urn Scheme, the finite version of the Chinese Restaurant Process, applies equally well to finite answer spaces with many answer choices (multiple-choice tasks).

4 A Decision-Theoretic Agent

We now discuss the construction of our decision-theoretic controller, LazySusan. Our control problem is as follows. Given an open question as input, the goal is to infer the correct answer. At each time-step, an agent can choose one of two actions. It can either stop and submit the most likely answer, or it can create another job and receive another response to the task from another crowdsourced worker. The question is: How do we determine the agent's policy?

To solve this problem, first we define the *world state* of LazySusan to be the pair (v, d), where $v \in \mathbb{N}$ is the correct answer of the task and d is the difficulty of the task. The space of world states is infinitely large, and LazySusan cannot directly observe the world state, so it has an *agent state* $\mathbf{S}$, which at time i, is the set of tuples, $\mathbf{S} = \{(v, d) | v \in \mathbf{A_i} \cup \{\perp\} \wedge d \in [0, 1]\}$. Here, $\perp$ represents the case when the true answer has not been seen by the agent so far. In order to keep track of what it believes to be the correct answer v, it maintains a *belief*, which is a probability distribution over $\mathbf{S}$.

The agent state allows us to fold an infinite number of probabilities into one, since to compute the belief, one only needs to calculate $P(v = \perp, d|\mathbf{B_i})$, the probability that no workers have provided the correct answer yet given $\mathbf{B_i}$, instead of $P(v = u, d|\mathbf{B_i})$ for all possible unseen answers $u \in \mathbb{N} \setminus \mathbf{A_i}$.

4.1 Belief Update

We now describe specifically how LazySusan updates its posterior belief $P(v, d|\mathbf{B_i}; i, k)$ after it receives its i^{th} ballot b_i. Here, $k = |\mathbf{A_i}|$ is the number of unique responses it has received. By Bayes' Rule, we have

$$P(v, d|\mathbf{B_i}; i, k) \propto P(\mathbf{B_i}|v, d; i, k)P(v, d; i, k)$$

Symbol	Meaning
$\mathbf{A_i}$	The set of unique responses made by workers $1, \ldots, i$.
$\mathbf{B_i}$	The multiset of responses made by workers $1, \ldots, i$ ($\{b_1, \ldots, b_i\}$)
b_i	Worker i's response to the task
C_C	The value of a correct answer
$C_{R_{i,v}}(y)$	The probability of a worker producing incorrect answer y in restaurant $R_{i,v}$.
C_W	The value of an incorrect answer
d	Difficulty of task
γ_i	Worker i's error parameter
θ	A task's bandwagon coefficient; Chinese Restaurant Process parameter
k	The number of unique worker responses ($\lvert\mathbf{A_i}\rvert$)
i	Number of ballots received so far
$Q(\mathbf{B_i}, \texttt{action})$	The utility of taking `action` with belief $\mathbf{B_i}$
$NT_{R_{i,v}}$	The probability of a worker producing an unseen answer in restaurant $R_{i,v}$.
$R_{i,v}$	An instance of the Chinese Restaurant Process instantiated using $\mathbf{B_i}$ and correct answer v.
$U(\mathbf{B_i})$	The utility of a belief derived from $\mathbf{B_i}$.
$V(a)$	The value of an answer a
v	Correct answer of task
x_i	Did worker i answer the task correctly

Table 1: Summary of notation used in this paper

The likelihood of the worker responses $P(\mathbf{B_i}|v, d; i, k)$ is easily calculated using our generative model:

$$P(\mathbf{B_i}|v, d; i, k) = \prod_{j=1}^{i} P(b_j|v, d, \mathbf{B_{j-1}})$$

The prior on the correct answer and difficulty can be further reduced:

$$P(v, d; i, k) = P(v|d; i, k)P(d; i, k)$$

The prior we must compute describes the joint probability of the correct answer and difficulty given i responses and k distinct responses. Notice that for all $a \in \mathbf{A_i}$, we do not know $P(v = a|d; i, k)$. However, they must be all the same, because knowing the difficulty of the task gives us no information about the correct answer. Therefore, we must only determine the probability the correct answer has yet to be seen given d, i, and k. We propose the following model:

$$P(v = \perp |d; i, k) = d^i$$

This definition is reasonable since intuitively, as the difficulty of the task increases the more likely workers have not yet provided a correct answer. On the other hand, as the number of observations increases, we become more certain that the correct answer is in $\mathbf{A_i}$.

Finally, we model $P(d; i, k)$. Consider for the moment that workers tend to produce answers that LazySusan has seen before (θ is low). Intuitively, as k approaches i, the difficulty should grow, because the agent is seeing a lot of different answers when it shouldn't, and as k approaches 1, the difficulty should become smaller, because everyone is agreeing on the same answer.

We choose to model $P(d; i, k) \sim Beta(\alpha, \beta)$ and define $\alpha \geq 1$ and $\beta \geq 1$ as

$$\begin{aligned} \alpha &= \left((i-1)\frac{k}{i} + 1\right)^{\frac{1}{\theta}} \\ \beta &= \left((1-i)\frac{k}{i} + i\right)^{\theta} \end{aligned}$$

First note that the bulk of a Beta distribution's density moves toward 1 as α increases relative to β, and toward 0 as β increases relative to α. Thus, as β increases, difficulty decreases, and as α increases, difficulty increases. Consider the case when $\theta = 1$. As k approaches i, α approaches i and β approaches 1, causing LazySusan to believe the difficulty is likely to be high, and as k approaches 1, LazySusan believes the difficulty is likely to be low. This behavior is exactly what we desire.

Now we consider the effect of θ. Fix i and k. As θ grows, β increases and α decreases. Therefore, for a fixed multiset of observations, as people become more likely to provide unseen answers, the probability that the difficulty is low becomes greater. In other words, LazySusan needs to see a greater variety of answers to believe that the problem is difficult if θ is high.

Let $\theta_1 > \theta_2$ and consider the following scenarios: Suppose k is close to i, so LazySusan believes, before factoring in θ, that the task is difficult. If $\theta = \theta_2$, LazySusan believes with more certainty that the task is difficult than if $\theta = \theta_1$. This behavior makes sense be-

cause LazySusan should expect a small k if θ is small. If $\theta = \theta_2$, LazySusan should see a smaller k than if $\theta = \theta_1$. If it sees a k that is larger than it expects, it correctly deduces that more people are getting the question wrong, and concludes the task is more difficult. Similarly, if k is close to 1, and $\theta = \theta_1$, then LazySusan believes with more certainty that the task is easy than if $\theta = \theta_2$, since even though workers tend to produce more random answers, k is small.

4.2 Utility Estimation

To determine what actions to take, LazySusan needs to estimate the utility of each action. The first step is to assign utilities to its beliefs. Since $\mathbf{B_i}$ solely determines its belief at time i, we denote $U(\mathbf{B_i})$ to be utility of its current belief. Next, LazySusan computes the utilities of its two possible actions. Let $Q(\mathbf{B_i}, \texttt{submit})$ denote the utility of submitting the most likely answer given its current state, and let $Q(\mathbf{B_i}, \texttt{request})$ denote the utility of requesting another worker to complete the task and then performing optimally. Then

$$\begin{aligned} U(\mathbf{B_i}) &= \max\{Q(\mathbf{B_i}, \texttt{submit}), \\ &\qquad Q(\mathbf{B_i}, \texttt{request})\} \\ Q(\mathbf{B_i}, \texttt{submit}) &= \sum_{a \in \mathbf{A_i}} V(a) \int_d P(v = a, d | \mathbf{B_i}; i, k) \mathrm{d}d \\ Q(\mathbf{B_i}, \texttt{request}) &= c + \sum_{a \in \mathbf{A_i}} P(b_{i+1} = a | \mathbf{B_i}) U(\mathbf{B_{i+1}}) \\ &\quad + P(b_{i+1} \notin \mathbf{A_i} | \mathbf{B_i}) U(\mathbf{B_{i+1}}) \end{aligned}$$

where c is the cost of creating another job and $P(b_{i+1}|\mathbf{B_i}) =$

$$\sum_{a \in \mathbf{A_i}} \int_d P(b_{i+1} | v = a, d, \mathbf{B_i}) P(v = a, d | \mathbf{B_i}) \mathrm{d}d$$

LazySusan takes as inputs C_C, the utility of a correct answer, and C_W, the utility of an incorrect answer. These values are provided by the requester to manage tradeoffs between accuracy and cost. LazySusan uses its own estimate of the correct answer to calculate $V(a)$:

$$\begin{aligned} a* &= \operatorname*{argmax}_{a \in \mathbf{A_i}} \int_d P(v = a, d | \mathbf{B_i}; i, k) \mathrm{d}d \\ V(a) &= \begin{cases} C_C & \text{if } a = a* \\ C_W & \text{otherwise} \end{cases} \end{aligned}$$

4.3 Worker Tracking

After submitting an answer, LazySusan updates its records about all the workers who participated in the task using $a*$. We follow the approach of Dai *et al.* [Dai et al., 2010], and use the following update rules: 1) $\gamma_w \leftarrow \gamma_w - d\epsilon$ should the worker answer correctly, and 2) $\gamma_w \leftarrow \gamma_w + (1-d)\epsilon$, should the worker answer incorrectly, where ϵ is a decreasing learning rate. Any worker that LazySusan has not seen previously begins with some starting $\overline{\gamma}$.

4.4 Decision Making

We note that the agent's state space continues to grow without bound as new answers arrive from crowdsourced workers. This poses a challenge since existing POMDP algorithms do not handle infinite-horizon problems in dynamic state spaces where there is no a-priori bound on the number of states. Indeed, the efficient solution of such problems is an exciting problem for future research. As a first step, LazySusan selects its actions at each time step by computing an l-step lookahead by estimating the utility of each possible sequence of l actions. If the l^{th} action is to request another response, then it will cut off the computation by assuming that it submits an answer on the $l+1^{th}$ action.

In many crowdsourcing platforms, such as Mechanical Turk, we cannot preselect the workers to answer a job. However, in order to conduct a lookahead search, we need to specify future workers' parameters for our generative model. To simplify the computation, we assume that every future worker has $\gamma = \overline{\gamma}$.

4.5 Joint Learning and Inference

We now describe an EM algorithm that can be used as an alternative to the working-tracking scheme from above. Given a set of worker responses from a set of tasks, $\mathbf{b}$, EM jointly learns maximum-likelihood estimates of $\boldsymbol{\gamma}, \mathbf{d}$, and $\boldsymbol{\theta}$, while inferring the correct answers $\mathbf{v}$. Thus, in this approach, after LazySusan submits an answer to a task, it can recompute all model parameters before continuing with the next task.

We treat the variables $\mathbf{d}, \boldsymbol{\gamma}$, and $\boldsymbol{\theta}$ as parameters. In the E-step, we keep parameters fixed to compute the posterior probabilities of the hidden true answers: $p(v_t | \mathbf{b}, \mathbf{d}, \boldsymbol{\gamma}, \boldsymbol{\theta})$ for each task t. The M-step uses these probabilities to maximize the standard expected complete log-likelihood L over $\mathbf{d}, \boldsymbol{\gamma}$, and $\boldsymbol{\theta}$:

$$L(\mathbf{d}, \boldsymbol{\gamma}, \boldsymbol{\theta}) = E[\ln p(\mathbf{v}, \mathbf{b} | \mathbf{d}, \boldsymbol{\gamma}, \boldsymbol{\theta})]$$

where the expectation is taken over $\mathbf{v}$ given the old values of $\boldsymbol{\gamma}, \boldsymbol{d}, \boldsymbol{\theta}$.

5 Experiments

This section addresses the following three questions: 1) How deeply should the lookahead search traverse? 2)

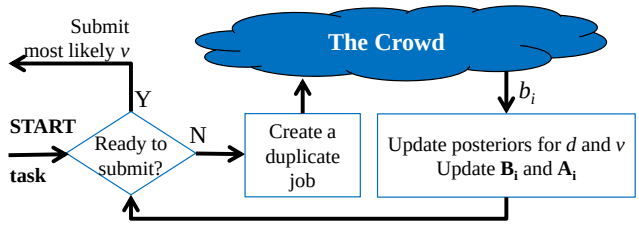


Figure 2: LazySusan's decisions when executing a task.

How robust is LazySusan on different classes of problems? 3) How well does LazySusan work in practice? and 4) How well does our EM algorithm work in practice?

To answer the first question, we compare LazySusan at different settings of lookahead depth. Then, to answer the second question, we test the robustness of LazySusan by applying it to various kinds of problems in simulation. Next, to answer the third question, we compare LazySusan to an agent that uses majority-voting with tasks that test the workers of Amazon Mechanical Turk on their SAT Math skills. Finally, to answer the fourth question, we compare our EM algorithm to a majority-voting strategy on a visualization task.

5.1 Implementation

Since numerical integration can be challenging, we discretize difficulty into nine equally-sized buckets with centers of $0.05, 0.15, \ldots, 0.85$, and 0.95.

For the purposes of simulation only, each response that LazySusan receives also contains perfect information about the respective worker's γ. Thus, LazySusan can update its belief state with no noise, which is the best-case scenario.

In all cases, we set the learning rate $\epsilon = \frac{1}{m_w+1}$, where m_w is the number of questions a worker w has answered so far. We also set the value of a correct answer to be $C_C = 0$. Finally, we set $\overline{\gamma} = 1$, and the bandwagon coefficient $\theta = 1$ for all tasks.

5.2 Best Lookahead Depth

We first determine the best lookahead depth among 2, 3, and 4 with simulated experiments. We evaluate our agents using several different settings of the value of an incorrect answer: $C_W \in \{-10, -50, -100\}$. Each difficulty setting is used 10 times, for a total 90 simulations per utility setting. (9 difficulty settings $\times$ 10 $=$ 90). We set the cost of requesting a job, c, from a (simulated) worker to -1. Our simulated environment draws worker $\gamma \in (0, 2)$ uniformly.

Figure 3 shows the results of our simulation. LazySusan(l) denotes a lookahead depth of l. We also examine an agent that uses a majority-of-7-vote strategy, MV. Expectedly, as the utility of an incorrect answer decreases, the average net utility achieved by each agent drops. We find that for all settings of lookahead depth, LazySusan dramatically outperforms MV. We also see that LazySusan(3) and LazySusan(4) both achieve small, but sure gains over LazySusan(2). However, LazySusan(3) and LazySusan(4) seem to do about the same. Since LazySusan(4) runs significantly slower, we decide to use LazySusan(3) in all future experiments, and refer to it as LazySusan.

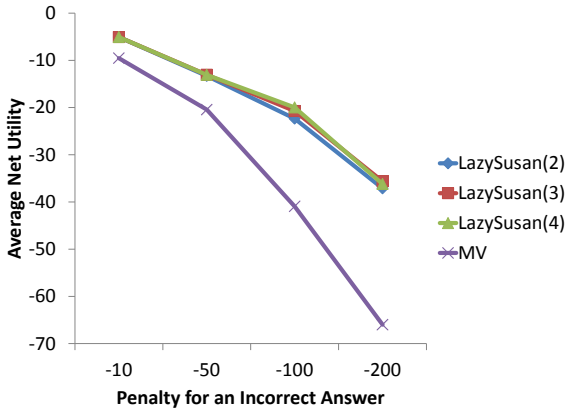

Figure 3: In simulation, our lookahead search does well at all depths.

5.3 Noisy Workers

We examine the effect of poor workers. We compare two simulation environments. In the first, we draw workers' $\gamma \in (0, 1)$ uniformly and in the second, we draw workers' $\gamma \in (0, 2)$ uniformly. Recall that γ is the worker error parameter. Thus, the first environment has workers that are much more competent than those in the second. All other parameters remain as before. Each difficulty setting is simulated 100 times, for a total of 900 simulations per environment. The results of this experiment are shown in Table 2. When the workers are competent, LazySusan makes small gains over MV, reducing the error by 34.3%. However, when there exist noisier workers in the pool, LazySusan more decisively outperforms MV, reducing the error by 48.6%. In both cases, LazySusan spends less money than MV, netting average net utility gains of 55% and 75.9%.

5.4 Tasks with Correlated Errors

Next, we investigate the ability of LazySusan to deal with varying θ and d in the worst case — when all the workers are equally skilled. Recall that a high θ

	$\gamma \in (0,1)$		$\gamma \in (0,2)$	
	LazySusan	MV	LazySusan	MV
Avg Accuracy (%)	88.7	82.8	83.3	67.5
Avg Cost	3.472	5.7	4.946	6.01
Avg Net Utility	-14.772	-22.9	-21.646	-38.51

Table 2: Comparison of average accuracies, costs, and net utilities of LazySusan and MV when workers either have $\gamma \in (0,1)$ or $\gamma \in (0,2)$

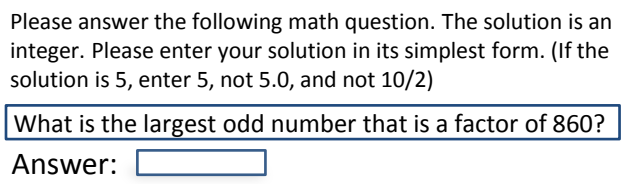

Figure 4: An example of an SAT Math Question task posed to workers for live experiments on Mechanical Turk.

means that workers who answer incorrectly will tend to produce previously unseen answers. We consider the following variations of tasks: 1) Low difficulty, 2) High difficulty, high θ, and 3) High difficulty, low θ. In the first two cases, we see expected behavior. LazySusan is able to use its model to infer correct answers.

However, in the third case, we see some very interesting behavior. Since the difficulty is high, workers more often than not produce the wrong answer. Additionally, since θ is low, they also tend to produce the same wrong answer, making it look like the correct answer. If the ratio is large enough, we find that LazySusan is unable to infer the correct answer, because of the unfortunate ambiguity between high difficulty, low θ problems and low difficulty problems. In fact, as LazySusan observes more ballots, it becomes more convinced that the common wrong answer is the right answer, because of the model dynamics we mention earlier (Section 3.1). This problem only arises, however, if the model produces adversarial 0, and we see in practice that workers on Mechanical Turk generally do not exhibit such behavior.

5.5 Experiments on Mechanical Turk

Next, we compare LazySusan to an agent using majority-vote (MV) using real responses generated by Mechanical Turk workers. We test these agents with 134 math questions with levels of difficulty comparable to those found on the SAT Math section. Figure 4 is an example of one such task and the user interface we provided to workers. We set the utility for an incorrect answer, C_W, to be -100, because with this utility setting, LazySusan requests about 7 jobs on average for each task, and a simple binary search showed

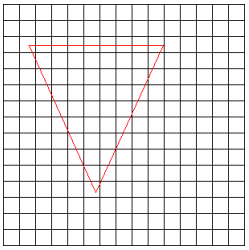

Figure 5: An example of a "triangle" task posed to workers for live experiments on Mechanical Turk. The area of this triangle, rounded down, is 38.

	LazySusan	MV
Avg Accuracy (%)	99.25	95.52
Avg Cost	5.17	5.46
Avg Net Utility	-5.92	-9.94

Table 3: Comparisons of average accuracies, costs, and net utilities of LazySusan and MV when run on Mechanical Turk.

this number to be satisfactorily optimal for MV. We find that the workers on Mechanical Turk are surprisingly capable at solving math problems. As Table 3 shows, LazySusan almost completely eliminates the error made by MV. Since the two agents cost about the same, LazySusan achieves a higher net utility, which we find to be statistically significant using a Student's t-test ($p < 0.0002$).

We examine the sequence of actions LazySusan made to infer the correct answer to the task in Figure 4. In total, it requested 14 ballots, and received the following responses: 215, 43, 43, 43, 5, 215, 43, 3, 55, 43, 215, 215, 215, 215. Since MV takes the majority of 7 votes, it infers the answer incorrectly to be 43. LazySusan on the other hand, uses its knowledge of correlated answers as well as its knowledge from previous tasks that the first three workers who responded with 43 were all relatively poor workers compared to the first two workers who claimed the answer is 215. So even though a clear majority of workers preferred 43, LazySusan was not confident about the answer. While it cost twice as much as MV, the cost was a worthy sacrifice with respect to the utility setting.

Finally, we compare our EM algorithm to MV, using

real responses generated by Mechanical Turk workers. We develop a "triangle" task (Figure 5) that presents workers with a triangle drawn on a grid, and asks them to find the area of the triangle, rounded down. We posted 200 of these tasks and solicited 5 responses for each. These tasks are difficult since many of the responses are off by 1. Our EM algorithm achieves an accuracy of 65.5% while MV achieves an accuracy of 54.1%.

6 Related Work

Modeling repeated labeling in the face of noisy workers when the label is assumed to be drawn from a known *finite* set has received significant attention. Romney *et al.* [Romney et al., 1986] are one of the first to incorporate a worker accuracy model to improve label quality. Sheng *et al.* [Sheng et al., 2008] explore when it is necessary to get another label for the purpose of machine learning. Raykar *et al.* [Raykar et al., 2010] propose a model in which the parameters for worker accuracy depend on the true answer. Whitehill *et al.* [Whitehill et al., 2009] and Dai *et al.* [Dai et al., 2010] address the concern that worker labels should not be modeled as independent of each other unless given problem difficulty. Welinder *et al.* [Welinder et al., 2010] design a multidimensional model for workers that takes into account competence, expertise, and annotator bias. Kamar *et al.* [Kamar et al., 2012] extracts features from the task at hand and use Bayesian Structure Learning to learn the worker response model. Parameswaran *et al.* [Parameswaran et al., 2010] conduct a policy search to find an optimal dynamic control policy with respect to constraints like cost or accuracy. Karger *et al.* [Karger et al., 2011] develop an algorithm based on low-rank matrix approximation to assign tasks to workers and infer correct answers, and analytically prove the optimality of their algorithm at minimizing a budget given a reliability constraint. Snow *et al.* [Snow et al., 2008] show that for labeling tasks, a small number of Mechanical Turk workers can achieve an accuracy comparable to that of an expert labeler. None of these works consider tasks that have an infinite number of possible solutions.

For more complex tasks that have an infinite number of possible answers, innovative workflows have been designed, for example, an iterative improvement workflow for creating complex artifacts [Little et al., 2009], find-fix-verify for an intelligent editor [Bernstein et al., 2010], and others for counting calories on a food plate [Noronha et al., 2011].

An AI agent makes an efficient controller for these crowdsourced workflows. Dai *et al.* [Dai et al., 2010, Dai et al., 2011] create a POMDP-based agent to control an iterative improvement workflow. Shahaf and Horvitz [Shahaf and Horvitz, 2010] develop a planning-based task allocator to assign subtasks to specific humans or computers with known abilities. We [Lin et al., 2012] create a POMDP-based agent to dynamically switch between workflows.

Weld *et al.* [Weld et al., 2011] discuss a broad vision for the use of AI techniques in crowdsourcing that includes workflow optimization, interface optimization, workflow selection and intelligent control for general crowdsourced workflows. Our work provides a more general method for intelligent control.

7 Conclusion & Future Work

This paper introduces LazySusan, an agent that takes a decision-theoretic approach to inferring the correct answer of a task that can have a countably infinite number of possible answers. We extend the probabilistic model of [Dai et al., 2010] using the Chinese Restaurant Process and use l-step lookahead to approximate the optimal number of crowdsourcing jobs to submit. We also design an EM algorithm to jointly learn the parameters of our model while inferring the correct answers to multiple tasks at a time. Live experiments on Mechanical Turk demonstrate the effectiveness of LazySusan. At comparable costs, it yields an 83.2% error reduction compared to majority vote, which is the current state-of-the-art technique for aggregating responses for tasks of this nature. Live experiments also show that that our EM algorithm outperforms majority-voting on "triangle" tasks.

In the future, we would like to address the ambiguity between high difficulty, low θ problems and low difficulty problems. We also hope to develop a generative model that does not change as responses are gathered from workers. We also hope to extend the ability of LazySusan to solving tasks that have multiple correct answers. Indeed, workers oftentimes provide the same answer in different forms (*e.g.*, in different units). Other questions may have several answers (*e.g.*, top executives often carry two mobiles). While multiple correct answers may be reduced with crisply-written instructions, an improved model may also prove useful.

Abstract

Previous work on recommender systems mainly focus on fitting the ratings provided by users. However, the response patterns, i.e., some items are rated while others not, are generally ignored. We argue that failing to observe such response patterns can lead to *biased* parameter estimation and sub-optimal model performance. Although several pieces of work have tried to model users' response patterns, they miss the effectiveness and interpretability of the successful matrix factorization collaborative filtering approaches. To bridge the gap, in this paper, we unify explicit response models and PMF to establish the Response Aware Probabilistic Matrix Factorization (RAPMF) framework. We show that RAPMF subsumes PMF as a special case. Empirically we demonstrate the merits of RAPMF from various aspects.

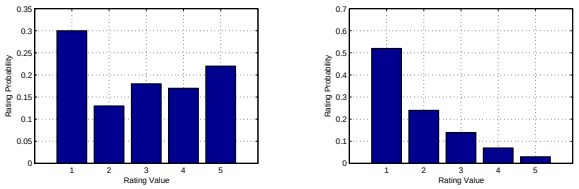
1 Introduction

Recently, online music and video streaming services have seen an explosive growth. As the user base and contents expanding tremendously, recommender systems become crucial for service providers. Cloud-based music streaming services such as iTunes Match, Google Music, Yahoo! Music, Pandora, Songify, etc. make it easier than ever to rate songs and buy new music. With the rocketing growth of the number of users, their explicit ratings become more and more accessible. Effective usage of these ratings can lead to high quality recommendation, which is vital for the cloud-based online streaming services. This is because most services charge very little subscription fee, if not none. The main income comes from the selling of music. Nowadays, online streaming services often have a large user base, so even if a small change in recommendation quality may have dramatic effect on sales.

Due to immense market value, various recommendation techniques have been proposed. Generally, these approaches can be classified into neighborhood-based methods and model-based methods. Typical neighborhood-based approaches includes user-based methods [1, 4] and item-based methods [3, 11, 25]. The state-of-the-art model-based methods include restricted Boltzmann machines [24], SVD++ [8, 9], Probabilistic Matrix Factorization (PMF) [22], and multi-domain collaborative filtering [32], graphical models [7], pair-wise tensor factorization [21], and matrix factorization with social regularization [14], etc.

However, in real-world rating systems, users' ratings carry twofold information. Firstly the rating value indicates a user's preference on a particular item as well as an item's inherent features. The scores that a user assigns to different items convey information on what the user likes and what the user dislikes. The rating values that an item received from different users also carry information on intrinsic properties of the item. Second, the ratings also reveal users' response patterns, i.e., some items are rated while others not. This information can be utilized to improve the model performance. However, previously proposed methods usually assume that all the users would rate *all* the inspected items, or more generally, *randomly* select inspected items to rate. These methods fit the users' ratings directly and ignore the key factor, users' response patterns. The ignorance will degrade the model performance. In this paper, we explore previously ignored response information to further boost recommender system's quality.

Practically, the assumption of *all inspection* or *randomly rate* is not true in real-world rating systems. Users are unlikely to rate all the inspected items or randomly select the inspected items to rate. Shown in Figure 1(a) is the rating value distribution of the items that users *choose to rate*, while Figure 1(b) shows the distribution of ratings for *randomly* selected songs



(a) User selected ratings (b) Randomly selected ratings

Figure 1: Distribution of ratings in a music website [16].

from the same group of users. Clearly these two distributions are very different. In the user selected ratings, there are far more items with high ratings than that in the randomly selected songs. This is compelling evidence showing that the assumption that all the users would rate all the inspected items or select random items to rate is unlikely to be true. The investigation of the Yahoo!LaunchCast data indicates that users are more likely to rate items they do love and hate, but not neutral [16, 26].

To further demonstrate the risk of *incorrect* parameter estimation and *biased* rating prediction when ignoring the response information, we show an intuitive example of five users' rating on five items in Table 1, where the ratings are skewed to either 4 or 5. Clearly, user-based approaches [1, 4] and item-based approaches [3, 11, 25] are more likely to predict rating values in the range of 4 to 5. Similarly, ignoring response information will cause the one-class issue for model-based approaches [10, 17, 18]. In a real-world recommender system, the case may not be as extreme as is in Table 1. Nevertheless, the effect is similar. By ignoring the response information, we will learn a model that has *bias*.

Currently, there are two main streams of work trying to solve the above response ignorance problem. One line of work try to model the above phenomena as a one-class collaborative filtering task [10, 17, 18]. A heuristic weight in the range of 0 to 1 is introduced to calibrate the loss on those unseen ratings, where the rating scores are set to zeros [17, 18]. Embedding user information is also adopted to optimize the weight on the unseen ratings via users' similarity [10]. However, these methods do not model the users' missing response information together with the ratings. The other line of work model the response ignorance through missing data theory [13]. The multinomial mixture model is adopted to model the non-random response [16]. The work is also extended for collaborative ranking [15]. These methods model users' response patterns and ratings via multinomial mixture model, but they discard the effectiveness and interpretability of the matrix factorization approaches [8, 22].

Table 1: Skewed ratings on 5 items from 5 users

	item1	item2	item3	item4	item5
user1	5	4			
user2		5		4	
user3	4			4	
user4	5		5		
user5		4			5

To bridge this gap, we are the first to integrate the users' response patterns into PMF to establish a unified framework, which we refer to as Response Aware PMF (RAPMF). The response models we propose include the rating dominating response model, and a generalized one, the context-aware response model. We demonstrate the advantages of our proposed RAPMF through detailed and fair experimental comparison.

The rest of the paper is organized as follows. In Section 2, we motivate the explicit modeling of user responses from a probabilistic point of view. In Section 3, we present how to incorporate response models into PMF and elaborate the proposed RAPMF model. Empirical study and comparison with previous work is conducted in Section 4. The paper is concluded in Section 5.

2 Response and Missing Theory

Modeling response patterns have a strong incentive from statistical missing data theory [13]. The response patterns can be hidden [2, 6] or explicit. In recommender system case, it is explicit. In the following, we show that without modeling the response patterns properly, we may learn a *bias* model.

2.1 Setup and Notation

Assume that we are given a partially observed $N \times M$ matrix X, where N is the number of users and M is the number of items, the (i, j) element of X denotes the rating assigned by user i to item j in the scale of 1 to D. Collaborative filtering approaches try to recover the original full matrix X_{full} to predict users' preferences.

In the matrix X, an unobserved entry is denoted by 0. Alternatively, we denote all the observations as a set of triplets $(i, j, x) \in \mathcal{Q}$. Moreover, we define a companion response indicator matrix R to denote whether the corresponding rating is observed in X. If $X_{ij} \neq 0$,

i.e., we have observed user i's rating on item j, then $R_{ij} = 1$. Otherwise $R_{ij} = 0$. Note that X is partially observed while R is fully observed.

2.2 Missing Data Theory

Following missing data theory in [13], we model the collaborative filtering data as a two-step procedure. First, a data model $P(X|\theta)$ generates the full data matrix X_{full}. Then, a response model $P(R|X, \mu)$ determines which elements in X_{full} are observed. Hence, we can take a parametric joint distribution on the observed data matrix X and the response matrix R, conditioned on the model parameters, θ and μ.

$$P(R, X|\mu, \theta) = P(R|X, \mu, \theta)P(X|\mu, \theta) \quad (1)$$
$$= P(R|X, \mu)P(X|\theta), \quad (2)$$

where $P(R|X, \mu)$ is also referred to as the missing data model. In the following, we use response model and missing data model interchangeably.

According to the missing data theory [13], there are three kinds of missing data assumptions: 1) Missing Completely At Random (MCAR); 2) Missing At Random (MAR), and 3) Not Missing At Random (NMAR). MCAR has the strongest independence assumption. Under the MCAR assumption, the missing mechanism cannot depend on the data in any way. Whether we will observe a response is fully determined by the parameter μ and is irrelevant to the users' rating, i.e.,

$$P(R|X, \mu) = P(R|\mu) \quad (3)$$

One typical example where MCAR holds is that given an inspected item, whether it will be observed is a Bernoulli trail with probability μ.

The MAR assumption is slightly different from the MCAR assumption. Let $X_{full} = (X_{obs}, X_{mis})$, i.e., the full data matrix X_{full} is separated into observed data matrix X_{obs} and missing data matrix X_{mis}. Under the MAR assumption, the response probability depends on the *observed* data and μ, i.e.,

$$P(R|X, \mu) = P(R|X_{obs}, \mu). \quad (4)$$

Marlin and Zemel [15] refer to this as the probability of observing a particular response only depending on the observed elements of the data vector. The assumption made by MAR may seem bizarre. However, it comes up naturally if we want to ignore response model and still learn *unbiased* data model parameters. We demonstrate this in the following.

Let $\mathcal{L}(\mu, \theta|X_{obs}, R)$ be the likelihood of μ and θ given the observation X_{obs} and R. Under the MAR assumption, we have

$$\begin{aligned}
& \mathcal{L}(\mu, \theta|X_{obs}, R) = P(R, X_{obs}|\mu, \theta) \\
= & \int_{X_{mis}} P(R, X|\mu, \theta)dX_{mis} \\
= & \int_{X_{mis}} P(R|X, \mu)P(X|\theta)dX_{mis} \\
= & \int_{X_{mis}} P(R|X_{obs}, \mu)P(X|\theta)dX_{mis} \quad (5) \\
= & P(R|X_{obs}, \mu) \int_{X_{mis}} P(X|\theta)dX_{mis} \\
= & P(R|X_{obs}, \mu)P(X_{obs}|\theta) \\
\propto & P(X_{obs}|\theta).
\end{aligned}$$

The key to marginalize the missing data is that the missing data model depends only on the observed data, i.e., MAR assumption in Eq. (4). Under the MCAR assumption, we can simplify Eq. (5) similarly, which only depends on μ. Note that the assumption made by MAR appears naturally in the derivation. This is the independence assumption we cannot release anymore without losing the ability to marginalize the complete data model independently of missing data model.

If both MCAR and MAR fail to hold, then NMAR assumption is made. Unlike MCAR and MAR, NMAR requires an explicit response model in order to learn unbiased model parameters. Otherwise, maximizing $P(X_{obs}|\theta)$ directly can yield a *biased* θ. With only a few exceptions [15, 16], nearly all the previous work on recommender systems try to maximize the data model directly [5, 14, 19, 22, 23]. In a typical recommender system, the data collected can easily violate the MAR assumption. The distinct distribution of rating values on user selected items and randomly selected items hints that the response pattern depends on not only the observed data. Also, a survey on the Yahoo! LanuchCast provides evidence that the response probability might depend on the fondness of particular items [16, 26].

3 Models and Analysis

In the following, we first review the Probabilistic Matrix Factorization (PMF). After that, we present the response aware PMF and show how it can incorporate PMF with the response models. More specifically, we introduce two response models, the rating dominant response model and the context-aware response model. The updating rules and complexity analysis are provided correspondingly.

3.1 Probabilistic Matrix Factorization

PMF [22] is one of the most famous matrix factorization models in collaborative filtering, which decomposes the partially observed data matrix X into the product of two low-rank latent feature matrices, U and V, where $U \in \mathbb{R}^{K\times N}$, $V \in \mathbb{R}^{K\times M}$, and $K \ll \min(N, M)$.

By assuming Gaussian distribution on the residual noise of observed data and placing Gaussian priors on the latent feature matrices, PMF tries to maximize the log-likelihood of the posterior distribution on the user and item features as follows:

$$\mathcal{L}_{PMF} = -\sum_{(i,j,x)\in\mathcal{Q}} \frac{(x - U_i^T V_j)^2}{2\sigma^2} - \frac{\|U\|_F^2}{2\sigma_U^2} - \frac{\|V\|_F^2}{2\sigma_V^2}. \tag{6}$$

This is equivalent to minimizing a squared loss with regularization defined as follows:

$$\mathcal{E} = \frac{1}{2}\sum_{(i,j,x)\in\mathcal{Q}} (x - U_i^T V_j)^2 + \frac{\lambda_U}{2}\|U\|_F^2 + \frac{\lambda_V}{2}\|V\|_F^2, \tag{7}$$

where $\lambda_U = \sigma^2/\sigma_U^2$ and $\lambda_V = \sigma^2/\sigma_V^2$ are positive constants to control the trade-off between the loss and the regularization terms. $\|\cdot\|_F^2$ denotes the Frobenious norm.

After training the PMF model via gradient descent or stochastic gradient algorithms [22], the predicted rating that user i would assign to item j can be computed as the expected mean of the Gaussian distribution $\hat{x}_{ij} = U_i^T V_j$.

3.2 Response Aware PMF

In Sec. 2, we have demonstrated that by neglecting response patterns, not only do we lose the potential information that might boost the model performance, but also can it lead to incorrect or biased parameters estimation. Due to the effectiveness and interpretability of PMF, we will unify it with explicit response models, which we refer to as Response Aware PMF (RAPMF).

Replacing θ in Eq. (2) by the low-rank latent feature matrices in PMF, we have

$$P(R, X|U, V, \mu, \sigma^2) = P(R|X, U, V, \mu, \sigma^2)P(X|U, V, \sigma^2). \tag{8}$$

The probability of full model, $P(R, X|U, V, \mu, \sigma^2)$, is decomposed into data model $P(X|U, V, \sigma^2)$ and the missing data model $P(R|X, U, V, \mu, \sigma^2)$.

3.3 Response Model

Modeling the missing data successfully requires a correct and tractable distribution on the response patterns. Bernoulli distribution is an intuitive distribution to explain data missing phenomena [16]. Depending on whether users' and items' features are incorporated, we propose two response models, *rating dominant response model* and *context-aware response model*.

3.4 Rating Dominant Response Model

For the sake of simplification, we assume the probability that a user chooses to rate an item follows a Bernoulli distribution given the rating assigned is k. Hence, for a scale of 1 to D, the rating dominant response model has D parameters $\mu_1, \mu_2, \cdots, \mu_D$.

If X is fully observed, then the response mechanism can be modeled as [16]:

$$\begin{aligned} &P(R|X, U, V, \mu, \sigma^2) = P(R|X, \mu) \\ &= \prod_{i=1}^{N}\prod_{j=1}^{M}\prod_{k=1}^{D} (\mu_k^{[r_{ij}=1]}(1-\mu_k)^{[r_{ij}=0]})^{[x_{ij}=k]}, \end{aligned} \tag{9}$$

where $[r = 0]$ is an indicator variable that outputs 1 if the expression is valid and 0 otherwise. It is noted that Eq. (9) adopts the "winner-take-all" scheme, i.e., a hard assignment scheme, to model users' response on a particular rating.

However, in real-world recommender system, the data is not fully observed. The "winner-take-all" scheme brings the risk of deteriorating assignment probability when the data is recovered based on the learned model. Hence, we adopt a soft assignment using probability of the possible rating values in the response model as follows:

$$\begin{aligned} &P(R|X, U, V, \mu, \sigma^2) = P(R|U, V, \mu, \sigma^2) \\ &= \prod_{i=1}^{N}\prod_{j=1}^{M}\sum_{k=1}^{D} (\mu_k^{[r_{ij}=1]}(1-\mu_k)^{[r_{ij}=0]})P(x_{ij} = k|U, V, \sigma^2), \end{aligned} \tag{10}$$

where $P(X|U, V, \sigma^2)$, the probability of X being assigned to k, can be set to $\mathcal{N}(k|U^T V, \sigma^2)$ as is in [22].

To relieve the inaccuracy issue when recovering the original model, we further introduce a discount parameter β on the assignment probability

$$P(R|X, U, V, \mu, \sigma^2) = P(R|U, V, \mu, \sigma^2) \tag{11}$$

$$\propto \prod_{i=1}^{N}\prod_{j=1}^{M} (\sum_{k=1}^{D} (\mu_k^{[r_{ij}=1]}(1-\mu_k)^{[r_{ij}=0]})\mathcal{N}(k|U^T V, \sigma^2))^{\beta}, \tag{12}$$

where the parameter β, in the range of 0 to 1, can be interpreted as the faith we have on the response model relative to the data model. As β decreases, the effect of the response model decreases correspondingly. When $\beta = 0$, the RAPMF collapses to PMF.

More importantly, the expectations of Bernoulli distributions, μ_k's should be in the range of 0 to 1. With the performance consideration, the logistic function is usually adopted to constrain the range of μ_k's [15],

$$g(\mu_k) = \frac{1}{1+\exp(-\mu_k)}, \quad k = 1, \ldots, D. \tag{13}$$

Similarly, we place a zero mean Gaussian prior on μ_k to regularize it.

Note that in Eq. (10), we use only one parameter for each possible rating value, so all the users and items share the same probability as long as the rating values are the same. This is a simple approach to capture the intuition that the rating assigned to an item may influence the chance that it got rated. This motivates us to name this model as *rating dominant response model*. We refer to PMF with Rating dominate response model as RAPMF-r.

By incorporating the response model in Eq. (12) and the PFM model in Eq. (6) into RAPMF in Eq. (8), we obtain the log-likelihood of the RAPMF-r as follows:

$$\begin{aligned}
&\mathcal{L}(U, V, \sigma^2, \mu) \\
&= \beta \sum_{i=1}^{N}\sum_{j=1}^{M} \log(\sum_{k=1}^{D} \alpha_{kij} \mathcal{N}(k|U^T V, \sigma^2)) - \frac{1}{2\sigma_\mu^2}\|\mu\|^2 - \\
&\sum_{(i,j,x)\in Q} \frac{(x_{ij} - U_i^T V_j)^2}{2\sigma^2} - \frac{1}{2\sigma_U^2}\|U\|_F^2 - \frac{1}{2\sigma_V^2}\|V\|_F^2 + C,
\end{aligned} \tag{14}$$

where C denotes the constant terms and α_{kij} is defined as

$$\alpha_{kij} = (g(\mu_k)^{[r_{ij}=1]}(1 - g(\mu_k))^{[r_{ij}=0]}). \tag{15}$$

The gradient of $\mathcal{L}$ with respect to U_i is:

$$\begin{aligned}
\frac{\partial \mathcal{L}}{\partial U_i} =& -\beta \sum_{j=1}^{M} \frac{\sum_{k=1}^{D} \alpha_{kij} \mathcal{N}(k|U^T V, \sigma^2)(U_i^T V_j - k) V_j}{\sum_{k=1}^{D} \alpha_{kij} \mathcal{N}(k|U^T V, \sigma^2)} \\
&- \sum_{j=1}^{M} (U_i^T V_j - x_{ij})[r_{ij} = 1] V_j - \lambda_U U_i.
\end{aligned} \tag{16}$$

Similarly, the gradient of $\mathcal{L}$ with respect to V_j is:

$$\begin{aligned}
\frac{\partial \mathcal{L}}{\partial V_j} =& -\beta \sum_{i=1}^{N} \frac{\sum_{k=1}^{D} \alpha_{kij} \mathcal{N}(k|U^T V, \sigma^2)(U_i^T V_j - k) U_i}{\sum_{k=1}^{D} \alpha_{kij} \mathcal{N}(k|U^T V, \sigma^2)} \\
&- \sum_{j=1}^{M} (U_i^T V_j - x_{ij})[r_{ij} = 1] U_i - \lambda_V V_j.
\end{aligned} \tag{17}$$

Both Eq. (16) and Eq. (17) consist of three terms. The first term corresponds to the change due to the response model, the second term is the change due to the data model and third is a regularization to avoid overfitting. Note that by adjusting β, we effectively alter the weight of the response model when updating parameters.

Finally, the gradient of $\mathcal{L}$ with respect to μ_l is

$$\frac{\partial \mathcal{L}}{\partial \mu_l} = \sum_{i=1}^{N}\sum_{j=1}^{M} \frac{\mathcal{N}(l|U^T V, \sigma^2) g'(\mu_l)(-1)^{[r_{ij}=0]}}{\sum_{k=1}^{D} \alpha_{kij} \mathcal{N}(k|U^T V, \sigma^2)} - \lambda_\mu \mu_l, \tag{18}$$

where $g'(x)$ is the derivative of the sigmoid function $g(x)$. In Eq. (16), (17), (18), $\lambda_U = \sigma^2/\sigma_U^2, \lambda_V = \sigma^2/\sigma_V^2$ and $\lambda_\mu = \sigma^2/\sigma_\mu^2$ and a multiplicative constant $1/\sigma^2$ is dropped in all three equations.

To learn model parameters, we alternatively update U, V and μ using the gradient algorithm with a learning rate η by maximizing the log-likelihood. First we update U, V by

$$U_i \leftarrow U_i + \eta \frac{\partial \mathcal{L}}{\partial U_i}, \qquad V_j \leftarrow V_j + \eta \frac{\partial \mathcal{L}}{\partial V_j}. \tag{19}$$

Then using the updated U, V, we update μ_l by

$$\mu_l \leftarrow \mu_l + \eta \frac{\partial \mathcal{L}}{\partial \mu_l}. \tag{20}$$

Similar to PMF [22], we linearly map the rating values in $[1, D]$ to $[0, 1]$ and pass $U_i^T V_j$ through the sigmoid function as defined in Eq. (13). To avoid cluttered notations, we drop all the logistic function in our derivation process. After obtained the trained model, we convert the expected value, $g(U_i^T V_j)$, back to the scale of 1 to D and set it as the predicted score of user i's rating on item j.

3.5 Context aware response model

In real-world recommender systems, the probability of an item being rated may not only depend on users' rating score. Many factors affect the response probabilities. For example, in a movie rating system, some popular movies such as Titanic, Avatar, may have much higher probability of being rated than a mediocre movie. Moreover, the features of users and items may contain group structure [30]. One may argue this might be caused by the higher inspection rate, i.e., it is likely that a reputable movie is being watched more than an obscure one. Nevertheless, it still makes sense that some items may have higher chance of receiving a rating due to the high quality that a user will not hesitate to rate it. In addition, different user may have distinct rating habits. Some users might be more willing to provide ratings in order to get high quality

recommendation. This is supported by the fact that the number of ratings received from different users can differ wildly in real-world deployed recommender systems.

To capture such factors, we generalize the rating dominant response model by including both item features and user features. To keep the model tractable and efficient, we introduce a linear combination of the item features, user features and a constant related to the rating scores and pass it through the logistic function to model the response probability,

$$\mu_{ijk} = \frac{1}{1+\exp(-(\delta_k + U_i^T\boldsymbol{\theta}_U + V_j^T\boldsymbol{\theta}_V))}. \quad (21)$$

We refer to Eq. (21) as context-aware response model, in which the response probability is on a per-user-item-rating basis. More sophisticated relationship definition can be referred to [28, 29, 31]. The PMF integrated with the context-aware response model is named RAPMF-c. Note that by setting $\boldsymbol{\theta}_U$ and $\boldsymbol{\theta}_V$ to zero, we can recover the rating dominant response model in Eq. (13).

The log-likelihood of RAPMF-c is in the same structure as RAPMF-r. We only need to substitute μ_k in Eq. (15) by μ_{ijk} defined in Eq. (21). Similarly, the gradients of $\mathcal{L}$ with respect to U_i and V_j are

$$\frac{\partial \mathcal{L}}{\partial U_i} = \beta \sum_{j=1}^{M} \frac{\sum_{k=1}^{D} t_{Ukij}\mathcal{N}(k|U^TV,\sigma^2)}{\sum_{k=1}^{D}\alpha_{kij}\mathcal{N}(k|U^TV,\sigma^2)} - \sum_{j=1}^{M}(U_i^TV_j - x_{ij})[r_{ij}=1]V_j - \lambda_U U_i, \quad (22)$$

$$\frac{\partial \mathcal{L}}{\partial V_j} = -\beta \sum_{i=1}^{N} \frac{\sum_{k=1}^{D} t_{Vkij}\mathcal{N}(k|U^TV,\sigma^2)}{\sum_{k=1}^{D}\alpha_{kij}\mathcal{N}(k|U^TV,\sigma^2)} - \sum_{j=1}^{M}(U_i^TV_j - x_{ij})[r_{ij}=1]U_i - \lambda_V V_j, \quad (23)$$

where the t_{Ukij} and t_{Vkij} is defined as following

$$t_{Ukij} = g'(\mu_{kij})(-1)^{[r_{ij}=0]}\boldsymbol{\theta}_U - \alpha_{kij}(U_i^TV_j - k)V_j, \quad (24)$$

$$t_{Vkij} = g'(\mu_{kij})(-1)^{[r_{ij}=0]}\boldsymbol{\theta}_V - \alpha_{kij}(U_i^TV_j - k)U_i. \quad (25)$$

Correspondingly, the gradients of $\mathcal{L}$ with respect to δ_l, $\boldsymbol{\theta}_U$ and $\boldsymbol{\theta}_V$ are

$$\frac{\partial \mathcal{L}}{\partial \delta_l} = \sum_{i=1}^{N}\sum_{j=1}^{M} \frac{\mathcal{N}(l|U^TV,\sigma^2)g'(\mu_{kij})(-1)^{[r_{ij}=0]}}{\sum_{k=1}^{D}\alpha_{kij}\mathcal{N}(k|U^TV,\sigma^2)} - \lambda_\mu\delta_l, \quad (26)$$

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}_U} = \sum_{i=1}^{N}\sum_{j=1}^{M} \frac{\sum_{k=1}^{D}\mathcal{N}(k|U^TV,\sigma^2)g'(\mu_{kij})(-1)^{[r_{ij}=0]}U_i}{\sum_{k=1}^{D}\alpha_{kij}\mathcal{N}(k|U^TV,\sigma^2)} - \lambda_\mu\boldsymbol{\theta}_U, \quad (27)$$

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}_V} = \sum_{i=1}^{N}\sum_{j=1}^{M} \frac{\sum_{k=1}^{D}\mathcal{N}(k|U^TV,\sigma^2)g'(\mu_{kij})(-1)^{[r_{ij}=0]}V_j}{\sum_{k=1}^{D}\alpha_{kij}\mathcal{N}(k|U^TV,\sigma^2)} - \lambda_\mu\boldsymbol{\theta}_V. \quad (28)$$

To learn RAPMF-c, we adopt the alternatively updating scheme to maximize the log-likelihood, where the updating rules of U and V are the same as those in Eq. (19). After updating U and V, we update δ_l, $\boldsymbol{\theta}_U$ and $\boldsymbol{\theta}_V$ by

$$\boldsymbol{\vartheta} \leftarrow \boldsymbol{\vartheta} + \eta\frac{\partial \mathcal{L}}{\partial \boldsymbol{\vartheta}},$$

where $\boldsymbol{\vartheta}$ is replaced by δ_l, $\boldsymbol{\theta}_U$ and $\boldsymbol{\theta}_V$, respectively.

3.6 Complexity and Parallelization

The training complexity of RAPMF, $O(MN)$, can be quite time consuming compared with the PMF, which is linear in number of observations, $O(|\mathcal{Q}|)$. However, we argue that the time spent on training is worthy since it can boost the model performance. More importantly, the prediction complexity of RAPMF is the same as PMF, $O(K)$, which can be taken as a constant time given a moderate sized K. Since the training procedure can be performed offline, RAPMF can accommodate the hard response time constraint in real-world deployed recommender systems due to the succinct prediction cost.

In addition, RAPMF can be speedup by parallelization. The intensive computation cost, calculating the gradients, can be decoupled and distributed to a cluster of computers. It is also possible to use online learning to speed up the training process [12].

4 Experiments and Results

We conduct empirical evaluation to compare the performance of PMF [22], CPT-v [16], Logit-vd [15], and our RAPMF. We try to answer the following questions:

1. How to collect data with benchmark response patterns to evaluate the models fairly?

2. How to design experiment protocols to evaluate the performance the models with and without response models fairly?
3. How the compared models perform on the collected data?
4. How the parameters, β and λ, affect the performance of RAPMF?

Section 4.1-4.4 answer the above questions, respectively.

4.1 Datasets

We conduct our empirical analysis on two datasets: a synthetic dataset and a real-world dataset, the *Yahoo! Music ratings for User Selected and Randomly Selected songs, version 1.0* (Yahoo dataset)[1].

Synthetic dataset. The data generation process consists of two steps: generating full rating matrix and generating response matrix. To generate the full rating matrix, we first generate the latent user features and item features from zero-mean spherical Gaussian as follows:

$$U_i \sim \mathcal{N}(\mathbf{0}_K, \sigma_U^2 \mathbf{I}_K), \quad V_j \sim \mathcal{N}(\mathbf{0}_K, \sigma_V^2 \mathbf{I}_K),$$

where $i = 1, \ldots, N$, $j = 1, \ldots, M$, $\mathbf{0}_K$ is a K-dimensional vector with each element being 0 and $\mathbf{I}_K$ is the $K \times K$ identity matrix. The full rating matrix X is then obtained by re-scale the sigmoid value of $U^T V$ to 1 to D by $X_{ij} = \lceil g(U_i^T V_j) \times D \rceil$.

To generate the response matrix R, we first set the inspection probability of a user inspecting an item, $P_{inspect}$. Then, the partitioning of inspected ratings and un-inspected ratings are done by the Bernoulli trails with success probability $P_{inspect}$. For all the inspected ratings, we model their response probability by a Bernoulli distribution with the success probability P_k, where $k \in \{1, 2, \ldots, D\}$. Table 2 summarizes the parameters used for generating the synthetic dataset. The parameters are selected so that they can faithfully simulate real users' ratings and response behaviors. The rating probabilities P_k are chosen according to Fig. 1. To minimize the effect of randomness, we generate the dataset independently 10 times and report the average result in the following. On average, we provide about 3.3% of the full matrix as training set, around 3.4% as testing set for traditional protocol, around 17.3% as testing set for adversarial protocol and all the remaining 80% as testing set for realistic protocol.

Yahoo dataset. It provides a unique opportunity to investigate the response ignorance problem. The dataset contains 311,704 *training ratings* collected from 15,400 users on 1,000 songs during the normal interaction between the users and the Yahoo! Music system, with at least 10 ratings for each user. During a survey conducted by Yahoo! Research, exactly 10 songs randomly selected from these 1,000 songs are presented to the user to listen and rate. In total there are 5,400 users participated this survey and these 54,000 ratings are the *testing ratings*.

[1]http://webscope.sandbox.yahoo.com

Table 2: Parameters for generating the synthetic dataset.

N	M	D	K	$P_{inspect}$
1000	1000	5	5	0.2
P_1	P_2	P_3	P_4	P_5
0.073	0.068	0.163	0.308	0.931

4.2 Setup and Evaluation Metrics

In a real-world deployed recommender system, the status of an item given a user follows exactly one of the three types: *un-inspected*, *inspected-unrated*, and *inspected-rated*. Traditional collaborative filtering approaches separate the inspected-rated data into training set and test set and evaluate the model on the test set. Since both the training set and the test set belongs to the inspected-rated type, their rating distributions are the same. Thus, the traditional evaluation scheme may hide the significance of the ignoring response model. In the experiment, we first investigate two existing experimental protocols:

- **Traditional protocol:** Both the training set and the test set are randomly selected from inspected-rated items together with their rating users and assigned scores. This is exactly the traditional experiment protocol [22].
- **Realistic protocol:** The training set is randomly selected from inspected-rated items, but the test set is randomly selected from un-inspected items. This is an experimental protocol adopted in [15, 16]. This protocol captures the ultimate goal of a recommender system, i.e., recommending un-inspected items to potential users who are interested.

Moreover, we will investigate a new experimental protocol:

- **Adversarial protocol:** The training set is randomly selected from inspected-rated items, but the test set is randomly selected from inspected-unrated items. This setting tests the model's performance when the distribution of the training set and test are very divergent. It can reveal the property of the model in some real-world cases where

most of inspected-rated items receive very high scores, while those inspected-unrated items have low scores. This setting also demonstrates the model performance when we have an adversary that manipulates the responses.

For the synthetic dataset, we use the same training set for all three protocols. For various protocols, different test set can reveal different properties of the PMF with and without the response models. We report the average performance on the 10 independently generated datasets.

For Yahoo dataset, we use only traditional and realistic protocol and do not evaluate the adversarial protocol due to the missing of necessary inspection information. For the traditional protocol, we perform 10 fold cross validation on the training ratings. For the realistic protocol, we train the model using training ratings and test on the testing ratings. We perform the experiment 10 times and report the average results.

In the experiment, we use Root Mean Square Error (RMSE) to evaluate the performance of various approaches [16, 22, 27], i.e., RMSE $= \sqrt{1/|\mathcal{T}| \sum_{(i,j,x)\in\mathcal{T}} (\hat{x}_{ij} - x)^2}$, where $\mathcal{T}$ is the set of (i, j, x) triplets reserved for testing and $\hat{x}_{ij}$ is model prediction for user i's rating on item j.

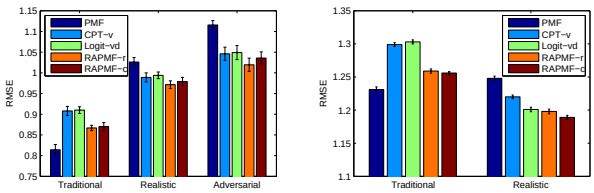
4.3 Model Comparison

For both the synthetic dataset and Yahoo dataset, we randomly select 10% of the testing ratings from realistic protocol as validation set to tune the parameters (more advanced techniques can be referred to [20]):

- λ_U and λ_V: They are tuned by the grid search scheme, i.e., first selecting from $\{10^{-3}, 10^{-2}, 10^{-1}, 10^0, 10, 10^2\}$, respectively. We then fine-tune the range to achieve the best performance of PMF; see an example in Fig. 3(a).
- β: We first fix the optimal λ_U and λ_V obtained from PMF, we then tune it in $\{0.0, 10^{-3}, 10^{-2}, 10^{-1}, 1.0\}$ and fine-tune it further for RAPMF-r; see an example in Fig. 3(b).
- λ_μ: As shown later in Fig. 3(c), this parameter is insensitive on a large range.

These parameters are then used across different protocols. The hyper-parameters used for CPT-v and Logit-vd follow the settings used in [15]. We choose $K = 5$ as the latent dimension size for all the experiments. All the models are trained using 500 iterations. According to our experience, the change in performance after 200 iterations is negligible.

Figure 2 shows the results of various models' performance under different protocols on both the synthetic and Yahoo datasets. Figure 2(a) shows the results on the synthetic datasets. We see that PMF performs best under traditional protocol. This is expected because under the traditional setting, the testing set and the training set have exactly the same distribution. The response model does not help. However, under realistic and adversarial protocol, the proposed RAPMF-r outperforms PMF by 5.5% and 9.2%, with 95% confidence level on the paired t-test, respectively. The RAPMF-c performs slightly worse than RAPMF-r. This is probably due to the reason that we does not take the user and item features into account when generating the dataset.



(a) Synthetic dataset (b) Yahoo dataset

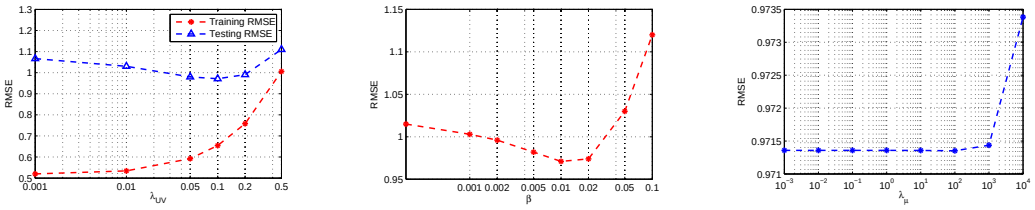
Figure 2: Relative performance of various models. Smaller value indicates a better model performance.

More importantly, the learned rating probability for a typical run of RAPMF-r is [0.0125, 0.0124, 0.0155, 0.0267, 0.105]. Comparing this with the parameter used in Table 2 when generating the data, we see that although RAPMF cannot recover the rating probabilities exactly, the overall trend is captured quite precisely. This explains the significant performance boost in realistic and adversarial protocol.

Figure 2(b) shows the results on the Yahoo dataset. Again, PMF attains the best performance under traditional protocol. Under realistic protocol, the RAPMF-r and RAPMF-c outperforms PMF by 4.1% and 4.9%, with 95% confidence level on the paired t-test, respectively. The performance gain is slightly less than that in the synthetic dataset, probably due to the reason that the rating probability in real-world dataset is not as dynamic as the value we choose in Table 2. The performance boost gained from context-awareness is not as significant as we have expected. This result hints that the rating value might impact a user's decision on whether to rate the item more than the user and item features.

4.4 Sensitivity Analysis

In the following, we investigate how the model parameters affect the performance of RAPMF. All the sensitivity analysis is done under the realistic setting in one-trial of the generated synthetic dataset.



(a) λ_{UV} (b) β (c) λ_μ

Figure 3: Sensitivity analysis of hyper-parameters on RAPMF on one-trial test.

4.4.1 Impact of β

The faith parameter β is arguably the most important parameter in our RAPMF model. As has been discussed in Section 3, we adopt a soft-margin approximation of the ideal hard-margin response model. When making this approximation, we unavoidably introduce some bias in the response model because we cannot fully recover the true U and V. Hence, we introduce β to control the weight of the response model.

Figure 3(b) plots the performance of RAPMF versus β on the logarithmic scale. When $\beta = 0$, RAPMF fall back to PMF, whose performance is 1.015, corresponding to the most left point in Fig. 3(b). Clearly, by incorporating an explicit response model, RAPMF is able to beat PMF by a large margin (nearly 5%) by using a proper β value. However, if we use too large a β, we quickly lose the boost provided by the response model. An observation of the experiment is that when β is too large, the model does not converge. This is because the model training starts from randomly initialized U and V, a large weight on the response model will pull the model away from the true model and cause divergence.

4.4.2 Impact of λ's

The regularization parameters λ are placed on U, V and μ. Since in the dataset, users and items are symmetric, we use the same regularization parameter λ_{UV} for U and V and use another parameter λ_μ to control μ.

Figure 3(a) shows the impact of λ_{UV} on the performance of RAPMF. When λ_{UV} is very small, although the RAPMF is able to fit the training data very well, it does not generalize well to the test set. This is a sign of over-fitting. As λ_{UV} becomes larger, which limits the norms of U and V, the training RMSE increases but the test RMSE decreases gradually. However, after a turning point, both the training RMSE and test RMSE start to increase. This is when the regularization is too stringent that it hinders the proper fitting of the model.

Figure 3(c) shows the impact of λ_μ on the model performance. As we can see, it is basically a straight line in a large range from 10^{-3} to 10^4, while the RMSE is changed only from 0.9714 to 0.9734, a very small scale. The effect of λ_μ is inappreciable. This is probably due to the fact that μ is a parameter in D-dimension (D=5) and no significant over-fitting can occur.

5 Conclusion and Future Work

In this paper, we propose two response models, rating dominant and context-aware response models, to capture users' response patterns. Further, we unify the response models with one of famous collaborative filtering model-based methods, the Probabilistic Matrix Factorization, to establish the Response Aware Probabilistic Matrix Factorization framework (RAPMF). The RAPMF also generalizes PMF as its special case. Empirically, we verify the performance of RAPMF under carefully designed experimental protocols and show that RAPMF performs best when it tries to fulfill the ultimate goal of real-world recommender systems, i.e., recommending items to those who may be interested in. The empirical evaluation demonstrates the potential of our RAPMF model in real-world recommender system deployment.

There are several interesting directions worthy of considering for future study. One direction is to study how to model the response when the response patterns are hidden. The second fascinating avenue is to study how to speed up our RAPMF through parallelization, online learning, or sampling techniques. The third direction is to design a smart way to efficiently tune the hyper-parameters or to design the learning scheme to automatically learn the model parameters.

Abstract

Large-scale multiple testing tasks often exhibit dependence, and leveraging the dependence between individual tests is still one challenging and important problem in statistics. With recent advances in graphical models, it is feasible to use them to perform multiple testing under dependence. We propose a multiple testing procedure which is based on a Markov-random-field-coupled mixture model. The ground truth of hypotheses is represented by a latent binary Markov random field, and the observed test statistics appear as the coupled mixture variables. The parameters in our model can be automatically learned by a novel EM algorithm. We use an MCMC algorithm to infer the posterior probability that each hypothesis is null (termed *local index of significance*), and the false discovery rate can be controlled accordingly. Simulations show that the numerical performance of multiple testing can be improved substantially by using our procedure. We apply the procedure to a real-world genome-wide association study on breast cancer, and we identify several SNPs with strong association evidence.

1 Introduction

Observations from large-scale multiple testing problems often exhibit dependence. For instance, in genome-wide association studies, researchers collect hundreds of thousands of highly correlated genetic markers (single-nucleotide polymorphisms, or SNPs) with the purpose of identifying the subset of markers associated with a heritable disease or trait. In functional magnetic resonance imaging studies of the brain, thousands of spatially correlated voxels are collected while subjects are performing certain tasks, with the purpose of detecting the relevant voxels. The most popular family of large-scale multiple testing procedures is the false discovery rate analysis, such as the p-value thresholding procedures (Benjamini & Hochberg, 1995, 2000; Genovese & Wasserman, 2004), the local false discovery rate procedure (Efron et al., 2001), and the positive false discovery rate procedure (Storey, 2002, 2003). However, all these classical multiple testing procedures ignore the correlation structure among the individual factors, and the question is *whether we can reduce the false non-discovery rate by leveraging the dependence, while still controlling the false discovery rate in multiple testing.*

Graphical models provide an elegant way of representing dependence. With recent advances in graphical models, especially more efficient algorithms for inference and parameter learning, it is feasible to use these models to leverage the dependence between individual tests in multiple testing problems. One influential paper (Sun & Cai, 2009) in the statistics community uses a hidden Markov model to represent the dependence structure, and has shown its optimality under certain conditions and its strong empirical performance. It is the first graphical model (and the only one so far) used in multiple testing problems. However, their procedure can only deal with a sequential dependence structure, and the dependence parameters are homogenous. *In this paper, we propose a multiple testing procedure based on a Markov-random-field-coupled mixture model which allows arbitrary dependence structures and heterogeneous dependence parameters.* This extension requires more sophisticated algorithms for parameter learning and inference. For parameter learning, we design an EM algorithm with MCMC in the E-step and persistent contrastive divergence algorithm (Tieleman, 2008) in the M-step. We use the MCMC algorithm to infer the posterior probability that each hypothesis is null (termed *local index of significance* or LIS). Finally, the false discovery rate can be controlled by thresholding the LIS.

Section 2 introduces related work and our procedure. Sections 3 and 4 evaluate our procedure on a variety of simulations, and the empirical results show that the numerical performance can be improved substantially by using our procedure. In Section 5, we apply the procedure to a real-world genome-wide association study (GWAS) on breast cancer, and we identify several SNPs with strong association evidence. We finally conclude in Section 6.

2 Method

2.1 Terminology and Previous Work

Table 1: Classification of tested hypotheses

	Not rejected	Rejected	Total
Null	N_{00}	N_{10}	m_0
Non-null	N_{01}	N_{11}	m_1
Total	S	R	m

Suppose that we carry out m tests whose results can be categorized as in Table 1. *False discovery rate* (FDR), defined as $E(N_{10}/R|R > 0)P(R > 0)$, depicts the expected proportion of incorrectly rejected null hypotheses (Benjamini & Hochberg, 1995). *False non-discovery rate* (FNR), defined as $E(N_{01}/S|S > 0)P(S > 0)$, depicts the expected proportion of false non-rejections in those tests whose null hypotheses are not rejected (Genovese & Wasserman, 2002). An FDR procedure is *valid* if it controls FDR at a nominal level, and *optimal* if it has the smallest FNR among all the valid FDR procedures (Sun & Cai, 2009). The effects of correlation on multiple testing have been discussed, under different assumptions, with a focus on the validity issue (Benjamini & Yekutieli, 2001; Finner & Roters, 2002; Owen, 2005; Sarkar, 2006; Efron, 2007; Farcomeni, 2007; Romano et al., 2008; Wu, 2008; Blanchard & Roquain, 2009). The efficiency issue has also been investigated (Yekutieli & Benjamini, 1999; Genovese et al., 2006; Benjamini & Heller, 2007; Zhang et al., 2011), indicating FNR could be decreased by considering dependence in multiple testing. Several approaches have been proposed, such as dependence kernels (Leek & Storey, 2008), factor models (Friguet et al., 2009) and principal factor approximation (Fan et al., 2012). Sun & Cai (2009) explicitly use a hidden Markov model (HMM) to represent the dependence structure and analyze the optimality under the compound decision framework (Sun & Cai, 2007). However, their procedure can only deal with sequential dependence, and it uses only a single dependence parameter throughout. In this paper, we replace HMM with a Markov-random-field-coupled mixture model, which allows richer and more flexible dependence structures. The Markov-random-field-coupled mixture models are related to the hidden Markov random field models used in many image segmentation problems (Zhang et al., 2001; Celeux et al., 2003; Chatzis & Varvarigou, 2008).

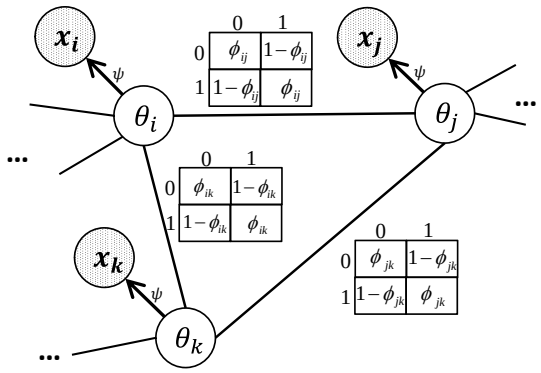

Figure 1: The MRF-coupled mixture model for three dependent hypotheses $\mathcal{H}_i$, $\mathcal{H}_j$ and $\mathcal{H}_k$ with *observed* test statistics (x_i, x_j and x_k) and *latent* ground truth (θ_i,θ_j and θ_k). The dependence is captured by potential functions parameterized by ϕ_{ij},ϕ_{jk} and ϕ_{ik}, and coupled mixtures are parameterized by ψ.

2.2 Our Multiple Testing Procedure

Let $\mathbf{x} = (x_1, ..., x_m)$ be a vector of test statistics from a set of hypotheses $(\mathcal{H}_1, ..., \mathcal{H}_m)$. The ground truth of these hypotheses is denoted by a latent Bernoulli vector $\boldsymbol{\theta} = (\theta_1, ..., \theta_m) \in \{0, 1\}^m$, with $\theta_i = 0$ denoting that the hypothesis $\mathcal{H}_i$ is null and $\theta_i = 1$ denoting that the hypothesis $\mathcal{H}_i$ is non-null. The dependence among these hypotheses is represented as a binary Markov random field (MRF) on $\boldsymbol{\theta}$. The structure of the MRF can be described by an undirected graph $\mathcal{G}(\mathcal{V}, \mathcal{E})$ with the node set $\mathcal{V}$ and the edge set $\mathcal{E}$. The dependence between $\mathcal{H}_i$ and $\mathcal{H}_j$ is denoted by an edge connecting node$_i$ and node$_j$ in $\mathcal{E}$, and the strength of dependence is parameterized by the potential function on the edge. Suppose that the probability density function of the test statistic x_i given $\theta_i = 0$ is f_0, and the density of x_i given $\theta_i = 1$ is f_1. Then, $\mathbf{x}$ is an MRF-coupled mixture. The mixture model is parameterized by a parameter set $\vartheta = (\boldsymbol{\phi}, \boldsymbol{\psi})$, where $\boldsymbol{\phi}$ parameterizes the binary MRF and $\boldsymbol{\psi}$ parameterizes f_0 and f_1. For example, if f_0 is standard normal $\mathcal{N}(0, 1)$ and f_1 is noncentered normal $\mathcal{N}(\mu, 1)$, then $\boldsymbol{\psi}$ only contains parameter μ. Figure 1 shows the MRF-coupled mixture model for three dependent hypotheses $\mathcal{H}_i$, $\mathcal{H}_j$ and $\mathcal{H}_k$.

In our MRF-coupled mixture model, $\mathbf{x}$ is observable, and $\boldsymbol{\theta}$ is hidden. With the parameter set $\vartheta = (\boldsymbol{\phi}, \boldsymbol{\psi})$, the joint probability density over $\mathbf{x}$ and $\boldsymbol{\theta}$ is

$$P(\mathbf{x}, \boldsymbol{\theta}|\boldsymbol{\phi}, \boldsymbol{\psi}) = P(\boldsymbol{\theta}; \boldsymbol{\phi}) \prod_{i=1}^{m} P(x_i|\theta_i; \boldsymbol{\psi}). \quad (1)$$

Define the marginal probability that $\mathcal{H}_i$ is null given all the observed statistics $\mathbf{x}$ under the parameters in ϑ, $P_\vartheta(\theta_i = 0|\mathbf{x})$, to be the *local index of significance* (LIS) for $\mathcal{H}_i$ (Sun & Cai, 2009). If we can accurately calculate the posterior marginal probabilities of $\boldsymbol{\theta}$ (or LIS), then we can use a step-up procedure to control FDR at the nominal level α as follows (Sun & Cai, 2009). We first sort LIS from the smallest value to the largest value. Suppose $\text{LIS}_{(1)}$, $\text{LIS}_{(2)}$, ..., and $\text{LIS}_{(m)}$ are the ordered LIS, and the corresponding hypotheses are $\mathcal{H}_{(1)}$, $\mathcal{H}_{(2)}$,..., and $\mathcal{H}_{(m)}$. Let

$$k = \max\left\{i : \frac{1}{i}\sum\nolimits_{j=1}^{i} \text{LIS}_{(j)} \leq \alpha\right\}. \qquad (2)$$

Then we reject $\mathcal{H}_{(i)}$ for $i = 1, ..., k$.

Therefore, the key inferential problem that we need to solve is that of computing the posterior marginal distribution of the hidden variables θ_i given the test statistics $\mathbf{x}$, namely $P_\vartheta(\theta_i = 0|\mathbf{x})$, for $i = 1, ..., m$. It is a typical inference problem if the parameters in ϑ are known. Section 2.3 provides possible inference algorithms for calculating $P_\vartheta(\theta_i = 0|\mathbf{x})$ for given ϑ. However, ϑ is usually unknown in real-world applications, and we need to estimate it. Section 2.4 provides a novel EM algorithm for parameter learning in our MRF-coupled mixture model.

2.3 Posterior Inference

Now we are interested in calculating $P_\vartheta(\theta_i = 0|\mathbf{x})$ for a given parameter set ϑ. One popular family of inference algorithms is the sum-product family (Kschischang et al., 2001), also known as belief propagation (Yedidia et al., 2000). For loop-free graphs, belief propagation algorithms provide exact inference results with a computational cost linear in the number of variables. In our MRF-coupled mixture model, the structure of the latent MRF is described by a graph $\mathcal{G}(\mathcal{V}, \mathcal{E})$. When $\mathcal{G}$ is chain structured, the instantiation of belief propagation is the forward-backward algorithm (Baum et al., 1970). When $\mathcal{G}$ is tree structured, the instantiation of belief propagation is the upward-downward algorithm (Crouse et al., 1998). For graphical models with cycles, loopy belief propagation (Murphy et al., 1999; Weiss, 2000) and the tree-reweighted algorithm (Wainwright et al., 2003a) can be used for approximate inference. Other inference algorithms for graphical models include junction trees (Lauritzen & Spiegelhalter, 1988), sampling methods (Gelfand & Smith, 1990), and variational methods (Jordan et al., 1999). Recent papers (Schraudolph & Kamenetsky, 2009; Schraudolph, 2010) discuss exact inference algorithms on binary Markov random fields which allow loops. In our simulations, we use belief propagation when the graph $\mathcal{G}$ has no loops. When $\mathcal{G}$ has loops (e.g. in the simulations on genetic data and the real-world application), we use a Markov chain Monte Carlo (MCMC) algorithm to perform inference for $P_\vartheta(\theta_i = 0|\mathbf{x})$.

2.4 Parameters and Parameter Learning

In our procedure, the dependence among these hypotheses is represented by a graphical model on the latent vector $\boldsymbol{\theta}$ parameterized by $\boldsymbol{\phi}$, and observed test statistics $\mathbf{x}$ are represented by the coupled mixture parameterized by $\boldsymbol{\psi}$. In Sun and Cai's work on HMMs, $\boldsymbol{\phi}$ is the transition parameter and $\boldsymbol{\psi}$ is the emission parameter. One implicit assumption in their work is that the transition parameter and the emission parameter stay the same for $i(i = 1, ..., m)$. Our extension to MRFs also allows us to untie these parameters. In the second set of basic simulations in Section 3, we make $\boldsymbol{\phi}$ and $\boldsymbol{\psi}$ heterogeneous and investigate how this affects the numerical performance. In the simulations on genetic data in Section 4 and the real-world GWAS application in Section 5, we have different parameters for SNP pairs with different levels of correlation.

In our model, learning $(\boldsymbol{\phi}, \boldsymbol{\psi})$ is difficult for two reasons. First, learning parameters is difficult by nature in undirected graphical models due to the global normalization constant (Wainwright et al., 2003b; Welling & Sutton, 2005). State-of-the-art MRF parameter learning methods include MCMC-MLE (Geyer, 1991), contrastive divergence (Hinton, 2002) and variational methods (Ganapathi et al., 2008). Several new sampling methods with higher efficiency have been recently proposed, such as persistent contrastive divergence (Tieleman, 2008), fast-weight contrastive divergence (Tieleman & Hinton, 2009), tempered transitions (Salakhutdinov, 2009), and particle-filtered MCMC-MLE (Asuncion et al., 2010). In our procedure, we use the persistent contrastive divergence algorithm to estimate parameters $\boldsymbol{\phi}$. Another difficulty is that $\boldsymbol{\theta}$ is latent and we only have one observed training sample $\mathbf{x}$. We use an EM algorithm to solve this problem. In the E-step, we run our MCMC algorithm in Section 2.3 to infer the latent $\boldsymbol{\theta}$ based on the currently estimated parameters $\vartheta = (\boldsymbol{\phi}, \boldsymbol{\psi})$. In the M-step, we run the persistent contrastive divergence (PCD) algorithm (Tieleman, 2008) to estimate $\boldsymbol{\phi}$ from the currently inferred $\boldsymbol{\theta}$. Note that PCD is also an iterative algorithm, and we run it until it converges in each M-step. In the M-step, we also do a maximum likelihood estimation of $\boldsymbol{\psi}$ from the currently inferred $\boldsymbol{\theta}$ and observed $\mathbf{x}$. We run the EM algorithm until both $\boldsymbol{\phi}$ and $\boldsymbol{\psi}$ converge. Although this EM algorithm involves intensive computation in both E-step and M-step, it converges very quickly in our experiments.

3 Basic Simulations

In the basic simulations, we investigate the numerical performance of our multiple testing approach on different fabricated dependence structures where we can control the ground truth parameters. We first simulate $\boldsymbol{\theta}$ from $P(\boldsymbol{\theta};\boldsymbol{\phi})$ and then simulate $\mathbf{x}$ from $P(\mathbf{x}|\boldsymbol{\theta};\boldsymbol{\psi})$ under a variety of settings of $\vartheta = (\boldsymbol{\phi},\boldsymbol{\psi})$. Because we have the ground truth parameters, we have two versions of our multiple testing approach, namely the oracle procedure (OR) and the data-driven procedure (LIS). The oracle procedure knows the true parameters ϑ in the graphical models, whereas the data-driven procedure does not and has to estimate ϑ. The baseline procedures include the BH procedure (Benjamini & Hochberg, 1995) and the adaptive p-value procedure (AP) (Benjamini & Hochberg, 2000; Genovese & Wasserman, 2004) which are compared by Sun & Cai (2009). We include another baseline procedure, the local false discovery rate procedure (localFDR) (Efron et al., 2001). The adaptive p-value procedure requires a consistent estimate of the proportion of the true null hypotheses. The localFDR procedure requires a consistent estimate of the proportion of the true null hypotheses and the knowledge of the distribution of the test statistics under the null and under the alternative. In our simulations, we endow AP and localFDR with the ground truth values of these in order to let these baseline procedures achieve their best performance.

In the simulations, we assume that the observed x_i under the null hypothesis (namely $\theta_i = 0$) is standard-normally distributed and that x_i under the alternative hypothesis (namely $\theta_i = 1$) is normally distributed with mean μ and standard deviation 1.0. We choose the setup and parameters to be consistent with the work of Sun & Cai (2009) when possible. In total, we consider three MRF models, namely a chain-structured MRF, tree-structured MRF and grid-structured MRF. For chain-MRF, we choose the number of hypotheses $m = 3,000$. For tree-MRF, we choose perfect binary trees of height 12 which yields a total number of $8,191$ hypotheses. For grid-MRF, we choose the number of rows and the number of columns to be 100 which yields a total number of $10,000$ hypotheses. In all the experiments, we choose the number of replications $N = 500$ which is also the same as the work of Sun & Cai (2009). In total, we have three sets of simulations with different goals as follows.

Basic simulation 1: We stay consistent with Sun & Cai (2009) in the simulations except that we use the three MRF models. In all three structures, $(\theta_i)_1^m$ is generated from the MRFs whose potentials on the edges are $\begin{pmatrix} \phi & 1-\phi \\ 1-\phi & \phi \end{pmatrix}$. Therefore, $\boldsymbol{\phi}$ only contains parameter ϕ, and $\boldsymbol{\psi}$ only includes parameter μ.

Basic simulation 2: One assumption in basic simulation 1 is that the parameters ϕ and μ are homogeneous in the sense that they stay the same for $i(i = 1,...,m)$. This assumption is carried down from the work of Sun & Cai (2009). However in many real-world applications, the transition parameters can be different across the multiple hypotheses. Similarly, the test statistics for the non-null hypotheses, although normally distributed and standardized, could have different μ values. Therefore, we investigate the situation where the parameters can vary in different hypotheses. The simulations are carried out for all three different dependence structures aforementioned. In the first set of simulations, instead of fixing ϕ, we choose ϕ's uniformly distributed on the interval $(0.8-\Delta(\phi)/2, 0.8+\Delta(\phi)/2)$. In the second set of simulations, instead of fixing μ, we choose μ's uniformly distributed on the interval $(2.0-\Delta(\mu)/2, 2.0+\Delta(\mu)/2)$. The oracle procedure knows the true parameters. The data-driven procedure does not know the parameters, and assumes the parameters are homogeneous.

Basic simulation 3: Another implicit assumption in basic simulation 1 is that each individual test in the multiple testing problem is exact. Many widely used hypothesis tests, such as Pearson's χ^2 test and the likelihood ratio test, are asymptotic in the sense that we only know the limiting distribution of the test statistics for large samples. As an example, we simulate the two-proportion z-test in this section and show how the sample size affects the performance of the procedures when the individual test is asymptotic. Suppose that we have n samples (half of them are positive samples and half of them are negative samples). For each sample, we have m Bernoulli distributed attributes. A fraction of the attributes are relevant. If the attribute A is relevant, then the probability of "heads" in the positive samples (p_A^+) is different from that in the negative samples (p_A^-). p_A^+ and p_A^- are the same if A is non-relevant. For each individual test, the null hypothesis is that the attribute is not relevant, and the alternative hypothesis is otherwise. The two-proportion z-test can be used to test whether $p_A^+ - p_A^-$ is zero, which yields an asymptotic $\mathcal{N}(0,1)$ under the null and $\mathcal{N}(\mu,1)$ under the alternative (μ is nonzero). In the simulations, we fix μ, but vary the sample size n, and apply the aforementioned tree-MRF structure ($m = 8,191$). The oracle procedure and localFDR only know the limiting distribution of the test statistics and assume the test statistics exactly follow the limiting distributions even when the sample size is small.

Figure 2 shows the numerical results in basic simulation 1. Figures (1a)-(1f) are for the chain structure. Figures (2a)-(2f) are for tree structure. Figures (3a)-(3f) are for the grid structure. In Figures (1a)-(1c),

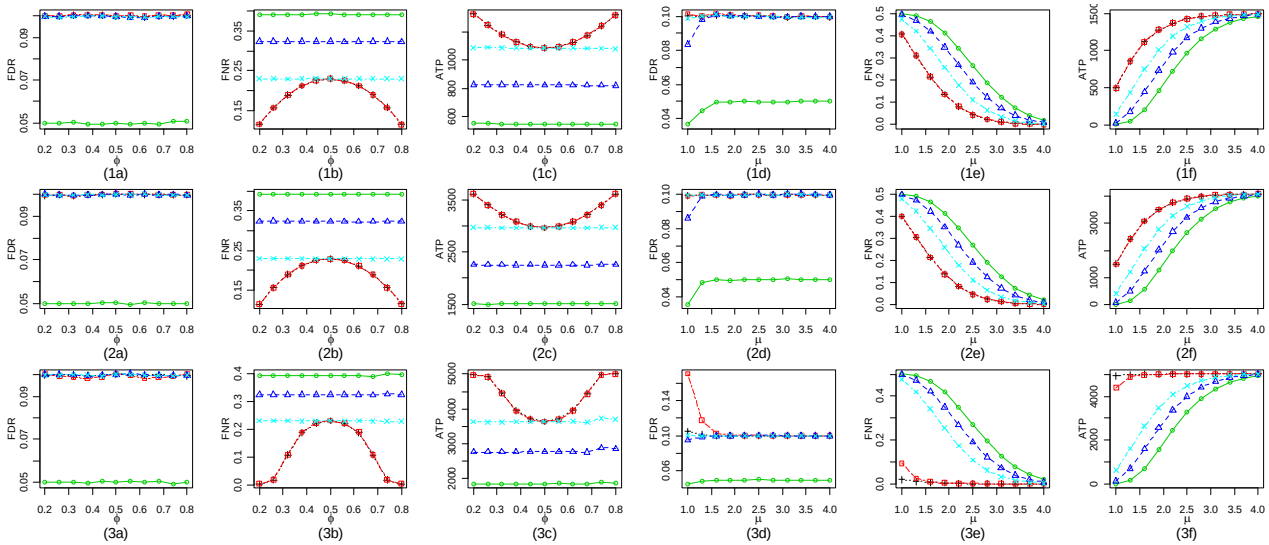

Figure 2: Comparison of BH(◯), AP(△), localFDR(×), OR (+), and LIS (□) in basic simulation 1: (1) chain-MRF, (2) tree-MRF, (3) grid-MRF; (a) FDR vs ϕ, (b) FNR vs ϕ, (c) ATP vs ϕ, (d) FDR vs μ, (e) FNR vs μ, (f) ATP vs μ.

(2a)-(2c) and (3a)-(3c), we set $\mu = 2$ and plot FDR, FNR and the average number of true positives (ATP) when we vary ϕ between 0.2 and 0.8. In Figures (1d)-(1f), (2d)-(2f) and (3d)-(3f), we set $\phi = 0.8$ and plot FDR, FNR and ATP when we vary μ between 1.0 and 4.0. The nominal FDR level is set to be 0.10. From Figure 2, we can observe comparable numerical results between the chain structure and tree structure. The FDR levels of all five procedures are controlled at 0.10 and BH is conservative. From the plots for FNR and ATP, we can observe that the data-driven procedure performs almost the same as the oracle procedure, and they dominate the p-value thresholding procedures BH and AP. The oracle procedure and the data-driven procedure also dominate localFDR except when $\phi = 0.5$, when they perform comparably. This is to be expected because the dependence structure is no longer informative when ϕ is 0.5. In this situation when the hypotheses are independent, our procedure reduces to the localFDR procedure. As ϕ departs from 0.5 and approaches either 0 or 1.0, the difference between OR/LIS and the baselines gets larger. When the individual hypotheses are easy to test (large μ values), the differences between them are not substantial. When we turn to the grid structure, the numerical performance is similar to that in the chain structure and the tree structure except for two observations. First, the data-driven procedure does not appear to control the FDR at 0.1 when μ is small (e.g. $\mu = 1.0$), although the oracle procedure does, which indicates the parameter estimation in the EM algorithm is difficult when μ is small. In other words, with a limited number of hypotheses, it is difficult to estimate the pairwise potential parameters if the test statistics of the non-nulls do not look much different from the test statistics of the nulls. The second observation is that the slopes of the FNR curve and ATP curve for the grid structure are different from those in the chain and tree structures. The reason is that the connectivity in the grid structure is higher than that in the chain and tree. Therefore we can observe that even when the individual hypotheses are difficult to test (small μ values), the FNR is still low because each individual hypothesis has more neighbors in the grid than in the chain or tree, and the neighbors are informative.

Figure 3 shows the numerical performance in basic simulation 2. Figures (1a)-(1f), (2a)-(2f), and (3a)-(3f) correspond to the chain structure, the tree structure and the grid structure respectively. In Figures (1a)-(1c), (2a)-(2c), and (3a-3c), we set $\mu = 2$ and vary $\Delta(\phi)$ between 0 and 0.4. In Figures (1d)-(1f), (2d)-(2f), and (3d)-(3f), we set $\phi = 0.8$ and vary $\Delta(\mu)$ between 0 and 4.0. Again, the nominal FDR level is set to be 0.10. From Figure 3, we observe that all five procedures control FDR at the nominal level and BH is conservative when the transition parameter ϕ is heterogeneous. However, the data-driven procedure becomes more and more conservative as we increase the variance of ϕ in the grid-structure. Nevertheless, the data-driven procedure does not lose much efficiency compared with the oracle procedure based on FNR and ATP. Both the data-driven procedure and the oracle procedure dominate the three baselines. When the μ parameter is heterogeneous, all five procedures

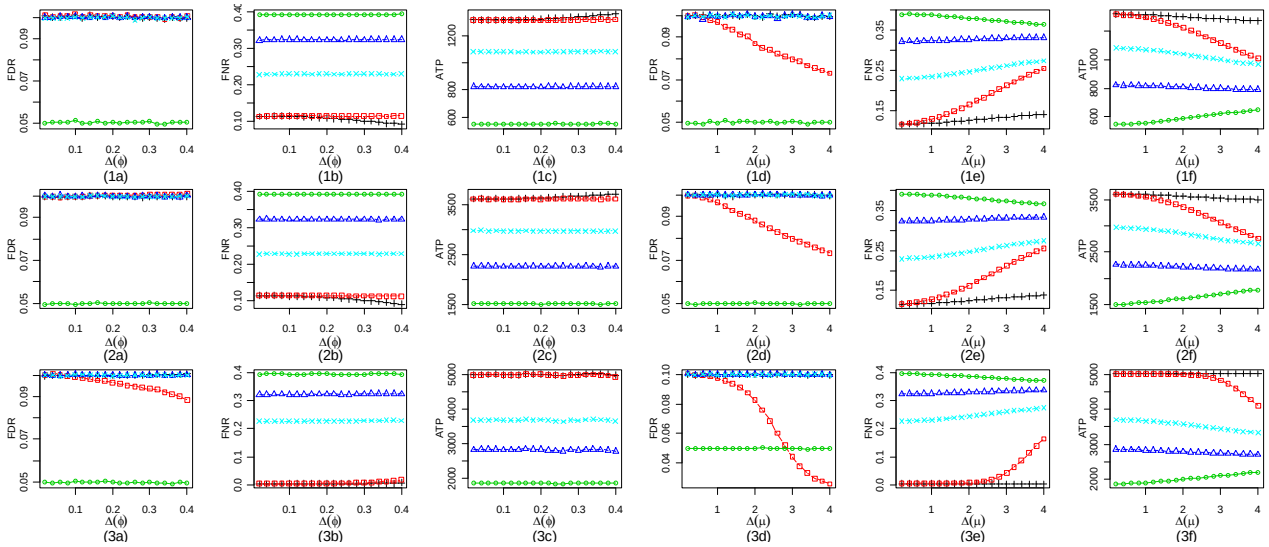

Figure 3: Comparison of BH(◯), AP(△), localFDR(×), OR (+), and LIS (□) in basic simulation 2: (1) chain-MRF, (2) tree-MRF, (3) grid-MRF; (a) FDR vs $\Delta(\phi)$, (b) FNR vs $\Delta(\phi)$, (c) ATP vs $\Delta(\phi)$, (d) FDR vs $\Delta(\mu)$, (e) FNR vs $\Delta(\mu)$, (f) ATP vs $\Delta(\mu)$.

are still valid, but the data-driven procedure becomes more and more conservative as we increase the variance of μ. The data-driven procedure can be more conservative than the BH procedure when $\Delta(\mu)$ is large enough. The conservativeness appears most severe in the grid-structure. However when we look at the FNR and ATP, the data-driven procedure still dominates BH, AP and localFDR substantially in all the situations, although the data-driven procedure loses a certain amount of efficiency compared with the oracle procedure when the variance of μ gets large.

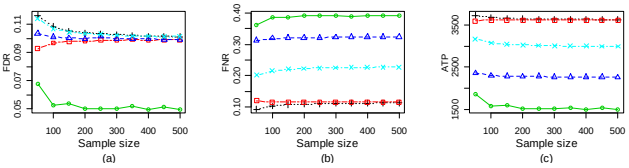

Figure 4: Comparing BH(◯), AP(△), localFDR(×), OR(+), and LIS(□) in basic simulation 3: (a)FDR vs n, (b)FNR vs n, (c)ATP vs n.

Figure 4 shows the results from basic simulation 3. The oracle procedure and localFDR are liberal when the sample size is small. This is because when the sample size is small, there exists a discrepancy between the true distribution of the test statistic and the limiting distribution. Quite surprisingly, the data-driven procedure stays valid. The reason is that the data-driven procedure can estimate the parameters from data. The data-driven procedure and the oracle procedure still have comparable performance and enjoy a much lower level of FNR compared with the baselines. For all the basic simulations, we set the nominal FDR level to be 0.10. We have also replicated the basic simulations by setting the nominal level to be 0.05, and similar conclusions can be made.

4 Simulations on Genetic Data

Unlike the fabricated dependence structures in the basic simulations in Section 3, the dependence structure in the simulations on genetic data in this section is real. We simulate the linkage disequilibrium structure of a segment on human chromosome 22, and treat a test of whether a SNP is associated as one individual test. We follow the simulation settings in the work of Wu et al. (2010). We use HAPGEN2 (Su et al., 2011) and the CEU sample of HapMap (The International HapMap Consortium, 2003) (Release 22) to generate SNP genotype data at each of the 2,420 loci between bp 14431347 and bp 17999745 on Chromosome 22. A total of 685 out of 2,420 SNPs can be genotyped with the Affymetrix 6.0 array. These are the typed SNPs that we use for our simulations. Within the overall 2,420 SNPs, we randomly select 10 SNPs to be the *causal* SNPs. All the SNPs on the Affymetrix 6.0 array whose r^2 values, according to HapMap, with any of the causal SNPs are above t are set to be the *associated* SNPs. In the simulations, we report results for three different t values, namely 0.8, 0.5 and 0.25. We also simulate three different genetic models (additive model, dominant model, and recessive model) with different levels of relative risk (1.2 and 1.3). In

total, we simulate 250 cases and 250 controls. The experiment is replicated for 100 times and the average result is provided. With the simulated data, we apply our multiple testing procedure (LIS) and three baseline procedures: the BH procedure, the adaptive p-value procedure (AP), and the local false discovery rate procedure (localFDR). Because the dependence structure is real and the ground truth parameters are unknown to us, we do not have the oracle procedure in the simulations on genetic data.

With the simulated genetic data, we use two commonly used tests in genetic association studies, namely two-proportion z-test and Cochran-Armitage's trend test (CATT) (Cochran, 1954; Armitage, 1955; Slager & Schaid, 2001; Freidlin et al., 2002) as the individual tests for the association of each SNP. CATT also yields an asymptotic $\mathcal{N}(0,1)$ under the null and $\mathcal{N}(\mu,1)$ under the alternative (μ is nonzero). Therefore, we parameterize $\boldsymbol{\psi} = (\mu_1, \sigma_1^2)$ where μ_1 and σ_1^2 are the mean and variance of the test statistics under alternative. The graph structure is built as follows. Each SNP becomes a node in the graph. For each SNP, we connect it with the SNP with the highest r^2 value with it. There are in total 490 edges in the graph. We further categorize the edges into a high correlation edge set $\mathcal{E}_h$ (r^2 above 0.8), medium correlation edge set $\mathcal{E}_m$ (r^2 between 0.5 and 0.8) and low correlation edge set $\mathcal{E}_l$ (r^2 between 0.25 and 0.5). We have three different parameters (ϕ_h, ϕ_m, and ϕ_l) for the three sets of edges. Then the density of $\boldsymbol{\theta}$ in formula (1) takes the form

$$P(\boldsymbol{\theta};\boldsymbol{\phi}) \propto \exp\{\sum_{(i,j)\in\mathcal{E}_h} \phi_h I(\theta_i=\theta_j) + \sum_{(i,j)\in\mathcal{E}_m} \phi_m I(\theta_i=\theta_j) + \sum_{(i,j)\in\mathcal{E}_l} \phi_l I(\theta_i=\theta_j)\}, \tag{3}$$

where $I(\theta_i=\theta_j)$ is an indicator variable that indicates whether θ_i and θ_j take the same value. In the MCMC algorithm, we run the Markov chain for $20,000$ iterations with a burn-in of 100 iterations. In the PCD algorithm, we generate 100 particles. In each iteration of PCD learning, the particles move forward for 5 iterations (the n parameter in PCD-n). The learning rate in PCD gradually decreases as suggested by Tieleman (2008). The EM algorithm converges after about 10 to 20 iterations, which usually take less than 10 minutes on a 3.00GHz CPU.

Figure 5 shows the performance of the procedures in the additive models with the homozygous relative risk set to 1.2 and 1.3. The test statistics are from a two-proportion z-test. We have also replicated the simulations on Cochran-Armitage's trend test, and the results are almost the same. In Figure 5, table (1) summarizes the empirical FDR and the total number of true positives (#TP) of our LIS procedure, BH, AP and localFDR (lfdr), in the additive models with different (homozygous) relative risk levels, when we vary t and when we vary the nominal FDR level α. We regard a SNP having r^2 above t with any causal SNP as an associated SNP, and we regard a rejection of the null hypothesis for an associated SNP as a true positive. Our LIS procedure and localFDR are valid while being conservative. BH and AP appear liberal in some of the configurations. In any of the circumstances, our LIS procedure can identify more associated SNPs than the baselines. We can find a clue to why our procedure LIS is being conservative from the results in Figure 3. In basic simulation 2, we observe that when the parameters μ and ϕ are heterogeneous and we carry out the data-driven procedure under the homogeneous parameter assumption, the data-driven procedure is conservative. The discrepancy between the nominal FDR level and the empirical FDR level increases as the parameters move further away from homogeneity. Although we assign three different parameters ϕ_h, ϕ_m, and ϕ_l to $\mathcal{E}_h$, $\mathcal{E}_m$ and $\mathcal{E}_l$ respectively, the edges within the same set (e.g. $\mathcal{E}_l$) may still be heterogeneous. The fact that the LIS procedure recaptures more true positives than the baselines while remaining more conservative in many configurations indicates that the local indices of significance provide a ranking more efficient than the ranking provided by the p-values from the individual tests. Therefore, we further plot the ROC curves and precision-recall (PR) curves when we rank SNPs by LIS and by the p-values from the two-proportion z-test. The ROC curve and PR curve are vertically averaged from 100 replications. Subfigures (2a)-(2f) are for the additive model with homozygous relative risk level set to be 1.2. Subfigures (3a)-(3f) are for the additive model with homozygous relative risk level set to be 1.3. It is observed that the curves from LIS dominate those from the p-values from individual tests in most places, which further suggests that LIS provides a more efficient ranking of the SNPs than the individual tests.

Figure 6 shows the performance of the procedures in the dominant model and the recessive model with the homozygous relative risk set to be 1.2. The test statistics are from a two-proportion z-test. In Figure 6, table (1) summarizes the empirical FDR and the total number of true positives (#TP) of our LIS procedure, BH, AP and localFDR (lfdr) in the dominant model and the recessive model when we vary t and when we vary the nominal FDR level α. Our LIS procedure and localFDR are valid while being conservative in all configurations, and they appear more conservative in the recessive model than in the dominant model. On the other hand, BH and AP appear liberal in the recessive model. Our LIS procedure still confers an advantage

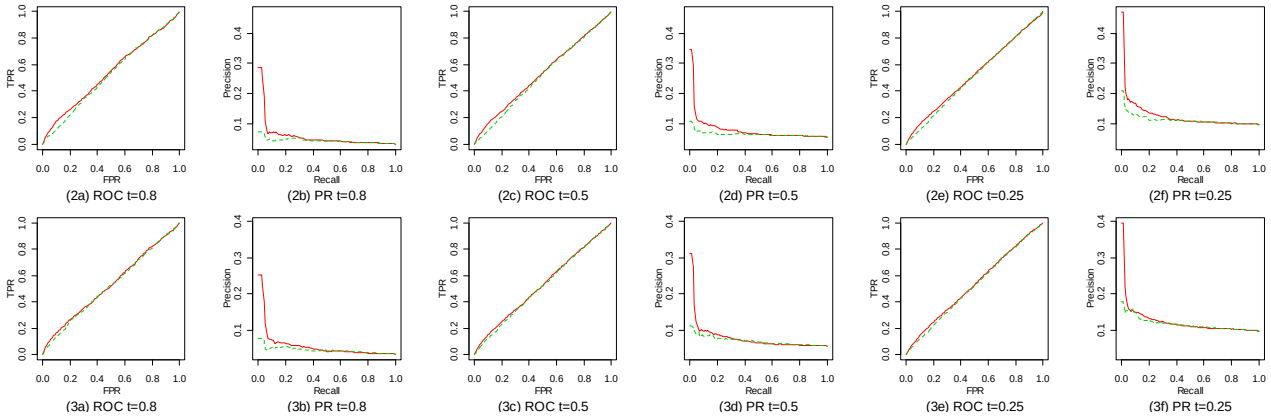

Figure 5: Comparison of BH, AP, localFDR and LIS in the additive models when we vary relative risk rr, t and the nominal FDR level α. Table (1) summarizes results. Subfigures (2a)-(2f) shows ROC and PR curves of LIS (solid red lines) and individual p-values (dashed green lines) with $rr = 1.2$. Subfigures (3a)-(3f) shows ROC and PR curves of LIS (solid red lines) and individual p-values (dashed green lines) with $rr = 1.3$.

over the baselines in the dominant model. The LIS procedure also recaptures almost the same number of true positives as BH and AP while maintaining a much lower FDR in the recessive model. Again, we further plot the ROC curves and precision-recall curves when we rank SNPs by LIS and by the p-values from individual tests. Subfigures (2a)-(2f) are for the dominant model. Subfigures (3a)-(3f) are for the recessive model. It is also observed that the curves from LIS dominate those from the p-values from individual tests in most places, which also suggests that LIS provides a more efficient ranking.

5 Real-world Application

Our primary GWAS dataset on breast cancer is from NCI's Cancer Genetics Markers of Susceptibility (CGEMS) (Hunter et al., 2007). 528,173 SNPs for 1,145 cases and 1,142 controls are genotyped on the Illumina HumanHap500 array. Our secondary GWAS dataset comes from Marshfield Clinic. The Personalized Medicine Research Project (McCarty et al., 2005), sponsored by Marshfield Clinic, was used as the sampling frame to identify 162 breast cancer cases and 162 controls. The project was reviewed and approved by the Marshfield Clinic IRB. Subjects were selected using clinical data from the Marshfield Clinic Cancer Registry and Data Warehouse. Cases were defined as women having a confirmed diagnosis of breast cancer. Both the cases and controls had to have at least one mammogram within 12 months prior to having a biopsy. The subjects also had DNA samples that were genotyped using the Illumina HumanHap660 array, as part of the eMERGE (electronic MEdical Records and Genomics) network by McCarty et al. (2011).

We apply our multiple testing procedure on the CGEMS data. The settings of the procedure are the same as in the simulations on genetic data in Section 4. The individual test is two-proportion z-test. Our procedure reports 32 SNPs with LIS value of 0.0 (an estimated probability 1.0 of being associated). We further calculate the per-allele odds-ratio of these SNPs on the Marshfield data, and 14 of them have an odds-ratio around 1.2 or above. The details about the 14 SNPs are given in supplementary material. There are two clusters among them. First, rs3870371, rs7830137 and rs920455 (on chromosome 8) locate near each other and near the gene hyaluronan synthase 2 (HAS2) which has been shown to be associated with invasive breast cancer by many studies (Udabage et al., 2005;

Li et al., 2007; Bernert et al., 2011). The other cluster includes rs11200014, rs2981579, rs1219648, and rs2420946 on chromosome 10. They are exactly the 4 SNPs reported by Hunter et al. (2007). Their associated gene FGFR2 is also well known to be associated with breast cancer. SNP rs4866929 on chromosome 5 is also very likely to be associated because it is highly correlated (r^2=0.957) with SNP rs981782 (not included in our data) which was identified from a much larger dataset (4,398 cases and 4,316 controls and a follow-up confirmation stage on 21,860 cases and 22,578 controls) by Easton et al. (2007).

6 Conclusion

In this paper, we use an MRF-coupled mixture model to leverage the dependence in multiple testing problems, and show the improved numerical performance on a variety of simulations and its applicability in a real-world GWAS problem. A theoretical question of interest is whether this graphical model based procedure is optimal in the sense that it has the smallest FNR among all the valid procedures. The optimality of the oracle procedure can be proved under the compound decision framework (Sun & Cai, 2007, 2009), as long as an exact inference algorithm exists or an approximate inference algorithm can be guaranteed to converge to the correct marginal probabilities. The asymptotic optimality of the data-driven procedure (the FNR yielded by the data-driven procedure approaches the FNR yielded by the oracle procedure as the number of tests $m \to \infty$) requires consistent estimates of the unknown parameters in the graphical models. Parameter learning in undirected models is more complicated than in directed models due to the normalization constant. To the best of our knowledge, asymptotic properties of parameter learning for hidden MRFs and MRF-coupled mixture models have not been investigated. Therefore, we cannot prove the asymptotic optimality of the data-driven procedure so far, although we can observe its close-to-oracle performance in the basic simulations.

Abstract

Variational inference algorithms such as belief propagation have had tremendous impact on our ability to learn and use graphical models, and give many insights for developing or understanding exact and approximate inference. However, variational approaches have not been widely adoped for *decision making* in graphical models, often formulated through influence diagrams and including both centralized and decentralized (or multi-agent) decisions. In this work, we present a general variational framework for solving structured cooperative decision-making problems, use it to propose several belief propagation-like algorithms, and analyze them both theoretically and empirically.

1 Introduction

Graphical modeling approaches, including Bayesian networks and Markov random fields, have been widely adopted for problems with complicated dependency structures and uncertainties. The problems of *learning*, i.e., estimating a model from data, and *inference*, e.g., calculating marginal probabilities or maximum *a posteriori* (MAP) estimates, have attracted wide attention and are well explored. Variational inference approaches have been widely adopted as a principled way to develop and understand many exact and approximate algorithms. On the other hand, the problem of *decision making* in graphical models, sometimes formulated via influence diagrams or decision networks and including both sequential centralized decisions and decentralized or multi-agent decisions, is surprisingly less explored in the approximate inference community.

Influence diagrams (ID), or *decision networks*, [Howard and Matheson, 1985, 2005] are a graphical model representation of structured decision problems under uncertainty; they can be treated as an extension of Bayesian networks, augmented with decision nodes and utility functions. Traditionally, IDs are used to model centralized, sequential decision processes under "perfect recall", which assumes that the decision steps are ordered in time and that all information is remembered across time; limited memory influence diagrams (LIMIDs) [Zhang et al., 1994, Lauritzen and Nilsson, 2001] relax the perfect recall assumption, creating a natural framework for representing decentralized and information-limited decision problems, such as team decision making and multi-agent systems. Despite the close connection and similarity to Bayes nets, IDs have less visibility in the graphical model and automated reseasoning community, both in terms of modeling and algorithm development; see Pearl [2005] for an interesting historical perspective.

Solving an ID refers to finding decision rules that maximize the expected utility function (MEU); this task is significantly more difficult than standard inference on a Bayes net. For IDs with perfect recall, MEU can be restated as a dynamic program, and solved with cost exponential in a constrained tree-width of the graph that is subject to the temporal ordering of the decision nodes. The constrained tree-width can be much higher than the tree-width associated with typical inference, making MEU significantly more complex. For LIMIDs, non-convexity issues also arise, since the limited shared information and simultaneous decisions may create locally optimal policies. The most popular algorithm for LIMIDs is based on policy-by-policy improvement [Lauritzen and Nilsson, 2001], and provides only a "person-by-person" notion of optimality. Surprisingly, the variational ideas that revolutionized inference in Bayes nets have not been adopted for influence diagrams. Although there exists work on transforming MEU problems into sequences of standard marginalization problems [e.g., Zhang, 1998], on which variational methods apply, these methods do not yield general frameworks, and usually only work for IDs with perfect recall. A full variational frame-

work would provide general procedures for developing efficient approximations such as loopy belief propagation (BP), that are crucial for large scale problems, or providing new theoretical analysis.

In this work, we propose a general variational framework for solving influence diagrams, both with and without perfect recall. Our results on centralized decision making include traditional inference in graphical models as special cases. We propose a spectrum of exact and approximate algorithms for MEU problems based on the variational framework. We give several optimality guarantees, showing that under certain conditions, our BP algorithm can find the globally optimal solution for ID with perfect recall and solve LIMIDs in a stronger locally optimal sense than coordinate-wise optimality. We show that a temperature parameter can also be introduced to smooth between MEU tasks and standard (easier) marginalization problems, and can provide good solutions by annealing the temperature or using iterative proximal updates.

This paper is organized as follows. Section 2 sets up background on graphical models, variational methods and influence diagrams. We present our variational framework of MEU in Section 3, and use it to develop several BP algorithms in Section 4. We present numerical experiments in Section 5. Finally, we discuss additional related work in Section 6 and concluding remarks in Section 7. Proofs and additional information can be found in the appendix.

2 Background

2.1 Graphical Models

Let $\boldsymbol{x} = \{x_1, x_2, \cdots, x_n\}$ be a random vector in $\mathbb{X} = \mathbb{X}_1 \times \cdots \times \mathbb{X}_n$. Consider a factorized probability on $\boldsymbol{x}$,

$$p(\boldsymbol{x}) = \frac{1}{Z} \prod_{\alpha \in \mathcal{I}} \psi_\alpha(x_\alpha) \;=\; \frac{1}{Z} \exp\Big[\sum_{\alpha \in \mathcal{I}} \theta_\alpha(x_\alpha) \Big],$$

where $\mathcal{I}$ is a set of variable subsets, and $\psi_\alpha : \mathbb{X}_\alpha \to \mathbb{R}^+$ are positive factors; the $\theta_\alpha(x_\alpha) = \log \psi_\alpha(x_\alpha)$ are the natural parameters of the exponential family representation; and $Z = \sum_{\boldsymbol{x}} \prod_{\alpha \in \mathcal{I}} \psi_\alpha$ is the normalization constant or partition function with $\Phi(\boldsymbol{\theta}) = \log Z$ the log-partition function. Let $\boldsymbol{\theta} = \{\theta_\alpha | \alpha \in \mathcal{I}\}$ and $\theta(\boldsymbol{x}) = \sum_\alpha \theta_\alpha(x_\alpha)$. There are several ways to represent a factorized distribution using graphs (i.e., *graphical models*), including Markov random fields, Bayesian networks, factors graphs and others.

Given a graphical model, *inference* refers to the procedure of answering probabilistic queries. Important inference tasks include marginalization, maximum *a posteriori* (MAP, sometimes called maximum probability of evidence or MPE), and marginal MAP (sometimes simply MAP). All these are NP-hard in general. Marginalization calculates the marginal probabilities of one or a few variables, or equivalently the normalization constant Z, while MAP/MPE finds the mode of the distribution. More generally, marginal MAP seeks the mode of a marginal probability,

$$\text{Marginal MAP:} \quad \boldsymbol{x}^* = \arg\max_{x_A} \sum_{x_B} \prod_{\alpha} \psi_\alpha(x_\alpha),$$

where A, B are disjoint sets with $A \cup B = V$; it reduces to marginalization if $A = \emptyset$ and to MAP if $B = \emptyset$.

Marginal Polytope. A marginal polytope $\mathbb{M}$ is a set of local marginals $\boldsymbol{\tau} = \{\tau_\alpha(x_\alpha) \colon \alpha \in \mathcal{I}\}$ that are extensible to a global distribution over $\boldsymbol{x}$, that is, $\mathbb{M} = \{\boldsymbol{\tau} | \; \exists \text{ a distribution } p(\boldsymbol{x}), \text{ s.t. } \sum_{x_{V \setminus \alpha}} p(\boldsymbol{x}) = \tau_\alpha(x_\alpha) \; \}$. Call $\mathcal{P}[\boldsymbol{\tau}]$ the set of global distributions consistent with $\boldsymbol{\tau} \in \mathbb{M}$; there exists a unique distribution in $\mathcal{P}[\boldsymbol{\tau}]$ that has maximum entropy and follows the exponential family form for some $\boldsymbol{\theta}$. We abuse notation to denote this unique global distribution $\tau(\boldsymbol{x})$.

A basic result for variational methods is that $\Phi(\boldsymbol{\theta})$ is convex and can be rewritten into a dual form,

$$\Phi(\boldsymbol{\theta}) = \max_{\boldsymbol{\tau} \in \mathbb{M}} \{ \langle \boldsymbol{\theta}, \boldsymbol{\tau} \rangle + H(\boldsymbol{x}; \boldsymbol{\tau}) \}, \tag{1}$$

where $\langle \boldsymbol{\theta}, \boldsymbol{\tau} \rangle = \sum_{\boldsymbol{x}} \sum_\alpha \theta_\alpha(x_\alpha) \tau_\alpha(x_\alpha)$ is the point-wise inner product, and $H(\boldsymbol{x}; \boldsymbol{\tau}) = -\sum_{\boldsymbol{x}} \tau(\boldsymbol{x}) \log \tau(\boldsymbol{x})$ is the entropy of distribution $\tau(\boldsymbol{x})$; the maximum of (1) is obtained when $\boldsymbol{\tau}$ equals the marginals of the original distribution with parameter $\boldsymbol{\theta}$. See Wainwright and Jordan [2008].

Similar dual forms hold for MAP and marginal MAP. Letting $\Phi_{A,B}(\boldsymbol{\theta}) = \log \max_{x_A} \sum_{x_B} \exp(\theta(\boldsymbol{x}))$, we have [Liu and Ihler, 2011]

$$\Phi_{A,B}(\boldsymbol{\theta}) = \max_{\boldsymbol{\tau} \in \mathbb{M}} \{ \langle \boldsymbol{\theta}, \boldsymbol{\tau} \rangle + H(x_B | x_A \,; \boldsymbol{\tau}) \}, \tag{2}$$

where $H(x_B | x_A \,; \boldsymbol{\tau}) = -\sum_{\boldsymbol{x}} \tau(\boldsymbol{x}) \log \tau(x_B | x_A)$ is the conditional entropy; its appearance corresponds to the sum operators.

The dual forms in (1) and (2) are no easier to compute than the original inference. However, one can approximate the marginal polytope $\mathbb{M}$ and the entropy in various ways, yielding a body of approximate inference algorithms, such as loopy belief propagation (BP) and its generalizations [Yedidia et al., 2005, Wainwright et al., 2005], linear programming solvers [e.g., Wainwright et al., 2003b], and recently hybrid message passing algorithms [Liu and Ihler, 2011, Jiang et al., 2011].

Junction Graph BP. Junction graphs provide a procedural framework to approximate the dual (1). A cluster graph is a triple $(\mathcal{G}, \mathcal{C}, \mathcal{S})$, where $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is an undirected graph, with each node $k \in \mathcal{V}$ associated

with a subset of variables $c_k \in \mathcal{C}$ (clusters), and each edge $(kl) \in \mathcal{E}$ a subset $s_{kl} \in \mathcal{S}$ (separator) satisfying $s_{kl} \subseteq c_k \cap c_l$. We assume that $\mathcal{C}$ subsumes the index set $\mathcal{I}$, that is, for any $\alpha \in \mathcal{I}$, there exists a $c_k \in \mathcal{C}$, denoted $c[\alpha]$, such that $\alpha \subseteq c_k$. In this case, we can reparameterize $\boldsymbol{\theta} = \{\theta_\alpha | \alpha \in \mathcal{I}\}$ into $\boldsymbol{\theta} = \{\theta_{c_k} | k \in \mathcal{V}\}$ by taking $\theta_{c_k} = \sum_{\alpha:\, c[\alpha]=c_k} \theta_\alpha$, without changing the distribution. A cluster graph is called a *junction graph* if it satisfies the *running intersection property* – for each $i \in V$, the induced sub-graph consisting of the clusters and separators that include i is a connected tree. A junction graph is a junction tree if $\mathcal{G}$ is tree.

To approximate the dual (1), we can replace $\mathbb{M}$ with a locally consistent polytope $\mathbb{L}$: the set of local marginals $\boldsymbol{\tau} = \{\tau_{c_k}, \tau_{s_{kl}} : k \in \mathcal{V}, (kl) \in \mathcal{E}\}$ satisfying $\sum_{x_{c_k \setminus s_{kl}}} \tau_{c_k}(x_{c_k}) = \tau(x_{s_{kl}})$. Clearly, $\mathbb{M} \subseteq \mathbb{L}$. We then approximate (1) by

$$\max_{\boldsymbol{\tau} \in \mathbb{L}} \{\langle \boldsymbol{\theta}, \boldsymbol{\tau} \rangle + \sum_{k \in \mathcal{V}} H(x_{c_k}; \boldsymbol{\tau}_{c_k}) - \sum_{(kl) \in \mathcal{E}} H(x_{s_{kl}}; \boldsymbol{\tau}_{s_{kl}})\},$$

where the joint entropy is approximated by a linear combination of the entropies of local marginals. The approximate objective can be solved using Lagrange multipliers [Yedidia et al., 2005], leading to a sum-product message passing algorithm that iteratively sends messages between neighboring clusters via

$$m_{k \to l}(x_{c_l}) \propto \sum_{x_{c_k \setminus s_{kl}}} \psi_{c_k}(x_{c_k}) m_{\sim k \setminus l}(x_{c_{\mathcal{N}(k)}}), \qquad (3)$$

where $\psi_{c_k} = \exp(\theta_{c_k})$, and $m_{\sim k \setminus l}$ is the product of messages into k from its neighbors $\mathcal{N}(k)$ except l. At convergence, the (locally) optimal marginals are

$$\tau_{c_k} \propto \psi_{c_k} m_{\sim k} \qquad \text{and} \qquad \tau_{s_{kl}} \propto m_{k \to l} m_{l \to k},$$

where $m_{\sim k}$ is the product of messages into k. Max-product and hybrid methods can be derived analogously for MAP and marginal MAP problems.

2.2 Influence Diagrams

Influence diagrams (IDs) or *decision networks* are extensions of Bayesian networks to represent structured decision problems under uncertainty. Formally, an influence diagram is defined on a directed acyclic graph $G = (V, E)$, where the nodes V are divided into two subsets, $V = R \cup D$, where R and D represent respectively the set of chance nodes and decision nodes. Each chance node $i \in R$ represents a random variable x_i with a conditional probability table $p_i(x_i | x_{\mathrm{pa}(i)})$. Each decision node $i \in D$ represents a controllable decision variable x_i, whose value is determined by a decision maker via a decision rule (or policy) $\delta_i : \mathbb{X}_{\mathrm{pa}(i)} \to \mathbb{X}_i$, which determines the values of x_i based on the observation on the values of $x_{\mathrm{pa}(i)}$; we call the collection

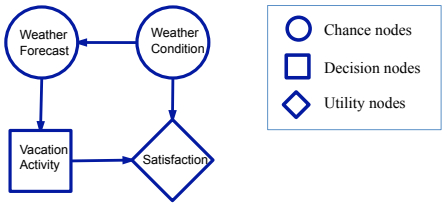

Figure 1: A simple influence diagram for deciding vacation activity [Shachter, 2007].

of policies $\boldsymbol{\delta} = \{\delta_i | i \in D\}$ a *strategy*. Finally, a utility function $u : \mathbb{X} \to \mathbb{R}^+$ measures the reward given an instantiation of $\boldsymbol{x} = [x_R, x_D]$, which the decision maker wants to maximize. It is reasonable to assume some decomposition structure on the utility $u(\boldsymbol{x})$, either additive, $u(\boldsymbol{x}) = \sum_{j \in U} u_j(x_{\beta_j})$, or multiplicative, $u(\boldsymbol{x}) = \prod_{j \in U} u_j(x_{\beta_j})$. A decomposable utility function can be visualized by augmenting the DAG with a set of leaf nodes U, called *utility nodes*, each with parent set β_j. See Fig. 1 for a simple example.

A decision rule δ_i is alternatively represented as a deterministic conditional "probability" $p_i^\delta(x_i | x_{\mathrm{pa}(i)})$, where $p_i^\delta(x_i | x_{\mathrm{pa}(i)}) = 1$ for $x_i = \delta_i(x_{\mathrm{pa}(i)})$ and zero otherwise. It is helpful to allow *soft decision rules* where $p_i^\delta(x_i | x_{\mathrm{pa}(i)})$ takes fractional values; these define a *randomized strategy* in which x_i is determined by randomly drawing from $p_i^\delta(x_i | x_{\mathrm{pa}(i)})$. We denote by Δ^o the set of deterministic strategies and Δ the set of randomized strategies. Note that Δ^o is a discrete set, while Δ is its convex hull.

Given an influence diagram, the optimal strategy should maximize the *expected utility function* (MEU):

$$\begin{aligned} \mathrm{MEU} &= \max_{\boldsymbol{\delta} \in \Delta} \mathrm{EU}(\boldsymbol{\delta}) = \max_{\boldsymbol{\delta} \in \Delta} \mathbb{E}(u(\boldsymbol{x}) | \boldsymbol{\delta}) \\ &= \max_{\boldsymbol{\delta} \in \Delta} \sum_{\boldsymbol{x}} u(\boldsymbol{x}) \prod_{i \in C} p_i(x_i | x_{\mathrm{pa}(i)}) \prod_{i \in D} p_i^\delta(x_i | x_{\mathrm{pa}(i)}) \\ &\overset{def}{=} \max_{\boldsymbol{\delta} \in \Delta} \sum_{\boldsymbol{x}} \exp(\theta(\boldsymbol{x})) \prod_{i \in D} p_i^\delta(x_i | x_{\mathrm{pa}(i)}) \qquad (4) \end{aligned}$$

where $\theta(\boldsymbol{x}) = \log[u(\boldsymbol{x}) \prod_{i \in C} p_i(x_i | x_{\mathrm{pa}(i)})]$; we call the distribution $q(\boldsymbol{x}) \propto \exp(\theta(\boldsymbol{x}))$ the *augmented distribution* [Bielza et al., 1999]. The concept of the augmented distribution is critical since it completely specifies a MEU problem without the semantics of the influence diagram; hence one can specify $q(\boldsymbol{x})$ arbitrarily, e.g., via an undirected MRF, extending the definition of IDs. We can treat MEU as a special sort of "inference" on the augmented distribution, which as we will show, generalizes more common inference tasks.

In (4) we maximize the expected utility over Δ; this is equivalent to maximizing over Δ^o, since

Lemma 2.1. *For any ID,* $\max_{\boldsymbol{\delta} \in \Delta} EU(\boldsymbol{\delta}) = \max_{\boldsymbol{\delta} \in \Delta^o} EU(\boldsymbol{\delta})$.

Perfect Recall Assumption. The MEU problem can be solved in closed form if the influence diagram satisfies a *perfect recall assumption* (PRA) — there exists a "temporal" ordering over all the decision nodes, say $\{d_1, d_2, \cdots, d_m\}$, consistent with the partial order defined by the DAG G, such that every decision node observes all the earlier decision nodes and their parents, that is, $\{d_j\} \cup \mathrm{pa}(d_j) \subseteq \mathrm{pa}(d_i)$ for any $j < i$. Intuitively, PRA implies a centralized decision scenario, where a global decision maker sets all the decision nodes in a predefined order, with perfect memory of all the past observations and decisions.

With PRA, the chance nodes can be grouped by when they are observed. Let r_{i-1} $(i = 1, \ldots, m)$ be the set of chance nodes that are parents of d_i but not of any d_j for $j < i$; then both decision and chance nodes are ordered by $o = \{r_0, d_1, r_1, \cdots, d_m, r_m\}$. The MEU and its optimal strategy for IDs with PRA can be calculated by a sequential sum-max-sum rule,

$$\mathrm{MEU} = \sum_{x_{r_0}} \max_{x_{d_1}} \sum_{x_{r_1}} \cdots \max_{x_{d_m}} \sum_{x_{r_m}} \exp(\theta(\boldsymbol{x})), \qquad (5)$$

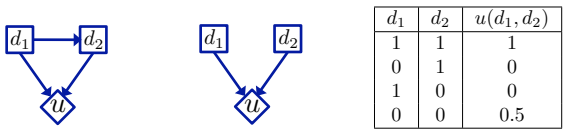
$$\delta^*_{d_i}(x_{\mathrm{pa}(d_i)}) = \arg\max_{x_{d_i}} \Big\{ \sum_{x_{r_i}} \cdots \max_{x_{d_m}} \sum_{x_{r_m}} \exp(\theta(\boldsymbol{x})) \Big\},$$

where the calculation is performed in reverse temporal ordering, interleaving marginalizing chance nodes and maximizing decision nodes. Eq. (5) generalizes the inference tasks in Section 2.1, arbitrarily interleaving the sum and max operators. For example, marginal MAP can be treated as a *blind decision problem*, where no chance nodes are observed by any decision nodes.

As in other inference tasks, the calculation of the sum-max-sum rule can be organized into local computations if the augmented distribution $q(\boldsymbol{x})$ is factorized. However, since the max and sum operators are not exchangeable, the calculation of (5) is restricted to elimination orders consistent with the "temporal ordering". Notoriously, this "constrained" tree-width can be very high even for trees. See Koller and Friedman [2009].

However, PRA is often unrealistic. First, most systems lack enough memory to express arbitrary policies over an entire history of observations. Second, many practical scenarios, like team decision analysis [Detwarasiti and Shachter, 2005] and decentralized sensor networks [Kreidl and Willsky, 2006], are distributed by nature: a team of agents makes decisions independently based on sharing limited information with their neighbors. In these cases, relaxing PRA is very important.

Imperfect Recall. General IDs with the perfect recall assumption relaxed are discussed in Zhang et al. [1994], Lauritzen and Nilsson [2001], Koller and Milch [2003], and are commonly referred as limited memory influence diagrams (LIMIDs). Unfortunately, the relaxation causes many difficulties. First, it is no longer possible to eliminate the decision nodes in a sequential "sum-max-sum" fashion. Instead, the dependencies of the decision nodes have cycles, formally discussed in Koller and Milch [2003] by defining a relevance graph over the decision nodes; the relevance graph is a tree with PRA, but is usually loopy with imperfect recall. Thus iterative algorithms are usually required for LIMIDs. Second and more importantly, the incomplete information may cause the agents to behave myopically, selfishly choosing locally optimal strategies due to ignorance of the global statistics. This breaks the strategy space into many local modes, making the MEU problem non-convex; see Fig. 2 for an illustration.



(a) Perfect Recall (b) Imperfect Recall

d_1	d_2	$u(d_1, d_2)$
1	1	1
0	1	0
1	0	0
0	0	0.5

(c) Utility Function

Figure 2: Illustrating imperfect recall. In (a) d_2 observes d_1; its optimal decision rule is to equal d_1's state (whatever it is); knowing d_2 will follow, d_1 can choose $d_1 = 1$ to achieve the global optimum. In (b) d_1 and d_2 do not know the other's states; both $d_1 = d_2 = 1$ and $d_1 = d_2 = 0$ (suboptimal) become locally optimal strategies and the problem is multi-modal.

The most popular algorithms for LIMIDs are based on policy-by-policy improvement, e.g., the *single policy update* (SPU) algorithm [Lauritzen and Nilsson, 2001] sequentially optimizes δ_i with $\boldsymbol{\delta}_{\neg i} = \{\delta_j : j \neq i\}$ fixed:

$$\delta_i(x_{\mathrm{pa}(i)}) \leftarrow \arg\max_{x_i} \mathbb{E}(u(\boldsymbol{x})|x_{\mathrm{fam}(i)}\,; \boldsymbol{\delta}_{\neg i}), \qquad (6)$$

$$\mathbb{E}(u(\boldsymbol{x})|x_{\mathrm{fam}(i)}; \boldsymbol{\delta}_{\neg i}) = \sum_{x_{\neg \mathrm{fam}(i)}} \exp(\theta(\boldsymbol{x})) \prod_{j \in D \setminus \{i\}} p^{\delta}_j(x_j|x_{\mathrm{pa}(j)}),$$

where $\mathrm{fam}(i) = \{i\} \cup \mathrm{pa}(i)$. The update circles through all $i \in D$ in some order, and ties are broken arbitrarily in case of multiple maxima. The expected utility in SPU is non-decreasing at each iteration, and it gives a locally optimal strategy at convergence in the sense that the expected utility can not be improved by changing any single node's policy. Unfortunately, SPU's solution is heavily influenced by initialization and can be very suboptimal.

This issue is helped by generalizing SPU to the strategy improvement (SI) algorithm [Detwarasiti and Shachter, 2005], which simultaneously updates subgroups of decisions nodes. However, the time and space complexity of SI grows exponentially with the sizes of subgroups. In the sequel, we present a novel variational framework for MEU, and propose BP-like algorithms that go beyond the naïve greedy paradigm.

3 Duality Form of MEU

In this section, we derive a duality form for MEU, generalizing the duality results of the standard inference in Section 2.1. Our main result is summarized in the following theorem.

Theorem 3.1. *(a). For an influence diagram with augmented distribution $q(\boldsymbol{x}) \propto \exp(\theta(\boldsymbol{x}))$, its log maximum expected utility* $\log \mathrm{MEU}(\boldsymbol{\theta})$ *equals*

$$\max_{\boldsymbol{\tau}\in\mathbb{M}}\{\langle\boldsymbol{\theta},\boldsymbol{\tau}\rangle + H(\boldsymbol{x};\boldsymbol{\tau}) - \sum_{i\in D} H(x_i|x_{\mathrm{pa}(i)};\boldsymbol{\tau})\}. \quad (7)$$

Suppose $\boldsymbol{\tau}^*$ is a maximum of (7), then $\boldsymbol{\delta}^* = \{\boldsymbol{\tau}^*(x_i|x_{\mathrm{pa}(i)})|i\in D\}$ is an optimal strategy.

(b). For IDs with perfect recall, (7) reduces to

$$\max_{\boldsymbol{\tau}\in\mathbb{M}}\{\langle\boldsymbol{\theta},\boldsymbol{\tau}\rangle + \sum_{o_i\in C} H(x_{o_i}|x_{o_{1:i-1}};\boldsymbol{\tau})\}, \quad (8)$$

where o is the temporal ordering of the perfect recall.

Proof. (a) See appendix; (b) note PRA implies $\mathrm{pa}(i) = o_{1:i-1}$ $(i\in D)$, and apply the entropy chain rule. □

The distinction between (8) and (7) is subtle but important: although (8) (with perfect recall) is always (if not strictly) a convex optimization, (7) (without perfect recall) may be non-convex if the subtracted entropy terms overwhelm; this matches the intuition that incomplete information sharing gives rise to multiple locally optimal strategies.

The MEU duality (8) for ID with PRA generalizes earlier duality results of inference: with no decision nodes, $D = \emptyset$ and (8) reduces to (1) for the log-partition function; when $C = \emptyset$, no entropy terms appear and (8) reduces to the linear program relaxation of MAP. Also, (8) reduces to marginal MAP when no chance nodes are observed before any decision. As we show in Section 4, this unification suggests a line of unified algorithms for all these different inference tasks.

Several corollaries provide additional insights.

Corollary 3.2. *For an ID with parameter $\boldsymbol{\theta}$, we have*

$$\log \mathrm{MEU} = \max_{\boldsymbol{\tau}\in\mathbb{I}}\{\langle\boldsymbol{\theta},\boldsymbol{\tau}\rangle + \sum_{o_i\in C} H(x_{o_i}|x_{o_{1:i-1}};\boldsymbol{\tau})\} \quad (9)$$

where $\mathbb{I} = \{\boldsymbol{\tau}\in\mathbb{M}\colon x_{o_i} \perp x_{o_{1:i-1}\setminus\mathrm{pa}(o_i)}|x_{\mathrm{pa}(o_i)}, \forall o_i \in D\}$, corresponding to those distributions that respect the imperfect recall constraints; "$x \perp y\,|\,z$" denotes conditional independence of x and y given z.

Corollary 3.2 gives another intuitive interpretation of imperfect recall vs. perfect recall: MEU with imperfect recall optimizes same objective function, but over a subset of the marginal polytope that restricts the observation domains of the decision rules; this non-convex inner subset is similar to the mean field approximation for partition functions. See Wolpert [2006] for a similar connection to mean field for bounded rational game theory. Interestingly, this shows that extending a LIMID to have perfect recall (by extending the observation domains of the decision nodes) can be considered a "convex" relaxation of the LIMID.

Corollary 3.3. *For any ϵ, if $\boldsymbol{\tau}^*$ is global optimum of*

$$\max_{\boldsymbol{\tau}\in\mathbb{M}}\{\langle\boldsymbol{\theta},\boldsymbol{\tau}\rangle + H(\boldsymbol{x}) - (1-\epsilon)\sum_{i\in D} H(x_i|x_{\mathrm{pa}(i)})\}. \quad (10)$$

and $\boldsymbol{\delta}^* = \{\tau^*(x_i|x_{\mathrm{pa}(i)})|i\in D\}$ is a deterministic strategy, then it is an optimal strategy for MEU.

The parameter ϵ is a temperature to "anneal" the MEU problem, and trades off convexity and optimality. For large ϵ, e.g., $\epsilon \geq 1$, the objective in (10) is a strictly convex function, while $\boldsymbol{\delta}^*$ is unlikely to be deterministic nor optimal (if $\epsilon = 1$, (10) reduces to standard marginazation); as ϵ decreases towards zero, $\boldsymbol{\delta}^*$ becomes more deterministic, but (10) becomes more non-convex and is harder to solve. In Section 4 we derive several possible optimization approaches.

4 Algorithms

The duality results in Section 3 offer new perspectives for MEU, allowing us to bring the tools of variational inference to develop new efficient algorithms. In this section, we present a junction graph framework for BP-like MEU algorithms, and provide theoretical analysis. In addition, we propose two double-loop algorithms that alleviate the issue of non-convexity in LIMIDs or provide convergence guarantees: a deterministic annealing approach suggested by Corollary 3.3 and a method based on the proximal point algorithm.

4.1 A Belief Propagation Algorithm

We start by formulating the problem (7) into the junction graph framework. Let $(\mathcal{G},\mathcal{C},\mathcal{S})$ be a junction graph for the augmented distribution $q(\boldsymbol{x}) \propto \exp(\theta(\boldsymbol{x}))$. For each decision node $i \in D$, we associate it with exactly one cluster $c_k \in \mathcal{C}$ satisfying $\{i, \mathrm{pa}(i)\} \subseteq c_k$; we call such a cluster a *decision cluster*. The clusters $\mathcal{C}$ are thus partitioned into decision clusters $\mathcal{D}$ and the other (normal) clusters $\mathcal{R}$. For simplicity, we assume each decision cluster $c_k \in \mathcal{D}$ is associated with exactly one decision node, denoted d_k.

Following the junction graph framework in Section 2.1, the MEU dual (10) (with temperature parameter ϵ) is

approximated by

$$\max_{\boldsymbol{\tau}\in\mathbb{L}}\{\langle\boldsymbol{\theta},\boldsymbol{\tau}\rangle+\sum_{k\in\mathcal{R}}H_{c_k}+\sum_{k\in\mathcal{D}}H^{\epsilon}_{c_k}-\sum_{(kl)\in\mathcal{E}}H_{s_{kl}}\},\quad(11)$$

where $H_{c_k}=H(x_{c_k})$, $H_{s_{kl}}=H(x_{s_{kl}})$ and $H^{\epsilon}(x_{c_k})=H(x_{c_k})-(1-\epsilon)H(x_{d_k}|x_{\mathrm{pa}(d_k)})$. The dependence of entropies on $\boldsymbol{\tau}$ is suppressed for compactness. Eq. (11) is similar to the objective of regular sum-product junction graph BP, except the entropy terms of the decision clusters are replaced by $H^{\epsilon}_{c_k}$.

Using a Lagrange multiplier method similar to Yedidia et al. [2005], a hybrid message passing algorithm can be derived for solving (11):

Sum messages: (normal clusters)
$$m_{k\to l}\propto\sum_{x_{c_k\setminus s_{kl}}}\psi_{c_k}m_{\sim k\setminus l},\quad(12)$$

MEU messages: (decision clusters)
$$m_{k\to l}\propto\sum_{x_{c_k\setminus s_{kl}}}\frac{\sigma_k[\psi_{c_k}m_{\sim k};\epsilon]}{m_{l\to k}},\quad(13)$$

where $\sigma_k[\cdot]$ is an operator that solves an annealed local MEU problem associated with $b(x_{c_k})\propto\psi_{c_k}m_{\sim k}$:

$$\sigma_k[b(x_{c_k});\epsilon]\overset{def}{=}b(x_{c_k})b_\epsilon(x_{d_k}|x_{\mathrm{pa}(d_k)})^{1-\epsilon}$$

where $b_\epsilon(x_{d_k}|x_{\mathrm{pa}(d_k)})$ is the "annealed" optimal policy

$$b_\epsilon(x_{d_k}|x_{\mathrm{pa}(d_k)})=\frac{b(x_{d_k},x_{\mathrm{pa}(d_k)})^{1/\epsilon}}{\sum_{x_{d_k}}b(x_{d_k},x_{\mathrm{pa}(d_k)})^{1/\epsilon}},$$

$$b(x_{d_k},x_{\mathrm{pa}(d_k)})=\sum_{x_{z_k}}b(x_{c_k}),\qquad z_k=c_k\setminus\{d_k,\mathrm{pa}(d_k)\}.$$

As $\epsilon\to0^+$, one can show that $b_\epsilon(x_{d_k}|x_{\mathrm{pa}(d_k)})$ is exactly an optimal strategy of the local MEU problem with augmented distribution $b(x_{c_k})$.

At convergence, the stationary point of (11) is:

$$\tau_{c_k}\propto\psi_{c_k}m_{\sim k}\quad\textit{for normal clusters}\quad(14)$$
$$\tau_{c_k}\propto\sigma_k[\psi_{c_k}m_{\sim k};\epsilon]\quad\textit{for decision clusters}\quad(15)$$
$$\tau_{s_{kl}}\propto m_{k\to l}m_{l\to k}\quad\textit{for separators}\quad(16)$$

This message passing algorithm reduces to sum-product BP when there are no decision clusters. The outgoing messages from decision clusters are the crucial ingredient, and correspond to solving local (annealed) MEU problems.

Taking $\epsilon\to0^+$ in the MEU message update (13) gives a fixed point algorithm for solving the original objective directly. Alternatively, one can adopt a deterministic annealing approach [Rose, 1998] by gradually decreasing ϵ, e.g., taking $\epsilon^t=1/t$ at iteration t.

Reparameterization Properties. BP algorithms, including sum-product, max-product, and hybrid message passing, can often be interpreted as reparameterization operators, with fixed points satisfying some sum (resp. max or hybrid) consistency property yet leaving the joint distribution unchanged [e.g., Wainwright et al., 2003a, Weiss et al., 2007, Liu and Ihler, 2011]. We define a set of "MEU-beliefs" $\boldsymbol{b}=\{b(x_{c_k}),b(x_{s_{kl}})\}$ by $b(x_{c_k})\propto\psi_{c_k}m_k$ for all $c_k\in\mathcal{C}$, and $b(x_{s_{kl}})\propto m_{k\to l}m_{l\to k}$; note that the "beliefs" $\boldsymbol{b}$ are distinguished from the "marginals" $\boldsymbol{\tau}$. We can show that at each iteration of MEU-BP in (12)-(13), the $\boldsymbol{b}$ satisfy

$$\textbf{Reparameterization:}\quad q(\boldsymbol{x})\propto\frac{\prod_{k\in\mathcal{V}}b(x_{c_k})}{\prod_{(kl)\in\mathcal{E}}b(x_{s_{kl}})},\quad(17)$$

and further, at a fixed point of MEU-BP we have

$$\textbf{Sum-consistency:}\ \text{(normal clusters)}\quad\sum_{c_k\setminus s_{ij}}b(x_{c_k})=b(x_{s_{kl}}),\quad(18)$$

$$\textbf{MEU-consistency:}\ \text{(decision clusters)}\quad\sum_{c_k\setminus s_{ij}}\sigma_k[b(x_{c_k});\epsilon]=b(x_{s_{kl}}).\quad(19)$$

Optimality Guarantees. Optimality guarantees of MEU-BP (with $\epsilon\to0^+$) can be derived via reparameterization. Our result is analogous to those of Weiss and Freeman [2001] for max-product BP and Liu and Ihler [2011] for marginal-MAP.

For a junction tree, a tree-order is a partial ordering on the nodes with $k\preceq l$ iff the unique path from a special cluster (called root) to l passes through k; the parent $\pi(k)$ is the unique neighbor of k on the path to the root. Given a subset of decision nodes D', a junction tree is said to be *consistent* for D' if there exists a tree-order with $s_{k,\pi(k)}\subseteq\mathrm{pa}(d_k)$ for any $d_k\in D'$.

Theorem 4.1. *Let $(\mathcal{G},\mathcal{C},\mathcal{S})$ be a consistent junction tree for a subset of decision nodes D', and $\boldsymbol{b}$ be a set of MEU-beliefs satisfying the reparameterization and consistency conditions (17)-(19) with $\epsilon\to0^+$. Let $\boldsymbol{\delta}^*=\{b_{c_k}(x_{d_k}|x_{\mathrm{pa}(d_k)})\colon d_k\in D\}$; then $\boldsymbol{\delta}^*$ is a locally optimal strategy in the sense that $\mathrm{EU}(\{\boldsymbol{\delta}^*_{D'},\boldsymbol{\delta}_{D\setminus D'}\})\le\mathrm{EU}(\boldsymbol{\delta}^*)$ for any $\boldsymbol{\delta}_{D\setminus D'}$.*

A junction tree is said to be *globally* consistent if it is consistent for all the decision nodes, which as implied by Theorem 4.1, ensures a globally optimal strategy; this notation of *global consistency* is similar to the *strong junction trees* in Jensen et al. [1994]. For IDs with perfect recall, a globally consistent junction tree can be constructed by a standard procedure which triangulates the DAG of the ID along reverse temporal order. For IDs without perfect recall, it is usually not possible to construct a globally consistent junction tree; this is the case for the toy example in Fig. 2b. However, coordinate-wise optimality follows as a consequence of Theorem 4.1 for general IDs with arbitrary junction trees, indicating that MEU-BP is at least as "optimal" as SPU.

Theorem 4.2. *Let $(\mathcal{G}, \mathcal{C}, \mathcal{S})$ be an arbitrary junction tree, and $\boldsymbol{b}$ and $\boldsymbol{\delta}^*$ defined in Theorem 4.1. Then $\boldsymbol{\delta}^*$ is a locally person-by-person optimal strategy: $\mathrm{EU}(\{\boldsymbol{\delta}_i^*, \boldsymbol{\delta}_{D\setminus i}\}) \leq \mathrm{EU}(\boldsymbol{\delta}^*)$ for any $i \in D$ and $\boldsymbol{\delta}_{D\setminus i}$.*

Additively Decomposable Utilities. Our algorithms rely on the factorization structure of the augmented distribution $q(\boldsymbol{x})$. For this reason, multiplicative utilities fit naturally, but additive utilities are more difficult (as they also are in exact inference) [Koller and Friedman, 2009]. To create factorization structure in additive utility problems, we augment the model with a latent "selector" variable, similar to that in mixture models. For details, see the appendix.

4.2 Proximal Algorithms

In this section, we present a proximal point approach [e.g., Martinet, 1970, Rockafellar, 1976] for the MEU problems. Similar methods have been applied to standard inference problems, e.g., Ravikumar et al. [2010].

We start with a brief introduction to the proximal point algorithm. Consider an optimization problem $\min_{\boldsymbol{\tau}\in\mathbb{M}} f(\boldsymbol{\tau})$. A proximal method instead iteratively solves a sequence of "proximal" problems

$$\boldsymbol{\tau}^{t+1} = \arg\min_{\boldsymbol{\tau}\in\mathbb{M}} \{f(\boldsymbol{\tau}) + w^t D(\boldsymbol{\tau}||\boldsymbol{\tau}^t)\}, \qquad (20)$$

where $\boldsymbol{\tau}^t$ is the solution at iteration t and w^t is a positive coefficient. $D(\cdot||\cdot)$ is a distance, called the proximal function; typical choices are Euclidean or Bregman distances or ψ-divergences [e.g., Teboulle, 1992, Iusem and Teboulle, 1993]. Convergence of proximal algorithms has been well studied: the objective series $\{f(\boldsymbol{\tau}^t)\}$ is guaranteed to be non-increasing at each iteration, and $\{\boldsymbol{\tau}^t\}$ converges to an optimal solution (sometimes superlinearly) for convex programs, under some regularity conditions on the coefficients $\{w^t\}$. See, e.g., Rockafellar [1976], Tseng and Bertsekas [1993], Iusem and Teboulle [1993].

Here, we use an entropic proximal function that naturally fits the MEU problem:

$$D(\boldsymbol{\tau}||\boldsymbol{\tau}') = \sum_{i\in D}\sum_{\boldsymbol{x}} \tau(\boldsymbol{x}) \log[\tau_i(x_i|x_{\mathrm{pa}(i)})/\tau_i'(x_i|x_{\mathrm{pa}(i)})],$$

a sum of conditional KL-divergences. The proximal update for the MEU dual (7) then reduces to

$$\boldsymbol{\tau}^{t+1} = \arg\max_{\boldsymbol{\tau}\in\mathbb{M}} \{\langle \boldsymbol{\theta}^t, \boldsymbol{\tau}\rangle + H(\boldsymbol{x}) - (1-w^t) H(x_i|x_{\mathrm{pa}(i)})\}$$

where $\theta^t(\boldsymbol{x}) = \theta(\boldsymbol{x}) + w^t \sum_{i\in D} \log \tau_i^t(x_i|x_{\mathrm{pa}(i)})$. This has the same form as the annealed problem (10) and can be solved by the message passing scheme (12)-(13). Unlike annealing, the proximal algorithm updates $\boldsymbol{\theta}^t$ each iteration and does not need w^t to approach zero.

We use two choices of coefficients $\{w^t\}$: (1) $w^t = 1$ (*constant*), and (2) $w^t = 1/t$ (*harmonic*). The choice $w^t = 1$ is especially interesting because the proximal update reduces to a standard *marginalization* problem, solvable by standard tools without the MEU's temporal elimination order restrictions. Concretely, the proximal update in this case reduces to

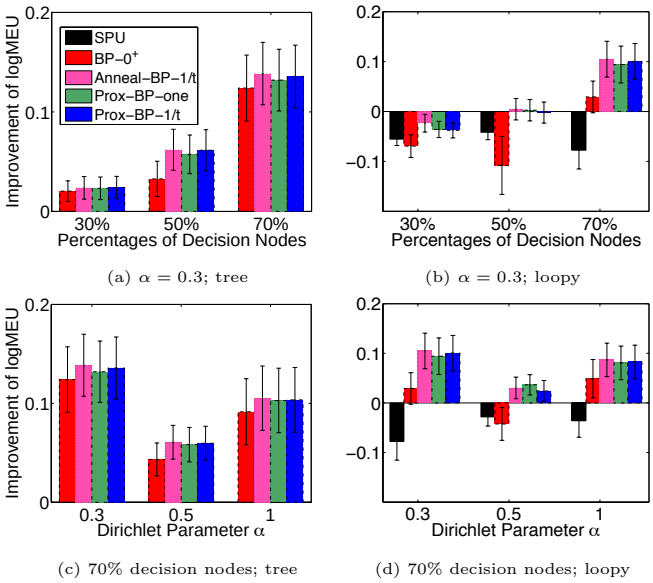
$$\tau_i^{t+1}(x_i|x_{\mathrm{pa}(i)}) \propto \tau_i^t(x_i|x_{\mathrm{pa}(i)}) \mathbb{E}(u(\boldsymbol{x})|x_{\mathrm{fam}(i)}\,;\, \boldsymbol{\delta}_{\neg i}^n)$$

with $\mathbb{E}(u(\boldsymbol{x})|x_{\mathrm{fam}(i)}\,;\, \boldsymbol{\delta}_{\neg i}^n)$ as defined in (6). This proximal update can be seen as a "soft" and "parallel" version of the greedy update (6), which makes a hard update at a single decision node, instead of a soft modification simutaneously for all decision nodes. The soft update makes it possible to correct earlier suboptimal choices and allows decision nodes to make cooperative movements. However, convergence with $w^t = 1$ may be slow; using $w^t = 1/t$ takes larger steps but is no longer a standard marginalization.

5 Experiments

We demonstrate our algorithms on several influence diagrams, including randomly generated IDs, large scale IDs constructed from problems in the UAI08 inference challenge, and finally practically motivated IDs for decentralized detection in wireless sensor networks. We find that our algorithms typically find better solutions than SPU with comparable time complexity; for large scale problems with many decision nodes, our algorithms are more computationally efficient than SPU because one step of SPU requires updating (6) (a global expectation) for all the decision nodes.

In all experiments, we test single policy updating (`SPU`), our MEU-BP running directly at zero temperature (`BP-0`$^+$), annealed BP with temperature $\epsilon^t = 1/t$ (`Anneal-BP-1/t`), and the proximal versions with $w^t = 1$ (`Prox-BP-one`) and $w^t = 1/t$ (`Prox-BP-1/t`). For the BP-based algorithms, we use two constructions of junction graphs: a standard junction tree by triangulating the DAG in backwards topological order, and a loopy junction graph following [Mateescu et al., 2010] that corresponds to Pearl's loopy BP; for SPU, we use the same junction graphs to calculate the inner update (6). The junction trees ensure the inner updates of `SPU` and `Prox-BP-one` are performed exactly, and has optimality guarantees in Theorem 4.1, but may be computationally more expensive than the loopy junction graphs. For the proximal versions, we set a maximum of 5 iterations in the inner loop; changing this value did not seem to lead to significantly different results. The BP-based algorithms may return non-deterministic strategies; we round to deterministic strategies by taking the largest values.



(a) $\alpha = 0.3$; tree (b) $\alpha = 0.3$; loopy

(c) 70% decision nodes; tree (d) 70% decision nodes; loopy

Figure 3: Results on random IDs of size 20. The y-axes show the log MEU of each algorithm compared to SPU on a junction tree. The left panels correspond to running the algorithms on junction trees, and right panels on loopy junction graphs. (a) & (b) shows MEUs as the percentage of decision nodes changes. (c) & (d) show MEUs v.s. the Dirichlet parameter α. The results are averaged on 20 random models.

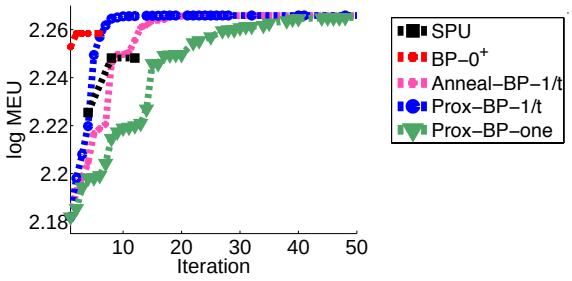


Figure 4: A typical trajectory of MEU (of the rounded deterministic strategies) v.s. iterations for the random IDs in Fig. 3. One iteration of the BP-like methods denotes a forward-backward reduction on the junction graph; One step of SPU requires $|D|$ (number of decision nodes) reductions. SPU and BP−0+ are stuck at a local model in the 2nd iteration.

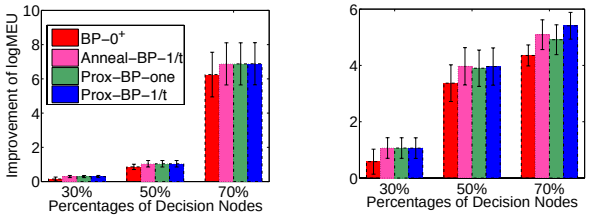


(a). Diagnostic BN 1 (b). Diagnostic BN 2

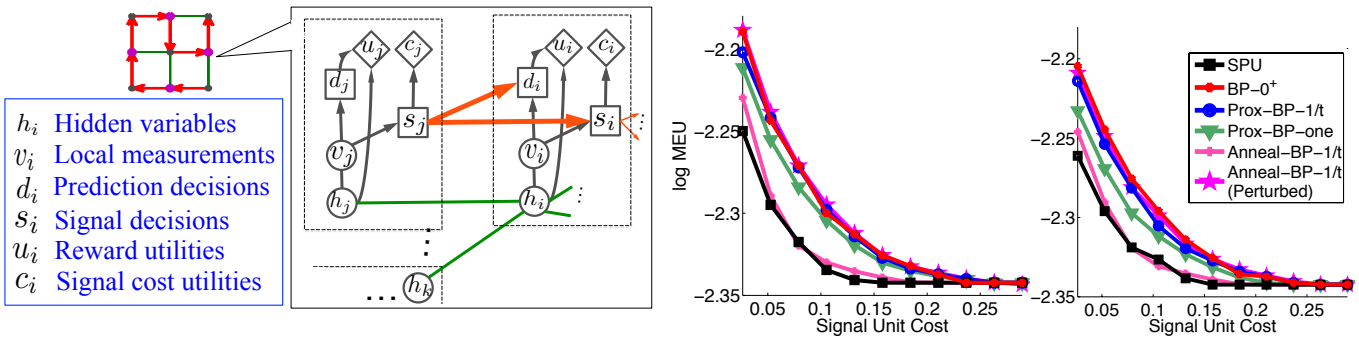
Figure 5: Results on IDs constructed from two diagnostic BNs from the UAI08 challenge. Here all algorithms used the loopy junction graph and are initialized uniformly. (a)-(b) the logMEU of algorithms normalized to that of SPU. Averaged on 10 trails.

Random Bayesian Networks. We test our algorithms on randomly constructed IDs with additive utilities. We first generate a set of random DAGs of size 20 with maximum parent size of 3. To create IDs, we take the leaf nodes to be utility nodes, and among non-leaf nodes we randomly select a fixed percentage to be decision nodes, with the others being chance nodes. We assume the chance and decision variables are discrete with 4 states. The conditional probability tables of the chance nodes are randomly drawn from a symmetric Dirichlet distribution $\mathrm{Dir}(\alpha)$, and the entries of the utility function from Gamma distribution $\Gamma(\alpha, 1)$.

The relative improvement of log MEU compared to the SPU with junction tree are reported in Fig. 3. We find that when using junction trees, all our BP-based methods dominate SPU; for loopy junction graphs, BP−0+ occasionally performs worse than SPU, but all the annealed and proximal algorithms outperform SPU with the same loopy junction graph, and often even SPU with junction tree. As the percentage of decision nodes increases, the improvement of the BP-based methods on SPU generally increases. Fig. 4 shows a typical trajectory of the algorithms across iterations. The algorithms were initialized uniformly; random initializations behaved similarly, but are omitted for space.

Diagnostic Bayesian networks. We construct larger scale IDs based on two diagnostic Bayes nets with 200-300 nodes and 300-600 edges, taken from the UAI08 inference challenge. To create influence diagrams, we made the leaf nodes utilities, each defined by its conditional probability when clamped to a randomly chosen state, and total utility as the product of the local utilities (multiplicatively decomposable). The set of decision nodes is again randomly selected among the non-leaf nodes with a fixed percentage. Since the network sizes are large, we only run the algorithms on the loopy junction graphs. Again, our algorithms significantly improve on SPU; see Fig. 5.

Decentralized Sensor Network. In this section, we test an influence diagram constructed for decentralized detection in wireless sensor networks [e.g., Viswanathan and Varshney, 1997, Kreidl and Willsky, 2006]. The task is to detect the states of a hidden process $p(h)$ (as a pairwise MRF) using a set of distributed sensors; each sensor provides a noisy measurement v_i of the local state h_i, and overall performance is boosted by allowing the sensor to transmit small (1-bit) signals s_i along an directional path, to



(a) The ID for sensor network detection (b) Junction tree (c) Loopy junction graph

Figure 6: (a) A sensor network on 3×3 grid; green lines denote the MRF edges of the hidden process $p(h)$, on some of which (red arrows) signals are allowed to pass; each sensor may be accurate (purple) or noisy (black). Optimal strategies should pass signals from accurate sensors to noisy ones but not the reverse. (b)-(c) The log MEU of algorithms running on (b) a junction tree and (c) a loopy junction graph. As the signal cost increases, all algorithms converge to the communication-free strategy. Results averaged on 10 random trials.

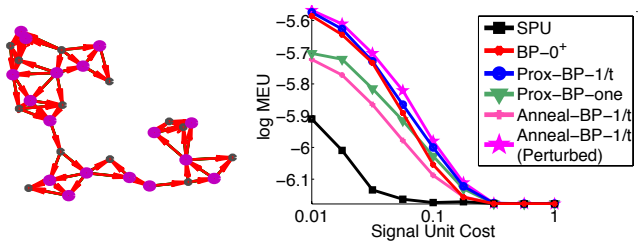
help the predictions of their downstream sensors. The utility function includes rewards for correct prediction and a cost for sending signals. We construct an ID as sketched in Fig. 6(a) for addressing the *offline* policy design task, finding optimal policies of how to predict the states based on the local measurement and received signals, and policies of whether and how to pass signals to downstream nodes; see appendix for more details.

To escape the "all-zero" fixed point, we initialize the proximal algorithms and SPU with 5 random policies, and `BP-0+` and `Anneal-BP-1/t` with 5 random messages. We first test on a sensor network on a 3×3 grid, where the algorithms are run on both a junction tree constructed by standard triangulation and a loopy junction graph (see the Appendix for construction details). As shown in Fig. 6(b)-(c), `SPU` performs worst in all cases. Interestingly, `Anneal-BP-1/t` performs relatively poorly here, because the annealing steps make it insensitive to and unable to exploit the random initializations; this can be fixed by a "perturbed" annealed method that injects a random perturbation into the model, and gradually decreases the perturbation level across iterations (`Anneal-BP-1/t (Perturbed)`).

A similar experiment (with only the loopy junction graph) is performed on the larger random graph in Fig. 7; the algorithm performances follow similar trends. SPU performs even worse in this case since it appears to over-send signals when two "good" sensors connect to one "bad" sensor.

6 Related Works

Many exact algorithms for ID have been developed, usually in a variable-elimination or message-passing form; see Koller and Friedman [2009] for a recent review. Approximation algorithms are relatively unexplored, and usually based on separately approximating individual components of exact algorithms [e.g., Sabbadin et al., 2011, Sallans, 2003]; our method instead builds an integrated framework. Other approaches, including MCMC [e.g., Charnes and Shenoy, 2004] and search methods [e.g., Marinescu, 2010], also exist but are usually more expensive than SPU or our BP-like methods. See the appendix for more discussion.



(a) Sensor network (b) Loopy junction graph

Figure 7: The results on a sensor network on a random graph with 30 nodes (the MRF edges overlap with the signal paths). Averaged on 5 random models.

7 Conclusion

In this work we derive a general variational framework for influence diagrams, for both the "convex" centralized decisions with perfect recall and "non-convex" decentralized decisions. We derive several algorithms, but equally importantly open the door for many others that can be applied within our framework. Since these algorithms rely on *decomposing* the global problems into local ones, they also open the possibility of efficiently distributable algorithms.

Closed-Form Learning of Markov Networks from Dependency Networks

Abstract

Markov networks (MNs) are a powerful way to compactly represent a joint probability distribution, but most MN structure learning methods are very slow, due to the high cost of evaluating candidates structures. Dependency networks (DNs) represent a probability distribution as a set of conditional probability distributions. DNs are very fast to learn, but the conditional distributions may be inconsistent with each other and few inference algorithms support DNs. In this paper, we present a closed-form method for converting a DN into an MN, allowing us to enjoy both the efficiency of DN learning and the convenience of the MN representation. When the DN is consistent, this conversion is exact. For inconsistent DNs, we present averaging methods that significantly improve the approximation. In experiments on 12 standard datasets, our methods are orders of magnitude faster than and often more accurate than combining conditional distributions using weight learning.

1 INTRODUCTION

Joint probability distributions are useful for representing and reasoning about uncertainty in many domains, from robotics to medicine to molecular biology. One of the most powerful and popular ways to represent a joint probability distribution compactly is with a Markov network (MN), an undirected probabilistic graphical model. Inference in an MN can compute marginal or conditional probabilities, or find the most probable configuration of a subset of variables given evidence. Although exact inference is usually intractable, numerous approximate inference algorithms exist to exploit the structure present in the MN representation.

One of the largest disadvantages of Markov networks is the difficulty of learning them from data. In the fully observed case, weight learning is a convex optimization problem, but cannot be done in closed form except in very special circumstances, e.g. [18]. Structure learning is even harder, since it typically involves a search over a large number of candidate structures, and weights must be learned for each candidate before it can be scored [4, 14, 3]. An increasingly popular alternative is to use local methods to select the structure, by finding the dependencies for each variable separately and combining them using weight learning [15, 12].

Dependency networks (DNs) [8] represent the joint distribution itself as a set of conditional probability distributions, one for each variable. In terms of representational power, DNs are comparable to MNs, since every MN can be represented as a consistent DN and vice versa. The advantage of DNs is that they are much easier to learn than MNs, since each conditional probability distribution can be learned separately. However, the local distributions may not be consistent with any joint distribution, making the model difficult to interpret. Furthermore, very few inference algorithms support DNs. As a result, DNs remain much less popular than MNs.

In this paper, we present a new method for converting dependency networks into Markov networks, allowing us to enjoy both the efficiency of DN learning and the convenience of the MN representation. Surprisingly, this translation can be done in closed-form without any kind of search or optimization. If the DN is consistent, then this conversion is exact. For the general case of an inconsistent DN, we present averaging methods that significantly improve the approximation. As long as the maximum feature length is bounded by a constant, our method runs in linear time and space with respect to the size of the original DN.

Our method is similar in spirit to previous work on learning MNs by combining local, conditional distributions with weight learning [12, 15]. However, instead of ignoring the parameters of those local distributions, we use them to directly compute the parameters of the joint distribution. Hulten et al. [9] proposed a method for converting DNs to Bayesian networks. However, this conversion process re-

quired searching through possible structures and led to less accurate models than learning a BN directly from data.

In experiments on 12 standard datasets, we find that our DN2MN conversion method is orders of magnitude faster than weight learning and often more accurate. For DNs with decision tree conditional distributions, the converted MN was often more accurate than the original DN. With logistic regression conditional distributions, the converted MNs were significantly more accurate than performing weight learning.

Our method has potential applications outside of MN structure learning as well. For domains where data is limited or unavailable, an expert could specify the conditional distributions of a DN, which could then be translated into the joint distribution of an MN. This could be much easier and less error-prone than attempting to specify the entire joint distribution directly.

Our paper is organized as follows. We begin with background on Markov networks and dependency networks in Sections 2 and 3. In Section 4, we describe how to convert consistent dependency networks into Markov networks that represent the exact same probability distribution. In Section 5, we discuss inconsistent conditional probability distributions and methods for improving the approximation quality through averaging. We evaluate our methods empirically in Section 6 and conclude in Section 7.

2 MARKOV NETWORKS

A *Markov network* (MN) represents a probability distribution over a set of random variables $\mathbf{X} = \{X_1, X_2, \ldots, X_n\}$ as a normalized product of factors:

$$P(\mathbf{X}) = \frac{1}{Z} \prod_i \phi_i(\mathbf{D}_i) \tag{1}$$

Z is the partition function, a normalization constant to make the distribution sum to one; ϕ_i is the ith factor, sometimes referred to as a potential function; and $\mathbf{D}_i \subset \mathbf{X}$ is the set of variables in the domain of ϕ_i.

A probability distribution where $P(\mathbf{x}) > 0$ for all $\mathbf{x} \in \mathbf{X}$ is said to be *positive*. An MN that represents a positive distribution can also be written as a *log-linear model*. In a log-linear model, the probability distribution is expressed as an exponentiated weighted sum of feature functions $f_i(\mathbf{D}_i)$ rather than as a product of factors:

$$P(\mathbf{X}) = \frac{1}{Z} \exp\left(\sum_i w_i f_i(\mathbf{D}_i)\right) \tag{2}$$

The correspondence between (1) and (2) is easily shown by letting $f_i = \log \phi_i$ and $w_i = 1$.

For discrete domains, a common choice is to use conjunctions of variable tests as the features. Each test is of the form $(X_i = v_i)$, where X_i is a variable in $\mathbf{X}$ and v_i is a value of that variable. We sometimes abbreviate tests of Boolean variables, so that $(X_i = T)$ is written as X_i and $(X_i = F)$ is written as $\neg X_i$. A conjunctive feature equals 1 if its arguments satisfy the conjunction and 0 otherwise. Any factor represented as a table can be converted into a set of conjunctive features with one feature for each entry in the table. When the factors have repeated values or other types of structure, a feature-based representation is often more compact than a tabular one.

The *Markov blanket* of a variable X_i, denoted $\mathrm{MB}(X_i)$, is the set of variables that render X_i independent from all other variables in the domain. In an MN, this set consists of all variables that appear in a factor or feature with X_i. These independencies, and others, are entailed by the factorization in (1).

2.1 INFERENCE

Given an MN, we often wish to answer queries such as the probability of one or more variables given evidence. In general, computing exact marginal and conditional probabilities is #P-complete [16], so approximate inference algorithms are commonly used instead. One of the most popular is Gibbs sampling [5].

Gibbs sampling is a Markov chain Monte Carlo method that generates a set of random samples and uses them to answer queries. The sampler is initialized to a random state consistent with the evidence. Samples are generated by resampling each non-evidence variable in turn, according to its conditional probability given the current states of the other variables. In early samples, the sampler may be in an unlikely and non-representative state, so these "burn-in" samples are typically excluded from consideration. The probability of a query is estimated as the fraction of samples consistent with the query. For positive distributions, Gibbs sampling will eventually converge to the correct probabilities, but this can take a very long time and convergence can be difficult to detect.

2.2 WEIGHT LEARNING

In maximum likelihood parameter estimation, the goal is to select a set of parameters that maximizes the log-likelihood of the model on the training data. Here we assume that the MN is expressed as a log-linear model with a fixed set of features and that all variables are observed in the training data. Since the log-likelihood of an MN is a concave function of the weights, parameter learning can be framed as a convex optimization problem and solved with standard gradient-based approaches. Since log-likelihood and its gradient are usually intractable to compute exactly and slow to approximate, a commonly-used alternative is pseudo-likelihood. Pseudo-log-likelihood (PLL) [2] is the sum of the conditional log-likelihood of each variable given

the other variables:

$$\log P_w^{\bullet}(\mathbf{X}=\mathbf{x}) = \sum_{i=1}^{n} \log P_w(X_i=x_i|\mathbf{X}_{-i}=\mathbf{x}_{-i})$$

where $\mathbf{X}_{-i} = \mathbf{X} - X_i$, the set of all variables except for X_i. Unlike log-likelihood, PLL and its gradient can both be evaluated efficiently. Like log-likelihood, PLL is a concave function, so any local optimum is also a global optimum. The main disadvantage of PLL is that it tends to handle long-range dependencies poorly. Optimizing PLL optimizes the model's ability to predict individual variables given large amounts of evidence, and this may lead to worse performance when less evidence is available. To control overfitting, a zero-mean Gaussian prior is typically placed on each weight.

2.3 STRUCTURE LEARNING

The goal of MN structure learning is to find a set of factors and parameters or features and weights with a high score on the training data. As with weight learning, pseudo-likelihood is a common choice due to the intractability of the partition function. Of the many MN structure learning variations that have been proposed, we touch on just a few algorithms and their main themes.

One common approach to structure learning is to perform a greedy search through the space of possible structures. Della Pietra et al. [4] conduct this search in a top-down manner, starting with atomic features (individual variable tests) and extending and combining these simple features until convergence. Davis and Domingos [3] propose a bottom-up search instead, creating many initial features based on the training data and repeatedly merging features as learning progresses. Search-based algorithms tend to be slow, since scoring candidate structures can be expensive and there are many candidate structures to consider.

Another approach is to use local models to find the Markov blanket of each variable separately and then combine the features of these local models into a global structure. Ravikumar et al. [15] do this by learning a logistic regression model with L1 regularization for each variable. The use of L1 regularization encourages sparsity, so that most of the interaction weights are zero. All non-zero interactions are turned into conjunctive features. In other words, if the logistic regression model for predicting X_i has a non-zero weight for X_j then the feature $X_i \wedge X_j$ is added to the model. Lowd and Davis [12] adopt a similar approach, but use probabilistic decision trees as the local model. Each decision tree is converted into a set of conjunctive features by considering each path from the tree root to a leaf as a conjunction of variable tests. In both works, the authors select feature weights by performing weight learning. In addition to being much faster than the search-based methods, the local approaches often lead to more accurate models.

3 DEPENDENCY NETWORKS

A *dependency network* (DN) [8] consists of a set of conditional probability distributions (CPDs) $P_i(X_i|\mathrm{MB}(X_i))$, each defining the probability of a single variable given its Markov blanket. A DN is said to be *consistent* if there exists a probability distribution P that is consistent with the DN's conditional distributions. Inconsistent DNs are sometimes called *general* dependency networks.

Since Gibbs sampling only uses the conditional probability of each variable given its Markov blanket, it is easily applied to DNs. The probability distribution represented by a DN is defined as the stationary distribution of the Gibbs sampler, given a fixed variable order. If the DN is consistent, then its conditional distributions must be consistent with some MN, and Gibbs sampling converges to the same distribution as the MN. If the DN is inconsistent, then the stationary distribution may depend on the order in which the variables are resampled. Furthermore, the joint distribution determined by the Gibbs sampler may be inconsistent with the conditional probabilities in the CPDs.

Few other inference algorithms have been defined for DNs. Heckerman et al. [8] describe a method for using Gibbs sampling and CPD values together to estimate rare probabilities with lower variance; Toutanova et al. [17] do maximum a posteriori (MAP) inference in a chain-structured DN with an adaptation of the Viterbi algorithm; and Lowd and Shamaei [13] propose mean field inference for DNs. We know of no other methods.

A DN can be constructed from any MN by constructing a conditional probability distribution for each variable given its Markov blanket. A DN can also be learned from data by learning a probabilistic classifier for each variable. This makes DN learning trivial to parallelize with a separate process for each variable. However, when learned from data, the resulting CPDs may be inconsistent with each other.

Any standard method for learning a probabilistic classifier can be used. Heckerman et al. [8] learn a probabilistic decision tree for each variable. In a probabilistic decision tree, the interior nodes of the tree are variable tests (such as $(X_4 = T)$), the branches are labeled with test outcomes (such as *true* and *false*), and the leaves specify the marginal distribution of the target variable given the tests on the path from the root to leaf. Probabilistic decision trees can be learned greedily to maximize the conditional log-likelihood of the target variable.

Hulten et al. [9] investigated the problem of converting a DN to a Bayesian network (BN). However, rather than trying to match the distribution as closely as possible, they tried to find the highest-scoring acyclic subset of the DN structure. After proving the problem to be NP-hard, they proposed a greedy algorithm for removing the least essential edges. The resulting BN was consistently less accurate

than training one from scratch. Furthermore, it only applies to DNs with tree CPDs.

4 CONVERTING CONSISTENT DEPENDENCY NETWORKS

We now discuss how to construct a joint distribution from a set of positive conditional distributions. To begin with, we assume that the conditional distributions, $P(X_i|\mathbf{X}_{-i})$, are the conditionals of some unknown joint probability distribution P. Later, we will relax this assumption and discuss how to find the most effective approximation.

Consider two instances, $\mathbf{x}$ and $\mathbf{x}'$, that only differ in the state of one variable, X_j. In other words, $x_i = x'_i$ for all $i \neq j$, so $\mathbf{x}_{-j} = \mathbf{x}'_{-j}$. We can express the ratio of their probabilities as follows:

$$\frac{P(\mathbf{x})}{P(\mathbf{x}')} = \frac{P(x_j, \mathbf{x}_{-j})}{P(x'_j, \mathbf{x}_{-j})} = \frac{P(x_j|\mathbf{x}_{-j})P(\mathbf{x}_{-j})}{P(x'_j|\mathbf{x}_{-j})P(\mathbf{x}_{-j})} = \frac{P(x_j|\mathbf{x}_{-j})}{P(x'_j|\mathbf{x}_{-j})} \tag{3}$$

Note that the final expression only involves a conditional distribution, $P(X_j|X_{-j})$, not the full joint. The conditional distribution must be positive in order to avoid division by zero.

If $\mathbf{x}$ and $\mathbf{x}'$ differ in multiple variables, then we can express their probability ratio as the product of multiple single-variable transitions. We construct a sequence of instances $\{\mathbf{x}^{(0)}, \mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(n)}\}$, each instance differing in at most one variable from the previous instance in the sequence. Let order $o \in S_n$ be a permutation of the numbers 1 to n and let $o[i]$ refer to the ith number in the order. We define $\mathbf{x}^{(i)}$ inductively:

$$\mathbf{x}^{(0)} = \mathbf{x}$$
$$\mathbf{x}^{(i)} = (x'_{o[i]}, \mathbf{x}^{(i-1)}_{-o[i]})$$

In other words, the ith instance $\mathbf{x}^{(i)}$ simply changes the $o[i]$th variable from $x_{o[i]}$ to $x'_{o[i]}$ and is otherwise identical to the previous element, $\mathbf{x}^{(i-1)}$. Thus, in $\mathbf{x}^{(i)}$ the first i variables in the order are set to their values in $\mathbf{x}'$ and the latter $n-i$ are set to their values in $\mathbf{x}$. Note that $\mathbf{x}^{(n)} = \mathbf{x}'$, since all n variables have been changed to their values in $\mathbf{x}'$.

We can use these intermediate instances to express the ratio $P(\mathbf{x})/P(\mathbf{x}')$ as a product:

$$\begin{aligned}
\frac{P(\mathbf{x})}{P(\mathbf{x}')} &= \frac{P(\mathbf{x}^{(0)})}{P(\mathbf{x}^{(n)})} \\
&= \frac{P(\mathbf{x}^{(0)})}{P(\mathbf{x}^{(n)})} \times \frac{P(\mathbf{x}^{(1)})}{P(\mathbf{x}^{(1)})} \times \cdots \times \frac{P(\mathbf{x}^{(n-1)})}{P(\mathbf{x}^{(n-1)})} \\
&= \frac{P(\mathbf{x}^{(0)})}{P(\mathbf{x}^{(1)})} \times \frac{P(\mathbf{x}^{(1)})}{P(\mathbf{x}^{(2)})} \times \cdots \times \frac{P(\mathbf{x}^{(n-1)})}{P(\mathbf{x}^{(n)})} \\
&= \prod_{i=1}^{n} \frac{P(\mathbf{x}^{(i-1)})}{P(\mathbf{x}^{(i)})} = \prod_{i=1}^{n} \frac{P(x_{o[i]}|\mathbf{x}^{(i)}_{-o[i]})}{P(x'_{o[i]}|\mathbf{x}^{(i)}_{-o[i]})}
\end{aligned} \tag{4}$$

The last equality follows from substituting (3), since $\mathbf{x}^{(i-1)}$ and $\mathbf{x}^{(i)}$ only differ in the $o[i]$th variable, $X_{o[i]}$.

Letting $\phi_i(\mathbf{X} = \mathbf{x}) = P(x_{o[i]}|\mathbf{x}^{(i)}_{-o[i]})/P(x'_{o[i]}|\mathbf{x}^{(i)}_{-o[i]})$ and $Z = 1/P(\mathbf{x}')$:

$$\frac{1}{Z}\prod_i \phi_i(\mathbf{x}) = P(\mathbf{x}')\frac{P(\mathbf{x})}{P(\mathbf{x}')} = P(\mathbf{x})$$

Therefore, a Markov network with the factors $\{\phi_i\}$ exactly represents the probability distribution $P(\mathbf{X})$. Since the factors are defined only in terms of conditional distributions of one variable given evidence, any consistent dependency network can be converted to a Markov network representing the exact same distribution. This holds for any ordering o and base instance $\mathbf{x}'$.

Note that, unlike $\mathbf{x}'$, $\mathbf{x}$ is not a fixed vector of values but can be set to be any instance in the state space. This is necessary for ϕ_i to be a function $\mathbf{x}$. The following subsection will make this clearer with an example.

4.1 EXAMPLE

We now show how this idea can be applied to a simple, consistent DN. Consider the following conditional distributions over binary variables X_1 and X_2:

$$\begin{aligned}
P(X_1 = T|X_2 = T) &= 4/5 \\
P(X_1 = T|X_2 = F) &= 2/5 \\
P(X_2 = T|X_1 = T) &= 2/3 \\
P(X_2 = T|X_1 = F) &= 1/4
\end{aligned}$$

Let $\mathbf{x}' = [T, T]$ and $o = [1, 2]$. Following the earlier construction:

$$\phi_1(x_1, x_2) = \frac{P(x_1|\mathbf{x}^{(1)}_{-1})}{P(x'_1|\mathbf{x}^{(1)}_{-1})} = \frac{P(x_1|x_2)}{P(X_1 = T|x_2)}$$

$$\phi_2(x_2) = \frac{P(x_2|\mathbf{x}^{(2)}_{-2})}{P(x'_2|\mathbf{x}^{(2)}_{-2})} = \frac{P(x_2|X_1 = T)}{P(X_2 = T|X_1 = T)}$$

Note that ϕ_2 is not a function of x_1. This is because $x^{(2)}_1 = x'_1$, so the value of X_1 in the evidence is defined by the base

instance, $\mathbf{x}'$. In general, the ith converted factor ϕ_i is not a function of the first $i-1$ variables, since they are fixed to values in $\mathbf{x}'$.

By simplifying the factors, we obtain the following:

X_1	X_2	$\phi_1(X_1, X_2)$
T	T	1
T	F	1
F	T	1/4
F	F	3/2

X_2	$\phi_2(X_2)$
T	1
F	1/2

Multiplying the factors together and renormalizing yields:

X_1	X_2	$P(X_1, X_2)$
T	T	0.4
T	F	0.2
F	T	0.1
F	F	0.3

which matches both conditional distributions. Therefore, an MN with the factors ϕ_1 and ϕ_2 represents the exact same distribution as a DN with the conditional distributions $P(X_1|X_2)$ and $P(X_2|X_1)$. Since the original DN is consistent, any choice of $\mathbf{x}'$ or o will lead to the same result.

4.2 LOG-LINEAR MODELS WITH CONJUNCTIVE FEATURES

In the previous example, we showed how to convert a DN to an MN using tables as factors. However, this can be very inefficient when the conditional distributions have structure, such as decision trees or logistic regression models. Rather than treating each type of CPD separately, we discuss how to convert any distribution that can be represented as a log-linear model with conjunctive features.

Suppose the CPD for X_i is a log-linear model:

$$P(X_i|\mathbf{X}_{-i}) = \frac{1}{Z(\mathbf{X}_{-i})} \exp\left(\sum_j w_j f_j(\mathbf{D}_j)\right)$$

Note that the normalization Z is now a function of the evidence variables, $\mathbf{X}_{-i}$. To represent $P(X_i|\mathbf{x}^{(i)}_{-o[i]})$, we can condition each f_j on $\mathbf{x}^{(i)}_{-o[i]}$ separately:

$$P(X_i|\mathbf{x}^{(i)}_{-o[i]}) = \frac{1}{Z(\mathbf{x}^{(i)}_{-o[i]})} \exp\left(\sum_j w_j f_j(X_i, \mathbf{x}^{(i)}_{-o[i]})\right)$$

$\mathbf{x}^{(i)}_{-o[i]}$ uses values from $\mathbf{x}'$ for the first i variables in o and $\mathbf{x}$ for the rest. The values from $\mathbf{x}'$ are constant but those in $\mathbf{x}$ are free variables, so that the resulting distribution is a function of $\mathbf{x}$. When simplifying $f_j(\mathbf{x}^{(i)}_{-o[i]})$, if the constant values in $\mathbf{x}^{(i)}_{-o[i]}$ violate one of the variable tests in f_j, then f_j is always zero and it can be removed entirely. Otherwise, any conditions satisfied by constant values in $\mathbf{x}^{(i)}_{-o[i]}$ are always satisfied and can be removed.

Table 1: The Basic DN2MN Algorithm

function DN2MN($\{P_i(X_i|\mathbf{X}_{-i})\}, \mathbf{x}', o^{-1}$)
$M \leftarrow \emptyset$
for $i = 1$ to n **do**
  Convert P_i to a set of weighted features, F_i.
  for each weighted feature $(w, f) \in F_i$ **do**
    $f_n \leftarrow$ SIMPLIFYFEATURE($i, f, \mathbf{x}', o^{-1}$, true)
    $f_d \leftarrow$ SIMPLIFYFEATURE($i, f, \mathbf{x}', o^{-1}$, false)
    $M = M \cup (w, f_n) \cup (-w, f_d)$
  end for
end for
return M

For example, suppose $P(X_2|X_1, X_4)$ uses the following three conjunctive features:

$$f_1(X_1, X_2, X_4) = X_1 \wedge \neg X_2 \wedge X_4$$
$$f_2(X_1, X_2) = X_1 \wedge X_2$$
$$f_3(X_2, X_4) = X_2 \wedge \neg X_4$$

If $\mathbf{x}' = [T, T, T, T]$ and $o = [1, 2, 3, 4]$, then $\mathbf{x}^{(2)} = [X_1, X_2, T, T]$. After conditioning f_1, f_2, and f_3 on $\mathbf{x}^{(2)}_{-o[2]}$, they simplify to:

$$f_1(X_1, X_2) = X_1 \wedge \neg X_2$$
$$f_2(X_1, X_2) = X_1 \wedge X_2$$

f_3 is removed entirely, since it is inconsistent with $\mathbf{x}^{(2)}_{-o[2]}$.

To compute ϕ_2, we must additionally condition the function in the denominator on $X_2 = \mathbf{x}'_2 = T$. If the weights of f_1 and f_2 are w_1 and w_2, respectively, then:

$$\begin{aligned}
&\phi_2(X_1, X_2) \\
&\quad = \frac{P(X_2|X_1, X_4 = T)}{P(X_2 = T|X_1, X_4 = T)} \\
&\quad = \frac{\exp(w_1(X_1 \wedge \neg X_2) + w_2(X_1 \wedge X_2))/Z(\mathbf{x}^{(2)}_{-o[2]})}{\exp(w_2(X_1 \wedge X_2))/Z(\mathbf{x}^{(2)}_{-o[2]})} \\
&\quad = \exp(w_1(X_1 \wedge \neg X_2) + w_2(X_1 \wedge X_2) - w_2 X_1)
\end{aligned}$$

Note that the final factor ϕ_i is always a log-linear model where each feature is a subset of one of the features in the original conditional distribution. Therefore, converting each conditional distribution in this manner yields an MN represented as a log-linear model.

We summarize our complete method for consistent DNs with the algorithms in Tables 1 and 2. DN2MN takes a set of conditional probability distributions, $\{P_i(X_i|\mathbf{X}_{-i})\}$, a base instance $\mathbf{x}'$, and an inverse variable ordering o^{-1}. The inverse variable ordering is a mapping from variables to their corresponding indices in the desired ordering o, so that $o^{-1}[o[i]] = i$. DN2MN first converts the conditional

Table 2: Feature Simplifying Subroutine

function SIMPLIFYFEATURE($i, f, \mathbf{x}', o^{-1}$, *numerator*)
$f' \leftarrow \emptyset$
for each variable test $(X_j = v_j) \in f$ **do**
  if $o^{-1}[i] < o^{-1}[j]$ OR ($i = j$ AND *numerator*) **then**
    $f' \leftarrow f' \cup (X_j = v_j)$
  else if $v_j \neq x'_j$ **then**
    return $\emptyset$
  end if
end for
return f'

distributions into sets of weighted features. Then it conditions each feature on some of the values in $\mathbf{x}'$, depending on the variable order, to produce the simplified distributions for the numerator and denominator of (4). This is handled by SIMPLIFYFEATURE, which accepts a parameter to indicate if the simplified feature is for the numerator or denominator. Features in the denominator are assigned negative weights, since $1/\exp(wf) = \exp(-wf)$.

5 HANDLING INCONSISTENCIES

When the basic DN2MN algorithm is applied to an inconsistent DN, the result may depend on $\mathbf{x}'$ and o. For example, consider the following conditional distributions:

$$P_1(X_1 = T|X_2 = T) = 4/5$$
$$P_1(X_1 = T|X_2 = F) = 1/5$$
$$P_2(X_2 = T|X_1 = T) = 1/5$$
$$P_2(X_2 = T|X_1 = F) = 4/5$$

P_1 encourages X_1 and X_2 to be equal, while P_2 encourages them to have opposite values. By symmetry, it is easy to see that a Gibbs sampler with these transition probabilities must converge to a uniform distribution. However, the conditional distributions are not consistent with a uniform distribution, so the DN is inconsistent. We see that the choice of $\mathbf{x}'$ here does affect the converted MN:

When $\mathbf{x}' = [T, T]$ and $o = [1, 2]$:

X_1	X_2	$P(X_1, X_2)$
T	T	4/85
T	F	16/85
F	T	1/85
F	F	64/85

When $\mathbf{x}' = [F, F]$ and $o = [1, 2]$:

X_1	X_2	$P(X_1, X_2)$
T	T	64/85
T	F	1/85
F	T	16/85
F	F	4/85

Unsurprisingly, changing the ordering o also changes the resulting probability distribution for this example. However, no single choice of $\mathbf{x}'$ and o leads to the true, uniform distribution. To obtain a uniform distribution, we must average over several conversions.

5.1 AVERAGING OVER ALL BASE INSTANCES

A reasonable way to average is to convert the DN to an MN k times and take the geometric mean of the resulting distributions. With a log-linear model, this can be done by simply combining all features from all models and dividing the weights by k.

However, instead of merely summing over a small number of base instances $\mathbf{x}'$, we can sum over *all* base instances in linear time and space by exploiting the structure of conjunctive features. Given a feature f_j and an intermediate instance $\mathbf{x}^{(i)}_{-o[i]}$, suppose that k binary-valued variables in f_j have constant values in $\mathbf{x}^{(i)}_{-o[i]}$. Out of all possible $\mathbf{x}'$, only the fraction 2^{-k} will be consistent with the instance. Therefore, rather than enumerating all possible $\mathbf{x}'$, we can simply multiply the weight of f_j by 2^{-k}, to reflect the fact that it would be included in only that fraction of the converted MNs.

For inconsistent DNs, a uniform distribution over all $\mathbf{x}'$ may not be a good approach, since the DN may be more inconsistent in less probable regions of the state space, leading to worse behavior. We have found that a product of marginals distribution over $\mathbf{x}'$ works well. We use training data to estimate the marginal distribution of each variable, and then use those marginals to compute the modified weight of each conditioned feature. The uniform approach remains a special case. We also experimented with averaging over all training examples, but found that using the marginals worked slightly better.

5.2 AVERAGING OVER ORDERINGS

Since the conversion depends on the ordering, we would like to average over all possible orderings as well. Since every feature in the final model is a subset of one of the original features, a feature with k variable tests has at most 2^k subsets to consider. When converting the conditional distribution for variable X_i, all variables that come after i in the ordering are constant, so variable tests involving those variables will be removed. Consider a specific conjunctive subfeature that contains only l of the original k variable tests. There are $k!$ total orderings of the variables in the k conditions. There are $(l-1)!$ ways to order the remaining conditions (excluding the target), and $(k-l)$ ways to order the conditions that were removed.[1] Therefore, the fraction of orderings consistent with a particular subfeature is: $(l-1)!(k-l)!/k!$.

In a model with long conjuncts, the exponential number of subfeatures leads to prohibitively large model sizes. Alternately, we can sum over a *linear* number of orderings. Given a base ordering, o, we sum over all n orderings of the form:

$$[o[i], o[i+1], \ldots, o[n], o[1] \ldots, o[i-1]]$$

[1] We assume each variable appears in at most one condition, so they can be ordered independently. This assumption can easily be relaxed.

for all i. When averaging over a linear number of orderings, a conjunctive feature with k variable tests will be converted to k subfeatures, each determined by which of the variables comes first in the ordering.

For example, suppose the conditional distribution for X_7 contains the feature $X_4 \wedge X_6 \wedge X_7 \wedge X_{13}$ and we are summing over all rotations of $[1, 2, \ldots, n]$:

- If X_7 is first in the order, then the conditioned feature is $X_4 \wedge X_6 \wedge X_7 \wedge X_{13}$.
- If X_5 or X_6 comes first, then X_6 is fixed to its value in $\mathbf{x}'$, leaving $X_4 \wedge X_7 \wedge X_{13}$.
- If X_1 to X_4 or X_{14} to X_n comes first, then X_4 and X_6 come before X_7 in the ordering, leaving $X_7 \wedge X_{13}$.
- If X_8 to X_{12} comes first, then all variables come before X_7, so the conditioned feature is just X_7.

Note that these orderings should not be weighted equally. The weights for the four subfeatures should be multiplied by $1/n$, $2/n$, $(4 + (n - 13))/n$, and $5/n$, respectively.

For symmetry, we can average over all rotations of several different orderings. In our experiments, we average over all rotations of the orderings $[1, 2, \ldots, n]$ and $[n, n-1, \ldots, 1]$. For features of length 2, this is equivalent to summing over all orderings, since all subfeatures are included and the symmetry of the opposite orderings ensures balanced weights.

6 EXPERIMENTS

6.1 DATASETS

We used 12 standard MN structure learning datasets collected and prepared by Davis and Domingos [3], omitting EachMovie since it is no longer publicly available. All variables are binary-valued. The datasets vary widely in size and number of variables. See Table 3 for a summary, and Davis and Domingos [3] for more details on their origin. Datasets are in increasing order by number of variables.

6.2 METHODS

On each dataset, we learned DNs with decision tree CPDs and logistic regression CPDs. For decision tree CPDs, each probabilistic decision tree was greedily learned to maximize the conditional likelihood of the target variable given the others. To avoid overfitting, we used the structure prior of Heckerman et al. [8], $P(S) \propto \kappa^f$, where f is the number of free parameters in the model and $\kappa > 0$ is a tunable parameter. Parameters were estimated using add-one smoothing. We learned logistic regression CPDs with L1 regularization using the Orthant-Wise Limited-memory Quasi-Newton (OWL-QN) method [1]. Both κ and λ (the L1 regularization parameter) were tuned using held-out validation data. For κ, we started from a value of 10^{-4} and increased it by a factor of 10 until the score on the validation set decreased. For λ, we used the values 0.1, 0.2, 0.5, 1, 2, 5, ..., 1000 and selected the model with the highest score on the validation set. To score a DN on a validation set, we computed the product of the conditional probabilities of each variable according to their respective CPDs.

We converted the DNs to MNs with 6 different choices of base instances and orderings:

1. One ordering; one base instance
2. Two opposite orderings; one base instance
3. One ordering; expectation over all instances
4. Two opposite orderings; expectation over all instances
5. All rotations of one ordering; expectation over all instances
6. All rotations of two opposite orderings; expectation over all instances

The expectation over all instances was done using the marginal distribution of the variables, as estimated using the training data. To be as fair as possible, we include the time to read in the entire training data in our timing results, as well as the time to write the model to disk.

We also converted the DNs to MNs using weight learning, similar to the methods of [15, 12]. We first converted all DN CPDs to conjunctive features and removed duplicate features. Then we learned weights for all features to maximize the PLL of the training data, using a Gaussian prior on the weights to reduce overfitting. The standard deviation of the Gaussians was tuned to maximize PLL on the validation set. With decision tree CPDs, we used standard deviations of 0.05, 0.1, 0.2, 0.5, and 1.0, and the best-performing models always had standard deviations between 0.1 and 0.5. For logistic regression CPDs, a slightly wider range of standard deviations was required, ranging from 0.1 to 10. Optimization was done using the limited memory BFGS algorithm, a quasi-Newton method for convex optimization [11]. Weight learning was terminated after 100 iterations if it had not yet converged.

We did not compare to BLM [3] or the algorithm of Della Pietra et al. [4], since those algorithms have been shown to be less accurate and many orders of magnitude slower than Ravikumar et al. [15] on these datasets [12, 7].

In addition to PLL, we computed conditional marginal log-likelihood (CMLL), a common evaluation metric for Markov networks [3, 10, 12]. CMLL is the sum of the conditional log-likelihood of each variable, given a subset of the others as evidence. In our experiments, we followed the approach of Davis and Domingos [3], who partition the variables into four sets, $\mathbf{Q}_1$ through $\mathbf{Q}_4$. The marginal distribution of each variable is computed using the variables from the other three sets as evidence:

$$\text{CMLL}(\mathbf{X}) = \sum_j \sum_{X_i \in \mathbf{Q}_j} \log P(X_i | \mathbf{X} - \mathbf{Q}_j)$$

Marginals were computed using Gibbs sampling. We used a Rao-Blackwellized Gibbs sampler that adds counts to all states of a variable based on its conditional distribution before selecting the next value for that variable. We found that 100 burn-in and 1000 sampling iterations were sufficient for Gibbs sampling, and additional iterations did not affect the results very much.

All of our learning and inference methods are available in the latest version of the open-source Libra toolkit.[2]

6.3 RESULTS

First, we compare the different approaches to converting inconsistent DNs and compare the accuracy of the resulting MNs to the original DNs. Figure 1 shows the result of converting DNs with both decision tree CPDs (left) and logistic regression CPDs (right). We measure the relative accuracy by comparing the PLL of each MN to the original DN on the test data. In order to better show differences among datasets with different numbers of variables, we show the normalized PLL (NPLL), which divides the PLL by the number of variables in the domain. All graphs are rescaled so that the height of the tallest bar in each cluster is one, with its actual height listed above the graph. With consistent DNs, all methods would be equivalent and all differences would be zero. Since the DNs are inconsistent, converting to an MN may result in an altered distribution that is less accurate on test data.

Empirically, we see that using many orders and summing over all base instances leads to more accurate models. For the decision tree DNs, some of the bars are negative, indicating MNs that are more accurate than their source DNs. This can happen because the conditional distributions in the MN combine several conditional distributions from the original DN, leading to more complex dependencies than a single decision tree. With $2n$ orderings, the converted MN was more accurate on 10 out of 12 datasets. For logistic regression DNs, the converted MNs are very, very close in accuracy, but never better. With $2n$ orderings, the difference in NPLL is less than 0.005 for all datasets, and is less than 0.001 for 8 out of 12.

Table 4 shows the relative accuracy of converting DNs to MNs by learning weights (LW) or by direct conversion with $2n$ orderings and a marginal distribution over base instances (DN2MN). The result of the better performing algorithm is marked in bold. Differences on individual datasets are not always statistically significant, but the overall ranking trend shows the relative peroformance of the two methods. LW and DN2MN do similarly well on tree CPDs: neither PLL nor CMLL was significantly different according to a Wilcoxon signed ranks test. With logistic regression CPDs, DN2MN achieves higher PLL on 10 datasets and CMLL on 9. Both differences are significant at $p < 0.05$ under a two-tailed Wilcoxon signed ranks test.

Table 5 shows the time for converting DNs using our closed-form solution and weight learning. DN2MN is 7 to 250 times faster than weight learning with decision tree CPDs, and 160 to 1200 times faster than weight learning with logistic regression CPDs. These results include tuning time, which is necessary to obtain the best results for weight learning. If all tuning time is excluded, weight learning is 12 times slower with tree CPDs and 49 times slower with logistic regression CPDs, on average.

7 CONCLUSION

DN2MN learns an MN with very similar performance to the original DN, and does so very quickly. With decision tree CPDs, the MN is often more accurate than the original DN. With logistic regression CPDs, the MN is significantly more accurate than performing weight learning as done by Ravikumar et al. [15]. This makes DN2MN competitive with or better than state-of-the-art methods for learning MN structure. Furthermore, DN2MN can exploit many types of conditional distributions, including boosted trees and rule sets, and can easily take advantage of any algorithmic improvements in learning conditional distributions. Another important application of DN2MN is when the model is specified by experts, since conditional distributions could be much easier to specify than a joint distribution.

Abstract

Most analyses of manipulation of voting schemes have adopted two assumptions that greatly diminish their practical import. First, it is usually assumed that the manipulators have full knowledge of the votes of the nonmanipulating agents. Second, analysis tends to focus on the probability of manipulation rather than its impact on the social choice objective (e.g., social welfare). We relax both of these assumptions by analyzing *optimal Bayesian manipulation strategies* when the manipulators have only partial probabilistic information about nonmanipulator votes, and assessing the *expected loss in social welfare* (in the broad sense of the term). We present a general optimization framework for the derivation of optimal manipulation strategies given *arbitrary* voting rules and distributions over preferences. We theoretically and empirically analyze the optimal manipulability of some popular voting rules using distributions and real data sets that go well beyond the common, but unrealistic, impartial culture assumption. We also shed light on the stark difference between the loss in social welfare and the probability of manipulation by showing that even when manipulation is likely, impact to social welfare is slight (and often negligible).

1 INTRODUCTION

The use of voting rules to aggregate preferences has become a topic of intense study, and one of great importance in ranking, recommender systems, resource allocation, and other applications of social choice to computational systems. One of the most challenging topics in computational social choice is the study of *manipulation*: given a voting rule, there is usually some set of voter preferences such that one or more voters can obtain a more desirable outcome by misreporting their preferences. Indeed, except under very stringent assumptions, voting rules that are not manipulable do not exist [18, 33]. An important line of research, initiated by Bartholdi *et al.* [2, 3], shows that it can be computationally difficult to manipulate certain rules. However, since worst-case complexity is not itself a significant barrier to manipulation, recent attention has focused on theoretical and empirical demonstration that manipulation is often, or on average, tractable for certain stylized preference distributions [11, 31, 16, 35].

While our understanding of manipulation has improved immensely, some significant deficiencies remain in the state of the art. First, analysis of manipulation is often confined to cases in which the manipulators have complete knowledge of the preferences of sincere voters. While there are reasons for this, such analyses offer too pessimistic a picture of manipulability, since manipulators rarely have access to such information.

The main contribution of our work is a framework for analyzing *optimal Bayesian manipulation strategies* under realistic knowledge assumptions, namely, manipulators with *partial, probabilistic knowledge* of voter preferences. Since success of a manipulation is generally uncertain, the optimal strategy simply maximizes the odds of success. This depends critically on the voting rule, the number of voters, and the preference distribution—as a result, general analytical results are difficult to obtain. We instead present an empirical methodology that, assuming only the ability to sample vote profiles from the preference distribution, allows one to compute an optimal manipulation strategy. We illustrate this methodology on several preference distributions (including real-world data). We also derive sample complexity bounds that provide quality guarantees on the resulting strategies. This framework provides the ability to analyze the manipulability of most voting rules under any probabilistic knowledge assumptions—arbitrary priors, posteriors conditioned on available evidence, even the special case of complete knowledge—requiring only that the preference distribution be sampleable.

While the computational framework is general, we also analytically derive optimal manipulation strategies for

the k-approval rule (and the Borda rule in a limited fashion) under standard *impartial (and anonymous) culture* assumptions. However, since impartial culture is rare in practice [32], these results are primarily of theoretical interest.

A second deficiency of current manipulation analyses pertains to the emphasis on success probability. We adopt a decision-theoretic perspective that provides a more nuanced picture of manipulability of various voting rules. Intuitively, the more preferred an alternative is to the sincere voters, the more likely it is that manipulators can succeed in causing the alternative to be selected. As such, probability of manipulation does not tell the whole story, since alternatives with higher success probability cause less societal dissatisfaction. To this end, we interpret the "score" associated with specific alternatives under a given voting rule as an explicit social choice objective—i.e., a *social welfare function* in the broad sense of the term—and propose analyzing rules in this light. We recognize that voting protocols are often applied in settings where maximizing (some form of) social welfare is not the main objective; but we argue below that this perspective is natural in many applications, and our methodology applies to measures of social welfare different from the "score" used by the voting rule itself.

Along these lines, we derive theoretical bounds on the impact of manipulation on social welfare for the special case of positional scoring rules. More importantly, while distribution-dependent analytical results are difficult to obtain, we can exploit our ability to identify optimal manipulation strategies: by sampling vote profiles from the distribution, computing the loss in welfare under the *optimal* manipulation strategy, and averaging the results, we can readily determine the expected impact on welfare for any specific distribution. Our empirical results show that manipulation for certain rules, under realistic knowledge assumptions, generally causes little damage.

2 BACKGROUND

We briefly review relevant background; see [17, 9] for further detail on (computational) social choice.

2.1 VOTING RULES

We assume a set of n *voters* $N = \{1, \ldots, n\}$ and a set of m *alternatives* $A = \{a_1, \ldots, a_m\}$. A voter i's preferences are represented by a *ranking* or permutation v_i over A. If $v_i(a)$ is the *rank* of a in v_i, we say i prefers a_j to a_k, if $v_i(a_j) < v_i(a_k)$. We refer to v_i as i's *vote*. A *preference profile* is a collection of votes $\mathbf{v} = (v_1, \ldots, v_n)$. Let $\mathcal{V}$ be the set of all such profiles.

A *voting rule* $r : \mathcal{V} \rightarrow A$ selects a "winner" given a preference profile. Common voting rules include plurality, approval, Borda, single transferable vote (STV) and many others. We will use *positional scoring rules* frequently in the sequel. Let $\alpha = (\alpha_1, \ldots, \alpha_m)$ be a non-negative *positional scoring vector*, where $\alpha_i \geq \alpha_{i+1}$ for all $i \geq 1$. Intuitively, a earns score α_i for every vote that places it in position i, and the alternative with the greatest total score wins.[1] More formally, let the $m \times m$ *positional summary matrix (PSM)* $\mathbf{X}$ for profile $\mathbf{v}$ have entry X_{ij} equal to the number of votes that rank a_i in position j. Then the *score* $s_\alpha(a_i; \mathbf{v})$ of a_i is the i-th entry of $\mathbf{X}\alpha'$. Several important rules can be defined using positional scores: plurality by $(1, 0, \ldots, 0)$; k-approval by $(1, 1, \ldots, 0, 0)$, with k 1s; and Borda by $(m-1, m-2, \ldots, 0)$.

Many voting rules—not just positional rules, but rules such as maximin, Copeland, Bucklin, Kemeny, and many others—*explicitly score all alternatives*, assigning a score $s(a, \mathbf{v})$ that defines some measure of the quality of alternative a given a profile $\mathbf{v}$, then choosing the alternative with maximum score. This can be viewed as implicitly defining a *social choice objective* that is optimized by the voting rule, or more broadly as a *social welfare function*, that expresses some "societal utility" for each alternative.[2] While this interpretation may not be valid in all contexts, we will refer to $s(a, \mathbf{v})$ as the *social welfare* of a under rule r for voters with preferences $\mathbf{v}$, and write this as $SW(a, \mathbf{v})$ to emphasize this view. We discuss this further below.

2.2 MANIPULATION

By *manipulation* we refer to a coalition of one or more voters obtaining a more desirable outcome by misreporting their preferences. Indeed, except under very stringent conditions (e.g., single-peaked preferences), the classic Gibbard-Sattherwaite theorem shows that no scheme is immune to manipulation [18, 33]. In other words, there is some preference profile for which at least one voter can obtain a better outcome by misreporting. In the remainder of the paper, we focus on *constructive manipulation*, in which a coalition attempts to cause a single "preferred" candidate to win. We emphasize however that the general principles underlying our approach apply equally well to other forms of manipulation such as destructive manipulation or utility maximization (see below).

[1] In Sec. 3, we assume that tie-breaking works against the desired alternative of the manipulators.

[2] We we use the term "social welfare" in its broadest sense, referring to *any* means of ranking social outcomes. Specifically, we do *not* assume its more restricted definition, commonly used in mechanism design, as "sum of individual voter utilities."

Whether manipulation is a problem in practice depends on: how likely such manipulable preference profiles are; whether manipulators can detect the existence such a profile; and whether computing a suitable misreport is feasible. On this third point, the pioneering work of Bartholdi *et al.* [2, 3] demonstrated that, even given full knowledge of a profile, computing a suitable manipulation is computationally intractable for certain voting rules. This in turn led to the detailed computational analysis of many voting rules (e.g., the Borda rule [13, 4]). Of course, worst-case complexity results offer little comfort if "difficult profiles" are unlikely to arise in practice. Recent work suggests that common voting rules are in fact frequently manipulable, by studying heuristic algorithms that provide theoretical guarantees [31, 41, 39], identifying properties of voting rules that make them easy to manipulate in the typical case [11, 16, 40], and investigating (both theoretically and empirically) the relation between the number of manipulators and the probability of manipulation [30, 38, 35] (see [15] for an overview).

Analyses demonstrating ease of manipulation tend to suffer from two key drawbacks. First, they exclusively analyze manipulation assuming the manipulating coalition has full knowledge of the vote profile. While results showing that manipulation is *difficult* can be justified on these grounds, claiming *easiness* of manipulation has less practical import if the coalition is assumed to have unreasonable access to the preferences of sincere voters.[3] One exception considers manipulators who know only that the vote profile lies within some set [12], but unfortunately this work only analyzes the rather weak notion of *dominating manipulations*. Social choice research on manipulation under probabilistic knowledge is mostly negative in nature [23], or restricted to a single manipulator [1].

A second weakness of many analyses of probability of manipulation (which do assume complete information on the part of the manipulator) is their reliance on specific stylized models such as impartial culture (where every ranking in equally likely) [16, 40]. Much empirical work also considers very stylized distributions such as impartial culture, Polya's urn, and Condorcet (or Mallows) distributions. Some work does consider sub-sampling from real voting data, though with relatively small numbers of votes [36].

2.3 PROBABILISTIC RANKING MODELS

Probabilistic analysis of manipulation—including our Bayesian manipulation problem—requires some probabilistic model of voter preferences. By far the most common model in social choice is *impartial culture (IC)*, which assumes the preference of any voter is drawn from the uniform distribution over the set of permutations of alternatives [32]. A related model is the *impartial anonymous culture (IAC) model* in which each *voting situation* is equally likely [32].[4] Several other models (bipolar, urn, etc.) are considered in both theoretical and empirical social choice research.

Probabilistic models of rankings are widely considered in statistics, econometrics and machine learning as well, including models such as Mallows ϕ-model, Plackett-Luce, and mixtures thereof [25]. We use the *Mallows ϕ-model* [24] in Sec. 6, which is parameterized by a reference ranking σ and a dispersion $\phi \in (0, 1]$, with $P(r) = \frac{1}{Z}\phi^{d(r,\sigma)}$, where r is any ranking, d is Kendall's τ-distance, and Z is a normalizing constant. When $\phi = 1$, this model is exactly the impartial culture model studied widely in social choice—as such it offers considerable modelling flexibility. However, mixtures of Mallows models offer even greater flexibility, allowing (with enough mixture components) accurate modelling of any distribution over preferences. As a consequence, Mallows models, and mixtures thereof, have attracted considerable attention in the machine learning community [27, 8, 20, 26, 21]. We investigate these models empirically below.

3 OPTIMAL BAYESIAN MANIPULATION

We now consider how a manipulating coalition should act given *probabilistic* knowledge of the preferences of the sincere voters. We first formally define our setting, then present several analytical results. Finally, we present a general, sample-based optimization framework for computing optimal manipulation strategies and provide sample complexity results for positional scoring rules and k-approval.

3.1 THE MODEL

We make the standard assumption that voters are partitioned into n sincere voters, who provide their true rankings to a voting mechanism or rule r, and a coalition of c manipulators. We assume the manipulators have a *desired alternative* $d \in A$, and w.l.o.g. we assume $A = \{a_1, \ldots, a_{m-1}, d\}$. We make no assumptions about the manipulators' specific preferences, only that they desire to cast their votes so as to maximize the probability of d winning under r. A vote profile can be partitioned as $\mathbf{v} = (\mathbf{v}_n, \mathbf{v}_c)$, where $\mathbf{v}_n$ reflects the true

[3] This is implicit in [10], which shows that hardness of full-information manipulation implies hardness under probabilistic information.

[4] A voting situation simply counts the *number* of voters who hold each possible ranking of the alternatives.

preferences of the n sincere voters and $\mathbf{v}_c$ the *reported* preferences of the c manipulators.

In contrast to most models, we assume the coalition has only *probabilistic knowledge* of sincere voter preference: a distribution P reflects these *beliefs*, where $P(\mathbf{v}_n)$ is the coalition's degree of belief that the sincere voters will report $\mathbf{v}_n$. We refer to the problem facing the coalition as a *Bayesian manipulation problem*. Manipulator beliefs can take any form: a simple prior based on a standard preference distributions; a mixture model reflecting beliefs about different voter "types;" or a posterior formed by conditioning on evidence the coalition obtains about voter preferences (e.g., through polling, subterfuge, or other means). This latter indeed seems to be the most likely fashion in which manipulation will proceed in practice. Finally, the standard full knowledge assumption is captured by a point distribution that places probability 1 on the actual vote profile. We sometimes refer to P as a distribution over individual *preferences*, which induces a distribution over profiles by taking the product distribution P^n.

The coalition's goal is to cast a collective vote $\mathbf{v}_c$ that maximizes the chance of d winning:

$$\operatorname*{argmax}_{\mathbf{v}_c} \sum_{\mathbf{v}_n:\ r(\mathbf{v}_n,\mathbf{v}_c)=d} P(\mathbf{v}_n).$$

We refer to this $\mathbf{v}_c$ as an *optimal Bayesian manipulation strategy*. For most standard voting rules, this is equivalent to maximizing the *probability of manipulation*, which is the above sum restricted to profiles $\mathbf{v}_n$ such that $r(\mathbf{v}_n) \neq d$.

While we focus on constructive manipulation, our general framework can be applied directly to any reasonable objective on the part of the manipulating coalition. Plausible objectives include: *destructive manipulation*, which attempts to prevent a specific candidate from winning; *safe manipulation*, where a coalitional voter is unsure whether his coalitional colleagues will vote as planned [34, 19]; or *utility maximization*, which attempts to maximize (expected) utility over possible winning candidates. Notice that constructive manipulation can be interpreted as utility maximization with a 0-1 utility for the desired candidate d winning.

3.2 ANALYTICAL RESULTS

Our aim is to determine optimal manipulation strategies given any probabilistic beliefs that the coalition might hold, for arbitrary voting rules. Given this general goal, tight analytical results and bounds are infeasible, a point to which we return below. We do provide here two results for optimal manipulation under impartial (and impartial anonymous) culture. Since this style of analysis under partial information is rare, these results suggest the form that further results (e.g., for additional rules and more general distributions) might take. However, as argued elsewhere [32], this preference model is patently unrealistic, so we view these results as being largely of theoretical interest. Indeed, the difficulty in obtaining decent analytical results even for simple voting rules under very stylized distributions strongly argues for a more general computational approach to manipulation optimization that can be applied broadly—an approach we develop in the next section.

We begin with an analysis of the k-approval rule. When sincere votes are drawn from the uniform distribution over rankings, each alternative will obtain the same number of approvals in expectation. Intuitively, the coalition should cast its votes so that each approves d, and all alternatives apart from d receive the same number of approvals from the coalition (plus/minus 1 if $c(k-1)$ is not divisible by $m-1$): we refer to this as the *balanced strategy*. Indeed, this strategy is optimal:

Theorem 1. *The balanced manipulation strategy is optimal for k-approval under IC and IAC.*[5]

Things are somewhat more complex for the Borda rule, and we provide results only for the case of three candidates under IC and IAC. Apart from the balanced strategy, we use a *near-balanced strategy*, where the coalition's total approval score for d is c, and the scores for the two candidates apart from d differ by at most 2.

Theorem 2. *Let $A = \{x, y, d\}$ be a set of three alternatives, assume c is even. Then the either the balanced strategy or the near-balanced strategy is the optimal manipulation strategy for Borda under both IC and IAC. Furthermore, the balanced strategy is optimal if either: (i) n is even and $c+2$ is divisible by four; or (ii) n is odd and c is divisible by four.*

4 A GENERAL OPTIMIZATION FRAMEWORK

Analytical derivation of optimal Bayesian manipulation strategies is difficult; and even for a *fixed* voting rule, it is not viable for the range of beliefs that manipulators might possess about the voter preferences. For this reason, we develop a general optimization framework that can be used to estimate optimal strategies empirically given only the ability to sample vote profiles from the belief distribution. The model will allow direct estimation of the probability of manipulation

[5]The nontrivial proofs of the results in this section can be found in the appendix of a longer version of this paper; see: `http://www.cs.toronto.edu/~cebly/papers.html`.

(and social cost, see below). The model can be adapted to most voting rules, but we focus our development using positional scoring rules for ease of exposition.

The main idea is straightforward. Suppose we have a sample of T vote profiles from preference distribution P. For each vote profile, a given manipulation will either succeed or not; so we construct an optimization problem, usually in the form of a mixed-integer program (MIP), that constructs the manipulation that succeeds on the greatest number of sampled profiles. If enough samples are used, this approximately maximizes the probability of d winning, or equivalently, the probability of successful manipulation by the coalition. The formulation of the optimization problem—including the means by which one summarizes a sampled vote profile and formulates the objective—depends critically on the voting rule being used. We illustrate the method by formulating the problem for positional scoring rules.

Assume a positional scoring rule using score vector α. A sampled vote profile can be summarized by a *(summary) score vector* $\mathbf{s} = (s_1, \ldots, s_m)$, where s_i is the total score of a_i in that profile; hence we will treat a profile and its score vector interchangeably. Assume T sampled profiles $S = \{\mathbf{s}^1, \ldots, \mathbf{s}^T\}$. A *manipulation strategy* $\mathbf{v}_c$ can be represented by a PSM $\mathbf{X}$, where X_{ij} denotes the number manipulators who rank candidate a_i in jth position. The total score of each candidate for a given profile $\mathbf{s}$ is then $\mathbf{s} + \mathbf{X}\alpha'$.

This strategy representation simplifies the formulation of the optimization problem significantly (by avoiding search over of all possible collections of rankings). Moreover, it is not difficult to recover a set of manipulator votes $\mathbf{v}_c$ that induce any such $\mathbf{X}$, using properties of perfect matchings on c-regular bipartite graphs:

Lemma 3. *A matrix* $\mathbf{X}$ *is the PSM for some manipulation strategy* $\mathbf{v}_c$ *iff* $\mathbf{X} \in \mathbb{N}_{\geq 0}^{m \times m}$ *and* $\mathbf{X1} = \mathbf{X'1} = c\mathbf{1}$.

Our aim then reduces to finding a PSM $\mathbf{X}$ satisfying the above properties such that $\mathbf{X}\alpha'$ maximizes the probability of manipulation. We can recover the optimal manipulation strategy $\mathbf{v}_c^*$ (i.e., a set of c votes) in polynomial time using an algorithm to find c edge-disjoint perfect matchings in a c-regular bipartite graph. Specifically, we construct a bipartite graph with candidates forming one set of nodes and "vote positions" forming the second set. We connect these two sets of nodes with a multi-set of edges, with exactly X_{ij} (duplicate) edges connecting candidate i to position j. We find a perfect matching in this graph to determine one manipulator vote, remove the corresponding edges, and repeat the process (decreasing each row and column sum by one at each iteration).

We formulate the problem of finding an (approximately) optimal Bayesian manipulation strategy as a MIP which constructs a PSM $\mathbf{X}$ maximizing the number of sampled profiles in S on which d wins. We assume, for ease of exposition only, that α has integral entries. First note that in any optimal strategy, $X_{d1} = c$ and $X_{dj} = 0$ for all $j > 1$, which implies $X_{i1} = 0$ for all $a_i \neq d$. Otherwise we require $X_{ij} \in \{0, \ldots, c\}$ and row and column sum constraints:

$$\sum_{j=2}^{m} X_{ij} = c \quad \forall a_i \neq d, \qquad \sum_{\substack{i=1 \\ i \neq d}}^{m} X_{ij} = c \qquad \forall j > 1.$$

We use variables $I_i^t \in [0,1]$ for all $t \leq T, i \neq d$, where $I_i^t = 1$ iff candidate a_i's total score with manipulators is strictly less than d's total score, constrained as:

$$s_d^t + c\alpha_1 - s_i^t - \sum_{j=2}^{m} X_{ij}\alpha_j \geq \alpha_1(n+c)(I_i^t - 1) + 1 \quad \forall t, a_i \neq d. \quad (1)$$

The left-hand side of Eq. (1) is the score difference between d and a_i, bounded (strictly) from below by $-\alpha_1(n+c)$. If it is less than 0, then $I_i^t < 1$; otherwise, I_i^t is unconstrained by Eq. (1), and will take value 1 (due to the maximization objective below). Finally, we use variables $I^t \in \{0,1\}$ to indicate whether d wins under $\mathbf{X}$ on profile $\mathbf{s}^t$, requiring:

$$\sum_{a_i \neq d} I_i^t \geq (m-1)I^t \quad \forall t. \quad (2)$$

If d's score is less than that of some a_i, then the sum in Eq. (2) is smaller than $m-1$, forcing $I^t = 0$ (otherwise the maximization objective will force it to 1). We use the following natural maximization objective:

$$\max_{\mathbf{I},\mathbf{X}} \sum_{t=1}^{T} I_t. \quad (3)$$

If d wins in sample $\mathbf{s}$ prior to manipulation (see below), d still wins after manipulator votes are counted, but we do not consider this to be "successful manipulation." Thus, the estimated *probability of manipulation* (distinct from the probability of d winning) is the MIP objective value less the number of profiles in S where d would have won anyway.

The MIP can be simplified greatly. First notice that d cannot win, even with manipulation, in profile $\mathbf{s}^t$ if:

$$s_d^t + c\alpha_1 \leq c\alpha_m + \max_i s_i^t. \quad (4)$$

Any such profiles—and all corresponding variables and constraints—can be pruned from the MIP. Similarly, we can prune any profile where d wins regardless of the manipulation. This occurs when d wins without manipulator votes or is very close to winning:

$$s_d^t + c\alpha_1 > c\alpha_2 + \max_i s_i^t. \quad (5)$$

This pruning can greatly reduce the size of the MIP in practice, indeed, in expectation by a factor equal to the probability P that a random profile satisfies condition (4) or (5). The MIP has at most a total of $(T+2)m-2$ constraints, $(m-1)^2+T$ integer variables and $T(m-1)$ continuous variables, where T is the number of non-pruned profiles.

While pruning has a tremendous practical impact, the optimal Bayesian manipulation problem for scoring rules remains NP-hard: this follows from the NP-hardness of Borda manipulation with a known profile [13, 4], and the observation that a single known profile corresponds to a special case of our problem.[6]

The remaining question has to do with sample complexity: in order to have confidence in our estimate, how many samples T should we use? Specifically, if we set a PAC target, obtaining an ε-accurate estimate of the probability of d winning with confidence $1-\delta$, the required number of samples depends on the *VC dimension* D_α of the class of boolean-valued functions over vote profiles (or more generally the corresponding score vectors $\mathbf{s}=(s_1,\ldots,s_m)$):

$$\mathcal{F}_\alpha = \{\mathbf{s} \mapsto \mathbf{1}[d \text{ unique max of } \mathbf{X}\alpha' + \mathbf{s}] \mid \forall \mathbf{X}\}.$$

Using known results [14], on counting $|\mathcal{F}_\alpha|$ one obtains $\sup_\alpha D_\alpha \in O(cm\ln(cm)+c^2)$. Standard sample complexity results then apply directly:

Proposition 4. *There exists a constant $C>0$ such that if $T \geq C(cm\ln(cm)+c^2+\ln(1/\delta))/\varepsilon^2$ then for any distribution P, with probability $1-\delta$ over sample S of size T, we have $\hat{q} \leq q^*+\varepsilon$, where q^* is the probability of manipulation of the best strategy, and $\hat{q}$ is the probability of manipulation given the optimal solution to the MIP.*

For specific positional rules, the sample complexity may be smaller. For example, using standard results on compositions of integers, k-approval gives rise to a VC dimension of $D_{\text{kappr}} \leq \log_2 \binom{m+ck-1}{ck-1}$, giving the following sample complexity result:

Proposition 5. *If $T \geq 256(2\log_2 \binom{m+ck-1}{ck-1} + \ln(4/\delta))/\varepsilon^2$ then for any P, with probability $1-\delta$ over sample S of size T, we have $\hat{q} \leq q^*+\varepsilon$, where q^* is the probability of manipulation under the best strategy for k-approval and $\hat{q}$ is the probability of manipulation given the optimal solution to the MIP for k-approval.*

Furthermore, tighter results could be obtained with specific knowledge or constraints on the distribution P. Of course, such sample complexity results are conservative, and in practice good predictions can be realized with far fewer samples. Note also that this sample complexity is only indirectly related to the complexity of the MIP, due to the pruning of (typically, a great many) sampled profiles.

[6] A partial LP relaxation of the MIP may be valuable in practice: allowing entries of $\mathbf{X}$ to be continuous on $[0,1]$ provides an upper bound on (optimal Bayesian) success probability. Our computational experiments did not require this approximation, but it may be useful for larger problems.

5 IMPACT OF MANIPULATION ON SOCIAL WELFARE

As discussed above, characterizing the impact of a manipulating coalition's action solely in terms of its probability of succeeding can sometimes be misleading. This is especially true when one moves away from political domains—where a utility-theoretic interpretation of voting may run afoul of policy, process and fairness considerations—into other settings where voting is used, such as resource allocation, consumer group recommendations, hiring decisions, and team decision making [7]. In such domains, it is often natural to consider the utility that a group member ("voter") derives from the choice or decision that is made for the group as a whole. However, even in "classical" voting situations, most voting protocols are defined using an explicit score, social choice objective, or social welfare function; as such, analyzing the expected loss in this objective due to (optimal) manipulation is a reasonable approach to characterizing the manipulability of different voting rules.

Intuitively, manipulation is more likely to succeed when the desired candidate d is "closer to winning" under a specific voting rule (in the absence of manipulation) than if the candidate is "further from winning." In a (very loose) sense, if candidates that are "closer to winning" are those that are generally ranked more highly by group members, this means that such candidates are generally more desirable. As a consequence, social welfare for alternative d must be close to that of the optimal (non-manipulated) alternative if d has a reasonable chance of winning, which in turn means that the *damage*, or loss in social welfare, caused by manipulation will itself be limited. In this section we formalize this intuition and provide some simple bounds on such damage. We investigate this empirically in the next section.

Assume a voting rule r based on some social welfare measure $SW(a,\mathbf{v})$ over alternatives a and (reported) preference profiles $\mathbf{v}$; hence $r(\mathbf{v}) \in \text{argmax}_a\, SW(a,\mathbf{v})$. As above, we partition the vote profile: $\mathbf{v}=(\mathbf{v}_n,\mathbf{v}_c)$. We are interested in the loss in social welfare, or *regret*, imposed on the honest voters by a manipulation, so

define this to be:

$$R(\mathbf{v}_n, \mathbf{v}_c) = SW(r(\mathbf{v}_n), \mathbf{v}_n) - SW(r(\mathbf{v}), \mathbf{v}_n).^7 \quad (6)$$

The *expected regret* of a specific manipulation, given distribution P over preference profiles $\mathbf{v}_n$, is then:

$$ER(P, \mathbf{v}_c) = \mathop{\mathbb{E}}_{\mathbf{v}_n \sim P}[R(\mathbf{v}_n, \mathbf{v}_c)] \ . \quad (7)$$

Notice that any social welfare function SW that determines the quality of a candidate a given the sincere vote profile $\mathbf{v}_n$ can be used in Eq. 6; we need not commit to using r's scoring function itself. However, assessing loss does require the use of *some* measure of societal utility or welfare. If one is concerned only with whether the "true winner" is selected, then probability of manipulation, as discussed above, is the only sensible measure.

We illustrate the our framework by deriving several bounds on loss due to manipulation using positional scoring rules to measure social welfare.[8] We can derive theoretical bounds on expected regret for positional scoring rules. First, notice that expected regret can be bounded for arbitrary distributions:

Proposition 6. *Let r be a positional scoring rule with score vector α. Then for any distribution P, and any optimal manipulation strategy $\mathbf{v}_c$ w.r.t. P, we have*

$$\begin{aligned} ER(P, \mathbf{v}_c) < c[&(\alpha_1 - \alpha_m)P(r(\mathbf{v}_n) \neq d \wedge r(\mathbf{v}) = d) \\ &+ (\alpha_2 - \alpha_m)P(r(\mathbf{v}_n) \neq r(\mathbf{v}) \wedge r(\mathbf{v}) \neq d)]. \end{aligned} \quad (8)$$

Intuitively, this follows by considering the maximum increase in score the manipulating coalition can cause for d relative to an alternative a that would have won without the manipulators.

Proof of Prop. 6. Consider any $\mathbf{v}_n$. Clearly, d is ranked first by all votes in $\mathbf{v}_c$. Case 1: if d wins in $\mathbf{v}_n$ then d also wins on $\mathbf{v}$. Case 2: if a_i wins in $\mathbf{v}_n$ but d wins on $\mathbf{v}$ then $SW(a_i) + \alpha_m c \leq SW(a_i) + SW(a_i, \mathbf{v}_c) < SW(d) + \alpha_1 c$ implying $R(\mathbf{v}_n, \mathbf{v}_c) < c(\alpha_1 - \alpha_m)$. Case 3: if a_i wins in $\mathbf{v}_n$ and $a_j \neq a_i$ wins in $\mathbf{v}_c$ then $SW(a_i) + \alpha_m c \leq SW(a_i) + SW(a_i, \mathbf{v}_c) \leq SW(a_j) + \alpha_2 c$ implying $R(\mathbf{v}_n, \mathbf{v}_c) \leq c(\alpha_2 - \alpha_m)$. Case 4: if $r(\mathbf{v}_n) = r(\mathbf{v}_c)$ then regret is zero. Summing 2 and 3 gives the upper bound on expected regret. □

The proposition applies when P reflects full knowledge of $\mathbf{v}_n$ as well; and while this P-dependent bound will be crude for some P, it is in fact tight in the worst-case (which includes full knowledge distributions):

Proposition 7. *Suppose $\alpha_1 + \cdots + \alpha_m = M$, $m - 1$ divides c and $n - c \geq 0$ is even. Then*

$$\sup_{n,c,\alpha} \sup_{P} ER(P, \mathbf{v}_c) = cM. \quad (9)$$

Proof. The upper bound on the LHS follows from the RHS of Eq. 8 since it is at most $c(\alpha_1 - \alpha_m) \leq cM$. For the lower bound on the LHS, let P be a point mass on $\{\mathbf{v}_n\}$: in $\mathbf{v}_n$, the first c votes rank a_1 first and the remaining alternatives $a_2, \ldots, a_{m-1}, p$ in such a way that the number of times any is ranked i-th ($i \geq 2$) is $c/(m-1)$. Of the remaining $n-c$ votes, half rank a_1 first and d second, and half do the opposite (the remaining candidates are ranked in any manner). Thus $SW(a_1) - SW(d) = (\alpha_1 - \frac{\alpha_2 + \cdots + \alpha_m}{m-1})c$. Let $\alpha_2 = \delta + \xi$ and $\alpha_i = \delta$, for some $\delta, \xi > 0$, for all $i \geq 3$. One optimal strategy $\mathbf{v}_c$ is to always place d first and a_1 last, resulting in a score difference of $c(\alpha_1 - \alpha_m) = c(\alpha_1 - \delta)$ which is strictly larger than the above social welfare difference of $c(\alpha_1 - \delta - \xi/(m-1))$ within $\mathbf{v}_n$. Hence $\mathbf{v}_c$ causes d to win, inducing regret of $c(M - (m-1)\delta - \xi m/(m-1))$, which can be made arbitrarily close to cM using a small enough δ, ξ. □

We can obtain a tighter bound than that offered by Prop. 6 if, for a given P and r, we know the optimal manipulation strategy. For instance, exploiting Thm. 1 we obtain:

Proposition 8. *Consider the k-approval rule, where $SW(a, \mathbf{v}_n)$ is the approval score of a. Let P be impartial culture. Then*

$$\begin{aligned} ER(\mathbf{v}_n, BAL) \leq \left[\left\lceil \frac{ck}{m} \right\rceil - 1\right] \cdot [&P(r(\mathbf{v}_n) \neq d \wedge r(\mathbf{v}) = d) \\ &+ P(r(\mathbf{v}_n) \neq r(\mathbf{v}) \wedge r(\mathbf{v}) \neq d)]. \end{aligned} \quad (10)$$

Proof. Consider any $\mathbf{v}_n$. We use a case analysis similar to that in Prop. 6. Case 1 applies directly. For case 3, a_i must have received one more veto vote than a_j from the manipulators, and thus $SW(a_i) - SW(a_j) \leq 1$. For case 2, BAL implies that $SW(a_i) - \lceil \frac{ck}{m} \rceil + 1 \leq SW(p)$ (a_i might have received $\lfloor ck/m \rfloor$ veto votes, but the bound holds in any case). Thus $SW(a_i) - SW(d) \leq \lceil \frac{ck}{m} \rceil - 1$. Case 4 also applies directly. Summing cases 2 and 3 gives the required inequality. □

[7] We assume a voting rule and welfare measure that can accept variable numbers of voters, as is typical.

[8] One reason to consider positional scoring rules like Borda in analyzing impact on social welfare is the tight connection between scoring rules and social welfare maximization in its narrow sense (i.e., sum of individual utilities). In models where we desire to maximize sum of utilities relative to some underlying utility profile, voting is a relatively simple and low-cost way (i.e., with minimal communication) of eliciting partial preference information from voters. Analysis of the *distortion* of utilities induced by restricting voters to expressing ordinal rankings shows that, with carefully crafted positional rules, one can come close to maximizing (this form of) social welfare [37, 29, 6]. Borda scoring, in particular, seems especially robust in this sense.

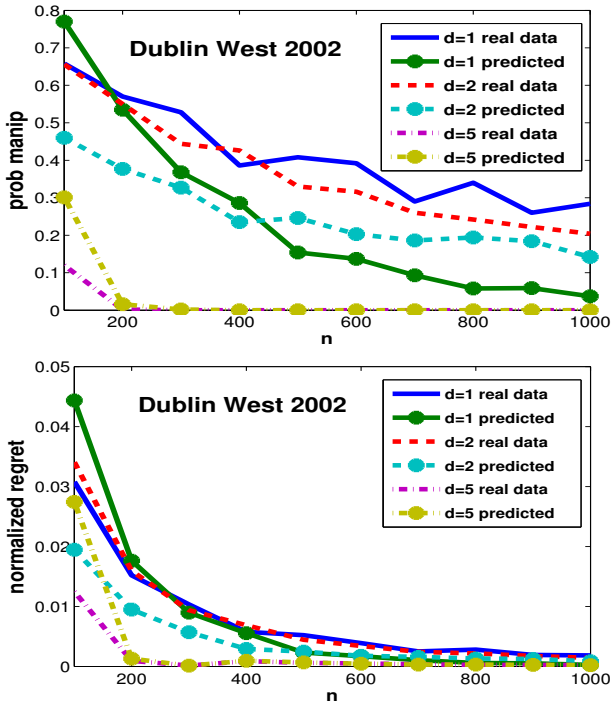

Fig. 1: Probability of manipulation and expected normalized regret for Irish election data.

We can also exploit our empirical optimization framework to assess the expected regret. While deriving optimal manipulation strategies is analytically intractable in general, we can exploit the ability to empirically determine (approximately) optimal Bayesian strategies to great effect. Given a collection of samples, we can—in the same MIP used to compute the optimal strategy—measure expected regret empirically.[9] Sample complexity results related to those above can be derived (we omit details). Notice the ability to accurately estimate the behavior of the manipulators is critical to being able to estimate expected regret.

6 EMPIRICAL EVALUATION

We experiment with several common preference distributions, as well as real voting data, to test the effectiveness of our approach. We are primaily interested in: (a) determining the computational effectiveness of our empirical framework for computing optimal manipulation strategies when manipulators have incomplete knowledge; and (b) measuring both the probability of manipulation and expected regret caused by manipulation in some prototypical scenarios. We focus on Mallows models, and mixtures of Mallows models, because of their flexibility and ability to represent a wide class of preferences (including impartial culture).

[9]Pruning of samples must be less aggressive when estimating regret, since damage may be caused by manipulation even in profiles where d cannot win.

However, it should be clear that our framework is not limited to such models. Space precludes a systematic investigation of multiple voting rules, so we focus here on the Borda rule.

Our first set of experiments uses 2002 Irish electoral data from the Dublin West constituency, with 9 candidates and 29,989 ballots of top-t form, of which 3800 are complete rankings.[10] We learn a Mallows mixture with three components (using the techniques of [21]) using a subsample of 3000 random (not necessarily complete) ballots: this represents a prior that manipulators might develop with intense surveying. We fix $c = 10$ manipulators and vary the number of sincere voters $n \in \{100, 200, \ldots, 1000\}$. The MIP is solved using 500 random profiles sampled from the learned Mallows mixture, which provides the manipulators with an approximately optimal strategy, as well as predicted probability of success and expected regret. We test the predictions by simulating the manipulators' strategy on the real data set, drawing 1000 random profiles (of the appropriate size n) from the set of 3800 full rankings to estimate true probability of manipulation and expected regret (normalized by $SW(r(\mathbf{v}_n), \mathbf{v}_n)$). Since manipulability varies greatly with the "expected rank" of a candidate, we show results for the candidates whose *expected* ranks in the learned model are first, second, and fifth (below this, probability of manipulation is extremely small).

Fig. 1 shows that the probability of manipulation is in fact quite high when d is the first- or second-ranked candidate (in expectation), but is much smaller when d is the fifth-ranked. Not surprisingly, probabilities gradually drop as n grows. The predicted probabilities based on the learned model are reasonably accurate, but of course have some error due to to imperfect model fit. Despite the high probability of manipulation, the second plot shows that expected regret (normalized to show percentage loss) is in fact extremely small. Indeed, maximal (average) loss in social welfare is just over 3%, when d is candidate 2 and $n = 100$, which means means nearly 10% of the voters are manipulators. Expected regret drops rapidly with increasing n. Notice that success probability and expected regret are greatest when the manipulators' desired candidate has expected rank 1 or 2: while the odds of 1 winning are higher than 2, 1 is also more likely to win without manipulator intervention.

Our second set of experiments use Mallows models over six alternatives with different variance ϕ (recall that with $\phi = 1$, Mallows is exactly IC). The reference ranking is $\sigma = 123456$ (i.e., alternative 1 is most preferred, 2 next most, etc.). We fix $c = 10$ and vary n from 100

to 1000 as above. Results in Fig. 2 show manipulation probability and expected regret as we vary ϕ and consider desired alternatives 1, 2 and 3.[11] While manipulation probability is high for these near-top alternatives (when n is small), expected regret (normalized in percentage terms) is negligible, with a maximum of 4%, and then only when the distribution is close to impartial culture ($\phi = 0.8$) and $n = 100$ (nearly 10% manipulators). As above, when manipulators want $d = 2$, expected regret is highest. Of some interest is the connection to both theoretical and empirical work that shows phase transitions often occur when the number of manipulators is roughly the square root of the number of sincere voters: any less makes manipulation very unlikely, while any more makes manipulation likely. While most of this work analyzes complete information settings, our results above show that *with realistic preference distributions*—even with restricted knowledge on the part of manipulators—the probability of manipulation is sometimes quite significant with far fewer manipulators than suggested by past work. Despite this, expected regret remains relatively small.

Fig. 3 shows the average and maximum running times of the MIP required to compute the optimal manipulation for the problems described above. As can be seen, even with a large number of sampled profiles, the MIP can be solved quickly across a range of problem sizes and distributions.

[11]Under IC (i.e., when $\phi = 1$), alternatives are probabilistically indistinguishable, so we show one row only.

7 CONCLUDING REMARKS

Our primary contribution is an empirical framework for the computation of optimal manipulation strategies when manipulators have incomplete information about voter preferences. This is an important methodology for the analysis of the manipulability of voting rules in realistic circumstances, without the need to restrict the analysis to specific voting rules or priors. Our experiments indicate that our algorithms are quite tractable. Furthermore, our results suggest that manipulation may not be as serious a problem as is commonly believed when realistic informational models are used, or when the quality of the outcome, rather than societal justice, is the main objective. Our empirical results, which exploit several innovations introduced in this paper, demonstrate this in the case of Borda voting; but our approach is easily adapted to different types of manipulation under different scoring rules, and can be applied to any "utility-based" voting rule with appropriate formulation of the optimization problem. Thus, our approach provides a compelling framework for the comparison of voting rules.

One nonstandard aspect of our approach is the use of the score under a voting rule as a proxy for social welfare. A similar regret-based approach is taken in preference elicitation [22]; and it is implicit in work on approximating voting rules [28, 5], which assumes that approximating the score also gives an approximation to the desirability of an alternative. One strong argument in favor of this view is that scores of certain voting rules, such as Borda, are provably good proxies for utilitarian social welfare when utilities are drawn from specific distributions [37]. That said, our framework can be used, in principle, to analyze any measure of impact or loss.

Our work suggests a number of interesting future directions. Of course, we must study additional voting rules, social welfare measures, and manipulator objectives within our framework to further demonstrate its viability. While our results suggest that incomplete knowledge limits the ability of a manipulating coalition to impact the results of an election, our framework can also be used to directly study the relationship between the "amount of information" (e.g., using entropy or equivalent sample size metrics) and the probability of manipulation. Finally, interesting computational questions arise within our approach: e.g., deriving tighter complexity results for optimal manipulation given a *collection* of vote profiles; or deriving simpler classes of manipulation policies (e.g., uncertainty-sensitive variants of the balanced manipulation strategy) that can be more readily optimized by a manipulating coalition.

Abstract

The Semantic Web effort has steadily been gaining traction in the recent years. In particular, Web search companies are recently realizing that their products need to evolve towards having richer semantic search capabilities. Description logics (DLs) have been adopted as the formal underpinnings for Semantic Web languages used in describing ontologies. Reasoning under uncertainty has recently taken a leading role in this arena, given the nature of data found on the Web. In this paper, we present a probabilistic extension of the DL $\mathcal{EL}^{++}$ (which underlies the OWL2 EL profile) using Markov logic networks (MLNs) as probabilistic semantics. This extension is tightly coupled, meaning that probabilistic annotations in formulas can refer to objects in the ontology. We show that, even though the tightly coupled nature of our language means that many basic operations are data-intractable, we can leverage a sublanguage of MLNs that allows to rank the atomic consequences of an ontology relative to their probability values (called ranking queries) even when these values are not fully computed. We present an anytime algorithm to answer ranking queries, and provide an upper bound on the error that it incurs, as well as a criterion to decide when results are guaranteed to be correct.

1 Introduction

Recently, it has become apparent that Semantic Web formalisms must be able to cope with uncertainty in a principled manner. The Web contains many examples where uncertainty comes in [22]: as an inherent aspect of Web data (such as in reviews of products or services, comments in blog posts, weather forecasts, etc.), as the result of automatically processing Web data (for instance, analyzing a document's HTML Document Object Model usually involves some degree of uncertainty), and as the result of integrating information from many different heterogeneous sources (such as in aggregator sites, which allow users to query multiple sites at once to save time). Finally, inconsistency and incompleteness are also ubiquitous as the result of over- and under-specification, respectively. To be applicable to Web-sized data sets, any machinery developed for dealing with uncertainty in these settings must be scalable. In this paper, we develop an extension of $\mathcal{EL}^{++}$ [1] by means of a probabilistic semantics based on Markov logic networks [20]. $\mathcal{EL}^{++}$ is a DL that combines tractability of several key reasoning problems with enough expressive power to model a variety of ontologies; for instance, it is expressive enough to model real-world ontologies such as the well-known SNOMED CT, large segments of the Galen medical knowledge base, as well as the Gene Ontology. Moreover, $\mathcal{EL}^{++}$ underlies the OWL2 EL profile, in which basic reasoning problems are solvable in polynomial time, and highly scalable implementations are available. One of the key aspects of the extension presented here is that it is *tightly coupled*, meaning that probabilistic annotations can refer to objects in the ontology, providing greater expressive power than similar efforts in the literature.

In the area of Web data extraction [16], uncertainty comes into play even for very basic tasks. Consider, as an example, the *form-labeling* problem, consisting of the association of blocks of text (i.e., the *labels*) to the corresponding *fields* in a Web form [6], illustrated in Figure 1, where three possible instances of the problem with decreasing likelihood of occurrence are shown. In the first case, the fields f_1 and f_2 have horizontally aligned blocks of text on their left and on their right; this case exemplifies the most typical situation where the blocks of text on the left of a field (denoted l_1 and l_2) are the actual labels, while those on the right (denoted t_1 and t_2) are either unrelated or carry additional information about the fields. The second case represents the symmetric situation, where the labels are on the right of the fields. This situation is typical for eastern Web sites where the content has right-to-left reading order (e.g., for Arabic). Another possibility is exemplified by the third case, where the labels occur in the north-west region of the field. In this

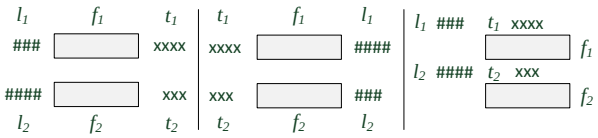

Figure 1: Uncertainty in form labeling.

setting, probabilistic DL formalisms are well-suited to the task, since they couple powerful modeling capabilities with sound and complete reasoning procedures.

Example 1. Consider the following $\mathcal{EL}^{++}$ formulas describing a simple ontology of Web forms. The ontology forces each field to be associated with a block of text representing its label. Fields and text blocks are disjoint sets.

$$\mathit{Field} \sqsubseteq \exists \mathit{label}.\mathit{Text}; \quad \mathit{dom}(\mathit{label}) \sqsubseteq \mathit{Field};$$
$$\mathit{Field} \sqcap \mathit{Text} \sqsubseteq \bot; \quad \mathit{ran}(\mathit{label}) \sqsubseteq \mathit{Text}. \qquad \blacksquare$$

The set of formulas above simply defines what a correct labeling of the form should be, without providing a measure of the likelihood that the labeling is correct. Example 1 shows the need for probabilistic modeling languages for reasoning over structured data on the Web, e.g., to leverage the statistical evidence that certain patterns are more likely to occur than others.

Markov logic networks [20] (MLNs), which were developed in recent years, are a simple approach to generalizing classical logic; their relative simplicity and lack of restrictions has recently caused them to be well-received in the reasoning under uncertainty community. To our knowledge, this work is the first to develop an MLN-based probabilistic extension of DLs, and in particular of $\mathcal{EL}^{++}$.

The following are the main contributions of this paper:

(i) Introduction of tightly coupled probabilistic (TCP) DLs, an expressive class of probabilistic ontology languages that allow probabilistic annotations to refer to objects in the ontology. The probabilistic semantics is based on MLNs.

(ii) Complexity results establishing the intractability of basic computations over TCP ontologies necessary to rank atomic consequences based on their probabilities.

(iii) The proposal of *conjunctive MLNs* (cMLNs), a subset of the MLN formalism. Though we prove that this model restriction does not alleviate the complexity issues of the general case for TCP ontologies, we propose the analysis of a special kind of *equivalence classes* of possible worlds, for which we prove useful properties: deciding emptiness and generation of members can both be done in polynomial time in the data complexity, all worlds in a class are guaranteed to have the same probability, and the highest-probability classes can be identified in polynomial time in the data complexity.

(iv) An anytime algorithm for answering *ranking queries* over TCP ontologies with cMLNs that leverages the properties of equivalence classes and is guaranteed to inspect worlds in decreasing order of probability. We provide an upper bound on the error that is incurred by this algorithm based on the number of worlds and equivalence classes inspected, and a criterion to decide when results are guaranteed to be correct.

The rest of this paper is organized as follows. Section 2 describes the preliminaries on the DL $\mathcal{EL}^{++}$ and MLNs. Section 3 presents tightly coupled probabilistic DLs, and a complexity result showing the intractability of computing probabilities of atoms. In Section 4, we present conjunctive MLNs, and we analyze how their structure can be leveraged in the definition of well-behaved equivalence classes over possible worlds, as well as in an anytime algorithm that exploits this equivalence class approach in order to tractably compute a heuristic answer to the ranking of atoms according to their probabilities. Finally, Sections 5 and 6 discuss related work and conclusions, respectively.

2 Preliminaries

In this section, we briefly recall the description logic (DL) $\mathcal{EL}^{++}$ and Markov logic networks (MLNs).

2.1 The DL $\mathcal{EL}^{++}$

We now recall the syntax and the semantics of $\mathcal{EL}^{++}$, a tractable DL especially suited for representing large amounts of data. Intuitively, DLs model a domain of interest in terms of concepts and roles, which represent classes of individuals and binary relations between individuals, respectively. While we restrict ourselves to $\mathcal{EL}^{++}$ here, the general approach continues to be valid for any DL or ontology language for which instance checking is data-tractable (for instance, the closely related Datalog+/– family of ontology languages contains such tractable subsets [3]). However, note that all results in this paper were derived for $\mathcal{EL}^{++}$, and thus certain results may not hold for other logics.

Syntax and Semantics. We first define concepts and then knowledge bases and instance checking in $\mathcal{EL}^{++}$. We assume pairwise disjoint sets $\mathbf{A}$, $\mathbf{R}$, and $\mathbf{I}$ of *atomic concept names*, *role names*, and *individual names*, respectively. Concepts are defined inductively via the constructors shown in the first five rows of the table in Figure 2; this table adopts the usual conventions of using C and D to refer to concepts, r to refer to a role, and a and b to refer to individuals. The semantics of these concepts is given, as usual in first-order logics, in terms of an *interpretation* $\mathcal{I} = (\Delta^{\mathcal{I}}, \cdot^{\mathcal{I}})$. The *domain* $\Delta^{\mathcal{I}}$ comprises a non-empty set of individuals and the *interpretation function* $\cdot^{\mathcal{I}}$ maps each concept name $A \in \mathbf{A}$ to $A^{\mathcal{I}} \subseteq \Delta^{\mathcal{I}}$, each role name $r \in \mathbf{R}$ to a binary relation $r^{\mathcal{I}}$ over $\Delta^{\mathcal{I}} \times \Delta^{\mathcal{I}}$, and each individual name $a \in \mathbf{I}$ to an individual $a^{\mathcal{I}} \in \Delta^{\mathcal{I}}$. The ex-

Name	Syntax	Semantics
Top	$\top$	$\Delta^{\mathcal{I}}$
Bottom	$\bot$	$\emptyset$
Nominal	$\{a\}$	$\{a^{\mathcal{I}}\}$
Conjunction	$C \sqcap D$	$C^{\mathcal{I}} \cap D^{\mathcal{I}}$
Existential Restriction	$\exists r.C$	$\{x \in \Delta^{\mathcal{I}} \mid \exists y \in \Delta^{\mathcal{I}} : (x,y) \in r^{\mathcal{I}} \wedge y \in C^{\mathcal{I}}\}$
Concrete Domain	$p(f_1,...,f_k)$ for $p \in \mathcal{P}^{\mathcal{D}_j}$	$\{x \in \Delta^{\mathcal{I}} \mid \exists y_1,...,y_k \in \Delta^{\mathcal{D}_j} : f_i^{\mathcal{I}}(x) = y_i, 1 \leq i \leq k \wedge (y_1,...,y_k) \in p^{\mathcal{D}_j}\}$
GCI	$C \sqsubseteq D$	$C^{\mathcal{I}} \subseteq D^{\mathcal{I}}$
RI	$r_1 \circ ... \circ r_k \sqsubseteq r$	$r_1^{\mathcal{I}} \circ ... \circ r_k^{\mathcal{I}} \subseteq r^{\mathcal{I}}$
Domain Restriction	$dom(r) \sqsubseteq C$	$r^{\mathcal{I}} \subseteq C^{\mathcal{I}} \times \Delta^{\mathcal{I}}$
Range Restriction	$ran(r) \sqsubseteq C$	$r^{\mathcal{I}} \subseteq \Delta^{\mathcal{I}} \times C^{\mathcal{I}}$
Concept Assertion	$C(a)$	$a^{\mathcal{I}} \in C^{\mathcal{I}}$
Role Assertion	$r(a,b)$	$(a^{\mathcal{I}}, b^{\mathcal{I}}) \in r^{\mathcal{I}}$

Figure 2: Syntax and Semantics of $\mathcal{EL}^{++}$ (rep. from [1]).

tension of $\cdot^{\mathcal{I}}$ to arbitrary concept descriptions is defined via the constructors in Figure 2.

Reference to concrete data objects is accomplished via the parameterization of $\mathcal{EL}^{++}$ by concrete domains $\mathcal{D}_1, ..., \mathcal{D}_n$, which correspond to OWL data types. Such concrete domains are pairs $(\Delta^{\mathcal{D}}, \mathcal{P}^{\mathcal{D}})$, where $\Delta^{\mathcal{D}}$ is a set and $\mathcal{P}^{\mathcal{D}}$ is a set of predicate names; each $p \in \mathcal{P}^{\mathcal{D}}$ has an arity $n > 0$ and an extension $p^{\mathcal{D}} \in (\Delta^{\mathcal{D}})^n$. The link between the DL and concrete domains is accomplished via the introduction of *feature names* $\mathbf{F}$ and the concrete domain constructor included in Figure 2; p is used to denote a predicate of a concrete domain, and $f_1, ..., f_k$ to denote feature names. The interpretation function maps each feature name f to a partial function from $\Delta^{\mathcal{I}}$ to $\bigcup_{1 \leq i \leq n} \Delta^{\mathcal{D}_i}$, where in general it is assumed that $\Delta^{\mathcal{D}_i} \cap \Delta^{\mathcal{D}_j} = \emptyset$ for $1 \leq i < j \leq n$.

$\mathcal{EL}^{++}$ Knowledge Bases. A KB consists of two sets, referred to as the ABox and the TBox, respectively containing the *extensional* knowledge about individual objects and *intensional* knowledge about the general notions for the domain in question. The ABox formally consists of a finite set of concept assertions and role assertions, while the TBox is comprised of a finite set of *constraints*, which can be general concept inclusions (GCIs), role inclusions (RIs), domain restrictions (DRs), or range restrictions (RRs) (cf. Figure 2). An interpretation $\mathcal{I}$ is a model of a TBox $\mathcal{T}$ (resp., ABox $\mathcal{A}$) iff, for each contained constraint (resp., assertion), the conditions in the "Semantics" column of Figure 2 are satisfied. We note that the expressive power of $\mathcal{EL}^{++}$ allows the expression of role hierarchies, role equivalences, transitive roles, reflexive roles, left- and right-identity rules, disjointness of complex concept descriptions, and the identity and distinctness of individuals.

Finally, here we adopt the syntactic restriction presented in [1] to avoid intractability/undecidability, which prevents intricate interplay between role inclusions and range restrictions; we do not describe it here for reasons of space.

2.2 Markov Logic Networks

Markov logic networks (MLNs) [20] combine first-order logic with Markov networks (abbreviated MNs; they are also known as Markov random fields) [19]. We now provide a brief introduction first to MNs, and then to MLNs.

Markov Networks. A Markov network (MN) is a probabilistic model that represents a joint probability distribution over a (finite) set of random variables $X = \{X_1, \ldots, X_n\}$. Each random variable X_i may take on *values* from a finite *domain* $Dom(X_i)$. A *value* for $X = \{X_1, \ldots, X_n\}$ is a mapping $x \colon X \to \bigcup_{i=1}^{n} Dom(X_i)$ such that $x(X_i) \in Dom(X_i)$; the *domain* of X, denoted $Dom(X)$, is the set of all values for X. An MN is similar to a Bayesian network (BN) in that it includes a graph $G = (V, E)$ in which each node corresponds to a variable, but, differently from a BN, the graph is undirected; in an MN, two variables are connected by an edge in G iff they are conditionally dependent. Furthermore, the model contains a *potential function* ϕ_i for each (maximal) clique in the graph; potential functions are non-negative real-valued functions of the values of the variables in each clique (called the *state* of the clique). In this work, we assume the *log-linear* representation of MNs, which involves defining a set of *features* of such states; a feature is a real-valued function of the state of a clique (we only consider binary features in this work). Given a value $x \in Dom(X)$ and a feature f_j for clique j, the probability distribution represented by an MN is given by $P(X = x) = \frac{1}{Z} \exp\left(\sum_j w_j \cdot f_j(x)\right)$, where j ranges over the set of cliques in the graph G, and $w_j = \log \phi_j(x_{\{j\}})$ (here, $x_{\{j\}}$ is the state of the j-th clique). The term Z is a normalization constant to ensure that the values given by the equation above are in $[0, 1]$; it is given by $Z = \sum_{x \in Dom(X)} \exp\left(\sum_j w_j \cdot f_j(x)\right)$. Probabilistic inference in MNs is intractable; however, approximate inference mechanisms, such as Markov Chain Monte Carlo, have been developed and successfully applied.

Markov Logic Networks. In the following, let Δ_{MLN}, $\mathcal{V}_{MLN}$, and $\mathcal{R}_{MLN}$ denote the set of constants, variables, and predicate symbols. The main idea behind Markov logic networks (MLNs) is to provide a way to soften the constraints imposed by a set of classical logic formulas. Instead of considering worlds that violate some formulas to be impossible, we wish to make them less probable. An MLN is a finite set L of pairs (F_i, w_i), where F_i is a formula in first-order logic over $\mathcal{V}_{MLN}$, Δ_{MLN}, and $\mathcal{R}_{MLN}$, and w_i is a real number. Such a set L, along with a finite set of constants Δ_{MLN}, defines a Markov network M that contains: (i) one binary node corresponding to each element of the Herbrand base of the formulas in L (i.e., all possible ground instances of the atoms), where the node's value is 1 iff the atom is true; and (ii) one feature for every possible

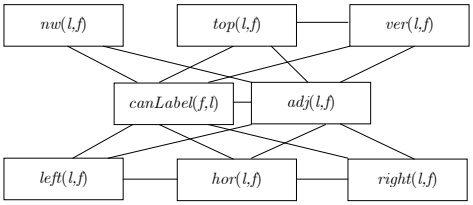

Figure 3: The graph representation of a simple grounding of the MLN from Example 2.

ground instance of a formula in L. The value of the feature is 1 iff the ground formula is true, and the weight of the feature is the weight corresponding to the formula in L. From this characterization and the description above of the graph corresponding to an MN, it follows that M has an edge between any two nodes corresponding to ground atoms that appear together in at least one formula in L. Furthermore, the probability of $x \in Dom(X)$ given this ground MLN is

$$P(X = x) = \frac{1}{Z} \cdot \exp\left(\sum_j w_j \cdot n_j(x)\right), \qquad (1)$$

where $n_i(x)$ is the *number of ground instances* of F_i made true by x, and Z is defined as above. This formula can be used in a generalized manner to compute the probability of any setting of a subset of random variables $X' \subseteq X$.

Example 2. Consider again the form-labeling problem of Example 1. The fact that certain text blocks are more likely to represent field labels than others (which is part of their *phenomenology*) can be described by assigning weights to the following first-order formulas:

$\phi_1 : canLabel(Y, X) \wedge hor(X, Y) \wedge left(X, Y) \wedge adj(X, Y)$;

$\phi_2 : canLabel(Y, X) \wedge hor(X, Y) \wedge right(X, Y) \wedge adj(X, Y)$;

$\phi_3 : canLabel(Y, X) \wedge ver(X, Y) \wedge top(X, Y) \wedge adj(X, Y)$;

$\phi_4 : canLabel(Y, X) \wedge nw(X, Y) \wedge adj(X, Y)$.

Formula ϕ_1 describes labels that are left-adjacent and horizontally aligned with the field. The dual case, with right-adjacent labels, is captured by ϕ_2. The case of top-adjacent labels that are vertically-aligned to the field is expressed by formula ϕ_3, while the last expression (ϕ_4) describes the case of labels appearing in the north-west area of the field.

The formulas above are part of the MLN associated with the $\mathcal{EL}^{++}$ formulas describing the form ontology. As an example, the following MLN formulas reflect the likelihood of the particular labeling phenomenology.

$\psi_1 : (\phi_1, 9), \;\; \psi_2 : (\phi_2, 6), \;\; \psi_3 : (\phi_3, 5), \;\; \psi_4 : (\phi_4, 1)$. ∎

Figure 3 shows a simple grounding of the MLN described in Example 2, relative to the set of constants $\{f, \ell\}$ (resp., one field and one label). This grounding also assumes that we have additional constraints (not shown here for simplicity) that only allow arguments of predicates to take the type of argument they expect; this sort of constraints is provided in certain implementations of MLNs such as Tuffy[1], where they are called *predicate scoping rules*.

3 Tightly Coupled Probabilistic DLs

Considering the basic setup from Sections 2.1 and 2.2, we now present the language of probabilistic $\mathcal{EL}^{++}$.

3.1 Syntax

Recall that we have (as discussed in Sections 2.1 and 2.2) an infinite universe of individual names $\mathbf{I}$, a finite set of concept names $\mathbf{C}$ and role names $\mathbf{R}$, a finite set of constants Δ_{MLN}, an infinite set of variables $\mathcal{V}_{MLN}$, and a finite set of predicate names $\mathcal{R}_{MLN}$ (such that $\mathcal{R}_{MLN} \cap \mathbf{C} = \emptyset$ and $\mathcal{R}_{MLN} \cap \mathbf{R} = \emptyset$). Finally, recall that the set of random variables in the MLN coincides with the set of ground atoms over $\mathcal{R}_{MLN}$ and Δ_{MLN}; alternatively, we denote this set with $X = \{X_1, \ldots, X_n\}$, as in Section 2.2.

Substitutions and Unifiers. We adopt the usual definitions from classical logic. A substitution is a function from variables to variables or constants. Two sets S and T *unify* via a substitution θ iff $\theta S = \theta T$, where θA denotes the application of θ to all variables in all elements of A (here, θ is a unifier). A *most general unifier* (mgu) is a unifier θ such that for all other unifiers ω, there exists a substitution σ such that $\omega = \sigma \circ \theta$.

Translation into FOL. In the rest of this work, we assume that $\mathcal{EL}^{++}$ TBoxes and ABoxes are translated into their equivalent first-order logic formulas; therefore, when clear from the context, we refer to *axioms* or *assertions* without distinguishing them from their translations into FOL. This is required for technical reasons, such as the need to be able to explicitly refer to the variables in the axioms in order to have the possibility of linking such variables with those in probabilistic annotations. Note that this does not affect the expressiveness of our formalism, nor its tractability, since the translation to FOL (and back to $\mathcal{EL}^{++}$) can be done in polynomial time in the size of the ontology.

Informally, probabilistic ontologies consist of a finite set of first-order logic formulas that correspond to the translation of $\mathcal{EL}^{++}$ axioms; each such formula is associated with a probabilistic annotation, as described next.

Definition 1. A *probabilistic annotation* λ relative to an MLN M defined over $\mathcal{R}_{MLN}$, $\mathcal{V}_{MLN}$, and Δ_{MLN} is a (finite) set of pairs $\langle A_i, x_i \rangle$, where: (i) A_i is an atom over $\mathcal{R}_{MLN}$, $\mathcal{V}_{MLN}$, and Δ_{MLN}; (ii) $x_i \in \{0, 1\}$; and (iii) for any two pairs $\langle A, x \rangle, \langle B, y \rangle \in \lambda$, there does not exist substitution θ that unifies A and B. If $|\lambda| = |X|$ and all $\langle A, x_i \rangle \in \lambda$ are such that A is ground, then λ is called a *(possible) world*.

[1] http://research.cs.wisc.edu/hazy/tuffy/

Intuitively, a probabilistic annotation λ is used to describe the class of events in which the random variables in an MLN are compatible with the settings of the random variables described by λ, i.e., each X_i has the value x_i.

Definition 2. Let F be the FOL translation of an $\mathcal{EL}^{++}$ axiom, and λ be a probabilistic annotation; a *probabilistic $\mathcal{EL}^{++}$ axiom* is of the form $F : \lambda$. We also refer to probabilistic axioms as *annotated formulas*.

Essentially, probabilistic axioms hold whenever the events associated with their annotations occur. Note that whenever a random variable's value is left unspecified in an annotation, the variable is *unconstrained*; in particular, an empty annotation means that the formula holds in every possible world (we sometimes refer to these axioms as *crisp*).

Definition 3. Let O be a set of (FOL translations of) probabilistic $\mathcal{EL}^{++}$ axioms and M be an MLN. A *tightly coupled probabilistic $\mathcal{EL}^{++}$ ontology* (TCP ontology, or knowledge base) is of the form $KB = (O, M)$, where the probabilistic annotations of formulas in O are relative to M.

Recall that random variables in our MLN setting are Boolean and written in the form of atoms over $\mathcal{R}_{MLN}$, $\mathcal{V}_{MLN}$, and Δ_{MLN}; if a is such an atom, $a = 1$ (resp., $a = 0$) denotes that the variable is *true* (resp., *false*); we also use the notation a and $\neg a$, respectively.

Definition 4. Let $KB = (O, M)$ be a *probabilistic $\mathcal{EL}^{++}$ ontology*, and λ be a possible world. The (non-probabilistic) $\mathcal{EL}^{++}$ ontology *induced* from KB by λ, denoted O_λ, is the set $\{\theta_i F_i \mid F_i : \lambda_i \in O \text{ and } \theta_i\lambda_i \subseteq \lambda\}$, where θ_i is an mgu for λ and λ_i.

The annotation of ontological axioms offers a clear modeling advantage by enabling a *clear separation of concerns* between the task of ontological modeling and the task of modeling the uncertainty around the axioms in the ontology. More precisely, in our formalism, it is possible to express the fact that the probabilistic nature of an ontological axiom is determined by elements that are *outside of the domain modeled by the ontology*.

Example 3. Consider the form-labeling ontology of Example 1 and the MLN of Example 2. In general, we expect only certain axioms to be probabilistic, while others are necessarily crisp. In our case, the fact that fields and text blocks are disjoint sets of objects, and that fields are labeled by text blocks are considered crisp axioms, since we do not want these assumptions to be violated by any model. However, we want to accept models where some field is left unlabeled, and therefore violating the axiom $Field \sqsubseteq \exists label.Text$ is possible. In addition, we want to link the probability that this axiom holds to the heuristics used to produce the actual labeling of the field, which are out of the domain of the form-labeling ontology. The following is a possible probabilistic $\mathcal{EL}^{++}$ ontology modeling this setup, where the first-order representation of the $\mathcal{EL}^{++}$ axioms discussed above is used to explicitly state the relationships between variables and constants in the MLN and in the ontology.

$$\forall X.\mathit{field}(X) \rightarrow \exists Y.\mathit{label}(X,Y) \wedge \mathit{text}(Y) : \{\langle \mathit{canLabel}(Y,X), 1\rangle\};$$

$$\forall X.\mathit{label}(X,Y) \rightarrow \mathit{field}(X) : \{\};$$

$$\forall X.\mathit{label}(X,Y) \rightarrow \mathit{text}(Y) : \{\};$$

$$\forall X.\mathit{field}(X) \wedge \mathit{text}(X) \rightarrow \bot : \{\}. \qquad \blacksquare$$

Data Complexity. In this setting, we extend the usual concept of data complexity as follows: the set of formulas in the MLN are considered to be fixed, as is the TBox; on the other hand, the sets $\mathbf{I}$ and Δ_{MLN} are not, and therefore the ground ABox on the ontology side and the set of random variables on the MLN side *are not fixed*, either.

3.2 Semantics

The semantics of TCP ontologies is given relative to probabilistic distributions over *interpretations* of the form $\mathcal{I}_{MLN} = \langle D, w\rangle$, where D is a database over $\mathbf{I} \cup \Delta_N$, and w is a world. We usually abbreviate "$true : \lambda$" with "λ".

Definition 5. An interpretation $\mathcal{I}_{MLN} = \langle D, w\rangle$ *satisfies* an annotated formula $F : \lambda$, denoted $\mathcal{I}_{MLN} \models F : \lambda$, iff whenever there exists an mgu θ such that for all $\langle V_i, x_i\rangle \in \lambda$ it holds that $X_i = \theta V_i$ and $w[i] = x_i$, then $D \models \theta F$.

A *probabilistic interpretation* is then a probability distribution *Pr* over the set of all possible interpretations such that only a finite number of interpretations are mapped to a non-zero value. The probability of an annotated formula $F : \lambda$, denoted $\mathit{Pr}(F : \lambda)$, is the sum of all $\mathit{Pr}(\mathcal{I}_{MLN})$ such that $\mathcal{I}_{MLN}$ satisfies $F : \lambda$.

Definition 6. Let *Pr* be a probabilistic interpretation, and $F : \lambda$ be an annotated formula. We say that *Pr satisfies* (or is a *model* of) $F : \lambda$ iff $\mathit{Pr}(F : \lambda) = 1$. Furthermore, *Pr* is a model of a probabilistic $\mathcal{EL}^{++}$ ontology $KB = (O, M)$ iff: (i) *Pr* satisfies all annotated formulas in O, and (ii) $1 - \mathit{Pr}(\mathit{false} : \lambda) = \mathit{Pr}_M(\lambda)$ for all possible worlds λ, where $\mathit{Pr}_M(\lambda)$ is the probability of $\bigwedge_{\langle V_i, x_i\rangle \in \lambda}(V_i = x_i)$ in the MLN M (and computed in the same way as $P(X = x)$ in Section 2.2).

In Definition 6 above, condition (ii) is stating that the probability values that *Pr* assigns are in accordance with those of MLN M (note that the equality in the definition implies that $\mathit{Pr}(true : \lambda) = \mathit{Pr}_M(\lambda)$) and that they are adequately distributed (since $\mathit{Pr}(true : \lambda) + \mathit{Pr}(false : \lambda) = 1$).

In the following, we are interested in computing the probabilities of atoms in a TCP ontology, working towards ranking of entailed atoms based on their probabilities.

Definition 7. Let $KB = (O, M)$ be a TCP ontology, and a be a ground atom that is constructed from predicates and

individuals in KB. The *probability* of a in KB, denoted $Pr^{KB}(a)$, is the infimum of $Pr(a:\{\})$ subject to all probabilistic interpretations Pr such that $Pr \models KB$.

Intuitively, an atom has the probability that results from summing the probabilities of all possible worlds under which the induced ontology entails the atom.

3.3 Ranking of Atoms based on Probabilities

In this paper, we focus on queries requesting the ranking of atoms based on their probability values.

Definition 8. Let $KB = (O, M)$ be a TCP ontology; the *answer* to a *ranking query* $Q = rank(KB)$ is a tuple $ans(Q) = \langle a_1, \ldots, a_n \rangle$ such that $\{a_1, \ldots, a_n\}$ are all of the atomic consequences of O_λ for any possible world λ, and $i < j \Rightarrow Pr^{KB}(a_i) \geq Pr^{KB}(a_j)$.

The straightforward approach to answering ranking queries is to compute the probabilities of all atoms inferred by the knowledge base; unfortunately, computing exact probabilities of atoms is intractable.

Theorem 1. *Let $KB = (O, M)$ be a TCP ontology. Computing $\Pr^{KB}(a)$ is $\#P$-hard in the data complexity.*

In the next section, we explore how this negative result can be avoided by considering a special kind of MLN that allows us to compute *scores* instead of probability values. Such scores are closely related to probabilities, and allow us to rank answers with respect to actual probability values.

4 Tractably Answering Ranking Queries

In this section, we consider a *special case of MLNs* that proves to be useful towards more tractable methods to answer ranking queries.

4.1 Conjunctive MLNs and Equivalence Classes

We now introduce a simple class of MLNs:

Definition 9. A *conjunctive* Markov logic network (cMLN) is an MLN in which all formulas (F, w) in the set are such that F is a conjunction of atoms, and $w \in \mathbb{R}$.

Informally, a cMLN is an MLN in which formulas are restricted to conjunctions of atoms. This restriction allows us to define an equivalence relation over the set of worlds. Given a cMLN M and its grounding $gr(M, \Delta_{MLN})$, we use the notation $Sat(\lambda, M)$ to denote the set of all ground formulas F in $gr(M, \Delta_{MLN})$ that are satisfied by world λ. It is easy to see that $gr(M, \Delta_{MLN})$ can be computed in polynomial time in the data complexity; we therefore work with ground cMLNs in the rest of the paper.

Definition 10. Let M be a ground cMLN, and λ_1 and λ_2 be possible worlds. We say that λ_1 and λ_2 are *equivalent* with respect to M, denoted $\lambda_1 \sim_M \lambda_2$, iff $Sat(\lambda_1, M) = Sat(\lambda_2, M)$.

Clearly, $\sim_M$ is an equivalence relation; we denote the equivalence classes induced by this relation with $C_1, \ldots, C_N$; note that, in general, there are $2^{|gr(M, \Delta_{MLN})|}$ such classes, making it intractable to inspect all of them.

Example 4. Consider the MLN in Example 2, and the grounding discussed above (cf. Figure 3). In this case, each of ψ_1 to ψ_4 has one possible grounding, which we call f_1 to f_4. There are therefore 16 equivalence classes in this case (each ground formula can be negated or not), which form a partition of the $2^8 = 256$ possible worlds. ■

There are several properties of equivalence classes that we can leverage. First, equivalence classes are not guaranteed to be non-empty, but it is simple to check for this condition.

Theorem 2. *Let M be a ground cMLN, and C be a $\sim_M$-equivalence class. Deciding $C = \emptyset$ can be done in polynomial time.*

Furthermore, generating worlds for a given equivalence class is also tractable:

Theorem 3. *Let M be a ground cMLN, and C be a $\sim_M$-equivalence class. All elements in C can be obtained in linear time with respect to the size of the output.*

Proof sketch. Let C be described by formula *pos* $\wedge$ *neg*, where *pos* is the conjunction of all formulas from M that are true in C, while *neg* is the conjunction of the negations of all formulas not true in C. The set of all atoms in the Herbrand base can be divided into two sets: *det* and *undet*; the former contains all (possibly negated) atoms that are determined by *pos*, while the latter contains the rest. The worlds in C are obtainable by traversing *neg* and assigning truth values to atoms in this formula in all possible ways that make C true, without contradicting the atoms in *det*. □

Finally, we point out an important characteristic of equivalence classes with respect to probability values:

Theorem 4. *Let M be a ground cMLN, and λ_1 and λ_2 be possible worlds. If $\lambda_1 \sim_M \lambda_2$, then $\Pr_M(\lambda_1) = \Pr_M(\lambda_2)$.*

Proof sketch. Follows from Definition 10. Since both worlds belong to the same class, they satisfy (and do not satisfy) the same formulas, and so the value $\exp\left(\sum_j w_j \cdot n_j(\lambda_i)\right)$ from Equation 1 is the same for both worlds; the denominator (factor Z) is equal across all worlds, which means that their probabilities are equal. □

However, computing exact probabilities remains intractable in cMLNs.

Theorem 5. *Let $KB = (O, M)$ be a* TCP *ontology, where M is a cMLN. Deciding $\Pr^{KB}(a) \geq k$ is PP-hard in the data complexity.*

The complexity class *PP* contains problems decidable by a probabilistic Turing machine in polynomial time, with error probability less than 1/2; like $\#P$, a polynomial time Turing machine with a *PP* oracle can solve all problems in the polynomial hierarchy [21]. This negative result does not prevent us, however, from tractably *comparing* the probabilities of two worlds.

Proposition 1. *Let M be a cMLN, and λ_1 and λ_2 be possible worlds. Deciding whether $\Pr_M(\lambda_1) \leq \Pr_M(\lambda_2)$ is in PTIME in the data complexity.*

The basic intuition behind this result is that we can compute the term $n_i(x)$ in Equation 1 in polynomial time; since the denominator in this equation is the same for all worlds, $\Pr_M(\lambda_1) \leq \Pr_M(\lambda_2)$ can be decided by only computing the numerators in this equation.

Example 5. Consider the following worlds relative to the MLN in Example 2 and the grounding from Example 4:

$$\begin{aligned}\lambda_1 &= \{\textit{canLabel}(f,\ell),\ \textit{hor}(\ell,f),\ \neg\textit{left}(\ell,f),\ \textit{adj}(\ell,f),\\ &\quad \textit{right}(\ell,f),\ \neg\textit{top}(\ell,f),\ \neg\textit{nw}(\ell,f),\ \neg\textit{ver}(\ell,f)\};\\ \lambda_2 &= \{\textit{canLabel}(f,\ell),\ \neg\textit{hor}(\ell,f),\ \neg\textit{left}(\ell,f),\ \textit{adj}(\ell,f),\\ &\quad \neg\textit{right}(\ell,f),\ \textit{top}(\ell,f),\ \neg\textit{nw}(\ell,f),\ \textit{ver}(\ell,f)\}.\end{aligned}$$

A quick inspection of the formulas in the MLN allows us to conclude that $\lambda_1 \models \neg f_1 \wedge f_2 \wedge \neg f_3 \wedge \neg f_4$, while $\lambda_2 \models \neg f_1 \wedge \neg f_2 \wedge f_3 \wedge \neg f_4$. Therefore, taking into account the weights of each formula, we can see that $\Pr(\lambda_1) > \Pr(\lambda_2)$; in fact, even though we cannot (tractably) compute the actual probabilities, we can conclude that $\Pr(\lambda_1) = \frac{e^6}{e^5}\Pr(\lambda_2)$, or that λ_1 is approximately 2.7 times more probable than λ_1. ■

4.2 An Anytime Algorithm

The results in the previous section point the way towards Algorithm anytimeRank for answering ranking queries; the pseudocode for this algorithm is shown in Figure 4; in the rest of this section, we will discuss its properties.

Algorithm anytimeRank takes a probabilistic ontology in which the MLN is assumed to be a ground cMLN (recall that the grounding can be computed in polynomial time in the data complexity); the other input corresponds to a *stopping condition* that can be based on whatever the user considers important (time, number of steps, number of inspected worlds, etc); cf. Section 4.2.2 for a discussion on ways to define the stopping condition based on properties of the output offering correctness guarantees.

The main `while` loop in line 3 iterates through the set of equivalence classes relative to M. Subroutine *compMostProbEqClass*, invoked in line 4, computes the i-th most probable equivalence class. Note that this can simply be done by taking the formulas in M and sorting them with respect to their weights; the classes are then generated by keeping track of a Boolean vector of which formulas are true and which are false. The next `while` loop, in line 7, is in charge of going through the current equivalence class. Subroutine *computePossWorld* takes the current class and a set of already inspected worlds and computes a new world (not in S). This can be done as described in the proof sketch of Theorem 3; in particular, the possible combinations of atoms in formula *neg* can be traversed in order, without the need to explicitly keep track of a set like S. The final lines of this loop take the computed world and obtain the atomic consequences from the (non-probabilistic) induced subontology (line 10), and adds the *score* to each such atom (lines 11 and 12). The *score* of a class consists of e to the power of the sum of the weights of formulas that are true in that class. Line 13 updates the output set of atoms. Finally, set *out* is returned in decreasing order of score.

Example 6. Consider the probabilistic $\mathcal{EL}^{++}$ ontology $\Phi = (O, M)$, where O is given as follows:

$$\begin{array}{ll}\forall X p(X) \rightarrow q(X) & : \{\langle m(X), 1\rangle, \langle n(X), 0\rangle\};\\ p(a) & : \{\langle m(a), 1\rangle\};\\ p(b) & : \{\langle n(a), 1\rangle\};\\ p(c) & : \{\langle m(c), 1\rangle, \langle n(c), 0\rangle\},\end{array}$$

and M is given by $\{(m(X), 1.5), (n(X), 0.8)\}$. Suppose we ground M with the set of constants $\{a, b, c\}$, yielding:

$$\begin{array}{lll} f_1 : (m(a), 1.5), & f_2 : (n(a), 0.8), & f_3 : (m(b), 1.5),\\ f_4 : (n(b), 0.8), & f_5 : (m(c), 1.5), & f_6 : (n(c), 0.8).\end{array}$$

This setup therefore yields $2^6 = 64$ equivalence classes (in this case, we have exactly one world per class). Figure 5 shows a subset of these classes in decreasing order of score (as they will be inspected by Algorithm anytimeRank). The algorithm will proceed as follows; cf. Figure 5 for the description of the classes (we use classes C_i to denote the single world λ_i in that class):

$O_{C_1} \models \{p(a), p(b)\}$; add $e^{6.9}$ to *score*$(p(a))$ and *score*$(p(b))$;

$O_{C_2} \models \{p(a), p(b), p(c), q(c)\}$; add $e^{6.1}$ to *score*$(p(a))$, *score*$(p(b))$, *score*$(p(c))$, and *score*$(q(c))$;

$O_{C_3} \models \{p(a)\}$; add $e^{6.1}$ to *score*$(p(a))$;

$O_{C_4} \models \{p(a), p(c), q(c)\}$; add $e^{6.1}$ to *score*$(p(a))$, *score*$(p(c))$, and *score*$(q(c))$;

$O_{C_5} \models \{p(a), p(b), q(a)\}$; add $e^{5.3}$ to *score*$(p(a))$, *score*$(p(b))$, and *score*$(q(a))$.

If the algorithm is stopped at this point, the scores are as follows (approximate, and in descending order):

$p(a) : 2530.18, p(b) : 1638.47, p(c) : 891.71, q(c) : 891.71$ ■

4.2.1 Correctness and Running Time of anytimeRank

The correctness of this algorithm lies in the fact that if all classes are inspected, the returned output set is clearly the answer to the ranking query. In the general case, only a

Algorithm anytimeRank($KB = (O, M)$, *stopCond*)
// M is assumed to be a ground cMLN
1. *score*:= empty mapping from atoms to $\mathbb{R}$ (default 0);
2. *out*:= empty set of atoms; $i := 1$;
3. while $\left(i \leq 2^{|M|}\right)$ and !*stopCond* do begin
   // i ranges over classes of possible worlds
4. $C := compMostProbEqClass(M, i)$;
5. $S := \emptyset$;
6. $i := i + 1$;
7. while $\left(|S| \neq |C|\right)$ and !*stopCond* do
8. $\lambda := computePossWorld(C, S)$;
   // compute world s.t. $\lambda \in C$ and $\lambda \notin S$
9. $S := S \cup \{\lambda\}$;
10. $O_\lambda := getInducedOnt(O, \lambda)$;
11. for all atoms $a \in$ *atomicCons*(O_λ) do
12. *score*(a)+= $\exp\left(\sum_{F_j \in M, C \models F_j} w_j\right)$;
13. *out*:= *out* $\cup$ *atomicCons*(O_λ);
14. end;
15. return *out* sorted in dec. order according to *score*.

Figure 4: An anytime algorithm to compute the answer to a ranking query over a TCP ontology (refer to text for description of subroutines).

Class	f_1	f_3	f_5	f_2	f_4	f_6	$\sum_j w_j$
C_1	1	1	1	1	1	1	6.9
C_2	1	1	1	1	1	0	6.1
C_3	1	1	1	1	0	1	6.1
C_4	1	1	1	0	1	1	6.1
C_5	1	1	1	1	0	0	5.3
...							

Figure 5: Equivalence classes from Example 6, sorted in descending order of the *score* assigned to possible worlds that belong to them (e to the power of the value in the last column); only 5 of the 64 classes are shown here.

subset of the worlds will be inspected; since the probabilities of worlds in a given equivalence class are all equal (Theorem 4), and this value depends directly on the formulas in the cMLN that are satisfied by the class, the iteration through the equivalence classes in decreasing order of probability is the optimal path to take. Though the total running time of course depends on the stopping condition, Theorem 3, along with the way in which equivalence classes are manipulated (as described above), guarantee a running time that is polynomial in the data complexity as long as the combined number of inspected worlds and equivalence classes is bounded by a polynomial as well.

4.2.2 Bounding the Error of anytimeRank

The following proposition provides a bound on the total "mass" of score that remains unassigned by our algorithm after a certain number of iterations.

Proposition 2. *Let $KB = (O, M)$ be a* TCP *ontology where M is a ground cMLN with n ground atoms, and let $C_1, ..., C_{2^{|M|}}$ be the set of equivalence classes of M sorted in decreasing order of their score. Then, after analyzing s worlds and t classes with Algorithm* anytimeRank*, the total unassigned class score mass is bounded by above by $U = (2^n - s) \cdot \exp\left(\sum_{F_j \in M, C_{t+1} \models F_j} w_j\right)$.*

This result is useful, for instance, in determining a *provably correct partial order* over the output of the algorithm. For example, if the output is $\{(a, 120), (b, 90), (c, 80), (d, 10)\}$ and $U = 30$, we can safely conclude that $\Pr^{KB}(a) > \Pr^{KB}(c)$, $\Pr^{KB}(a) > \Pr^{KB}(d)$, $\Pr^{KB}(b) > \Pr^{KB}(d)$, and $\Pr^{KB}(c) > \Pr^{KB}(d)$.

Theorem 6. *Let out be the output of Algorithm* anytimeRank *and U be the bound on the unassigned score mass as computed in Proposition 2. The partial order $\leq_U$ defined as: $a \leq_U b$ iff $s_a + U \leq s_b$, where $(a, s_a), (b, s_b) \in$ out, is such that if $a \leq_U b$ then $\Pr(a) \leq \Pr(b)$.*

Therefore, Theorem 6 allows us to glimpse into the total order over the set of atoms as established by the true probability values, without actually computing them.

5 Related Work

Ontology languages, rule-based systems, and their integrations are central for the Semantic Web [2]. Although many approaches exist to tight, loose, or hybrid integrations of ontology languages and rule-based systems, to our knowledge there is very little work on the combination of tractable description logics with MLNs. Probabilistic ontology languages in the literature can be classified according to the underlying ontology language, the supported forms of probabilistic knowledge, and the underlying probabilistic semantics (see [14] for a recent survey). Some early approaches [11] generalize the description logic $\mathcal{ALC}$ and are based on propositional probabilistic logics, while others [12] generalize the tractable DL CLASSIC and $\mathcal{FL}$, and are based on Bayesian networks as underlying probabilistic semantics. The fairly recent approach in [13], generalizing the expressive DL $\mathcal{SHIF}(\mathbf{D})$ and $\mathcal{SHOIN}(\mathbf{D})$ behind the sublanguages *OWL Lite* and *OWL DL*, respectively, of the Web ontology language *OWL* [18], is based on probabilistic default logics, and allows for rich probabilistic terminological and assertional knowledge. Other recent approaches [23] generalize OWL by probabilistic uncertainty using Bayesian networks.

In the probabilistic description logics literature, the most closely related work is that of Prob-$\mathcal{EL}$ [15, 10], a probabilistic extension to $\mathcal{EL}$ that belongs to a family of probabilistic DLs derived in a principled way from Halpern's probabilistic first-order logic [4]. One limitation in this line of research is that probabilistic annotations are somewhat restricted, leading to the inability to express uncertainty about certain kinds of general knowledge; note that our formalism does not suffer from this drawback, since probabilistic annotations can be associated with any axiom. In [15], the authors study various logics in this family and

show complexity of reasoning, ranging from PTIME for weak variants of $\mathcal{EL}$ to undecidable for expressive variants of $\mathcal{ALC}$. Prob-$\mathcal{EL}$ is more closely studied in [10], where the authors show that reasoning is PTIME as long as (i) probability values are restricted to 0 and 1, and (ii) probabilistic annotations are only allowed on concepts; if (i) is dropped, then it becomes EXPTIME-complete, while if (ii) is dropped it becomes PSPACE-hard. The complexity results in our work are further testament to how intractable simple tasks become when probabilistic computations are involved, even when the starting point is a tractable logic.

Other recent efforts focused on extending $\mathcal{EL}$ DLs with probabilistic uncertainty include [5], [9], and [17]. In [5], a formalism is presented in which probability assessments are only allowed on ABoxes. The authors study the problem of satisfiability of KBs, which involves determining whether there exists a probability distribution that satisfies all the assignments over the ABoxes. The work of [9] is similar in spirit to [5], but there an MLN is employed in order to infer the probabilities of atoms in the ABox as a means to generate explanations as part of abductive inference. Though they use MLNs, this work is quite different from ours since only the ABox is assumed to be probabilistic, and the assertions are themselves part of the MLN instead of being annotated by external events as in our formalism. In [17], the authors present ELOG, which is $\mathcal{EL}^{++}$ without nominals or concrete domains combined with probabilistic log-linear models (a class which contains MLNs). The resulting probabilistic formalism basically assigns weights to axioms reflecting how likely the axiom is to hold. The main problem then corresponds to finding the most probable coherent ontology, a problem that is essentially different from the one tackled here.

Finally, a related formalism from the recent databases literature is that of probabilistic Datalog+/– [8, 7]. Datalog+/– is a language that arose from the generalization of rule-based constraints with the goal of expressing ontological axioms. The probabilistic extension in [8, 7] also makes use of MLNs, though the integration is loose in the sense that probabilistic annotations cannot refer to objects in the ontology, which leads to data-tractable algorithms but also limits the expressive power of the formalism.

6 Discussion, Conclusions, and Future Work

In this work, we have extended the DL $\mathcal{EL}^{++}$ with probabilistic uncertainty, based on the annotation of axioms. Such annotations refer to events whose probabilities are described by an associated MLN; one of the advantages of this formalism is that it is tightly coupled, which means that probabilistic annotations can refer to objects in the ontology. The proposed application of our formalism is in managing uncertainty in the Semantic Web, showing examples of how it can be applied in the analysis of Web forms, an important task in information extraction efforts.

Our focus here is on ranking queries, which request the set of atomic inferences sorted in descending order of probability. The algorithm we developed works in an anytime fashion, and therefore allows partial computations depending on the available resources; most importantly, we provide bounds on the error incurred by runs of this algorithm and conditions that allow to conclude when certain pairs in the output are correctly ordered. This algorithm works over cMLNs, in which only conjunctions of atoms are allowed. Regarding the expressivity of cMLNs, we can say that: (i) They are rich enough to simulate disjunction for a specific propositional subset. For instance, if the formula $p(X) \vee q(X)$ with a given weight needs to be enforced for the subset of individuals $\{a, b\}$, MLN learning algorithms can be directed to give corresponding weights to the specific worlds in which $\big(p(a)$ or $q(a)\big)$ and $\big(p(b)$ or $q(b)\big)$ hold. So, it is possible to represent certain special cases that may need to be handled. (ii) For the case of (atomic) negation, it is known to be representable via negative weights. (iii) Though material implications cannot be represented, this sort of constraint is more adequately placed on the ontology side, and the TBox is capable of representing them.

Regarding the practical applicability of the formalism, we can say that, despite probabilistic instance-checking being already intractable for cMLNs, it is often possible to bound the number of scenarios in practice. Consider, for instance, the problem of reasoning over data structures on the Web (related to the running example). Web pages are usually processed in isolation, since structured data do not usually span across pages and are often delimited by a certain DOM sub-tree. This implies that the number of possible worlds is bounded by a function of the constants appearing in a subset of the page. This bound can work together with the good computational behavior of cMLNs to allow tractability of reasoning in practice. Other applications where cMLNs can be leveraged are semantic and natural language-based Web search.

Future work involves investigating other DLs that can be extended in this manner, and pushing the known line between tractability and expressivity. We also need to empirically evaluate our approach both on synthetic and real-world data, as well as studying the application of other techniques such as random sampling, which may provide increased scalability at the cost of lost guarantees.

Abstract

This paper explores a new framework for reinforcement learning based on *online convex optimization*, in particular *mirror descent* and related algorithms. Mirror descent can be viewed as an enhanced gradient method, particularly suited to minimization of convex functions in high-dimensional spaces. Unlike traditional gradient methods, mirror descent undertakes gradient updates of weights in both the dual space and primal space, which are linked together using a Legendre transform. Mirror descent can be viewed as a proximal algorithm where the distance generating function used is a Bregman divergence. A new class of *proximal-gradient* based temporal-difference (TD) methods are presented based on different Bregman divergences, which are more powerful than regular TD learning. Examples of Bregman divergences that are studied include p-norm functions, and Mahalanobis distance based on the covariance of sample gradients. A new family of sparse mirror-descent reinforcement learning methods are proposed, which are able to find sparse fixed points of an l_1-regularized Bellman equation at significantly less computational cost than previous methods based on second-order matrix methods. An experimental study of mirror-descent reinforcement learning is presented using discrete and continuous Markov decision processes.

Reinforcement learning (RL) models the interaction between the agent and an environment as a *Markov decision process* (MDP), a widely adopted model of sequential decision-making. The major aim of this paper is to investigate a new framework for reinforcement learning and sequential decision-making, based on ideas from *online convex optimization*, in particular mirror descent [NY83] and related algorithms [BT03, Nes09]. Mirror descent generalizes classical first-order gradient descent to non-Euclidean geometries by using a distance-generating function specific to a particular geometry. Mirror descent can be viewed as a proximal algorithm [BT03], where the distance generating function used is a Bregman divergence [Bre67]. Mirror descent is a powerful framework for convex optimization in high-dimensional spaces: an early success of this approach was its use in positron-emission tomography (PET) imaging involving an optimization problem with millions of variables [BTMN01]. The mirror descent algorithm has led to new methods for sparse classification and regression [DHS11, SST11a]. Mirror descent has also been extended from its original deterministic setting [NY83] to a stochastic approximation setting [NJLS09], which makes it highly appropriate for RL, as the standard temporal-difference (TD) learning method for solving MDPs also has its origins in stochastic approximation theory [Bor08].

l_1 regularized methods for solving MDPs have become a topic of recent attention, including a technique combining least-squares TD (LSTD) with least-angle regression (LARS) [KN09]; another method for combining l_1 regularization with approximate linear programming [PTPZ10]; finally, a linear complementarity formulation of l_1 regularization [JPWP10]. These methods involve matrix inversion, requiring near cubic complexity in the number of (active) features. In contrast, mirror-descent based RL methods promise similar performance guarantees involving only linear complexity in the number of features. Recent work in online learning [DHS11, SST11a] has explored the application of mirror descent in developing sparse methods for regularized classification and regression. This paper investigates the use of mirror-descent for sparse reinforcement learning.

1 Technical Background

1.1 Reinforcement Learning

The most popular and widely used RL method is temporal-difference (TD) learning [Sut88]. TD is a stochastic approximation approach [Bor08] to solving Markov decision

processes (MDPs), comprised of a set of states S, a set of (possibly state-dependent) actions A (A_s), a dynamical system model comprised of the transition probabilities $P^a_{ss'}$ specifying the probability of transition to state s' from state s under action a, and a reward model R. A policy $\pi : S \rightarrow A$ is a deterministic mapping from states to actions. Associated with each policy π is a value function V^π, which is a fixed point of the Bellman equation:

$$V^\pi = T^\pi(V^\pi) = R^\pi + \gamma P^\pi V^\pi \quad (1)$$

where $0 \leq \gamma < 1$ is a discount factor. Any optimal policy π^* defines the same unique optimal value function V^* that satisfies the nonlinear system of equations:

$$V^*(s) = \max_a \sum_{s'} P^a_{ss'} \left(R^a_{ss'} + \gamma V^*(s')\right)$$

The *action value* $Q^*(s,a)$ represents a convenient reformulation of the value function, defined as the long-term value of performing a first, and then acting optimally according to V^*:

$$Q^*(s,a) = E\left(r_{t+1} + \gamma \max_{a'} Q^*(s_{t+1}, a') | s_t = s, a_t = a\right) \quad (2)$$

where r_{t+1} is the actual reward received at the next time step, and s_{t+1} is the state resulting from executing action a in state s_t. The (optimal) action value formulation is convenient because it can be approximately solved by a temporal-difference (TD) learning technique called Q-learning [Wat89]. The simplest TD method, called TD(0), estimates the value function associated with the fixed policy using a normal stochastic gradient iteration:

$$V_{t+1}(s_t) = V_t(s_t) + \alpha_t(r_t + \gamma V_t(s_{t+1}) - V_t(s_t))$$

TD(0) converges to the optimal value function V^π for policy π as long as the samples are "on-policy", namely following the stochastic Markov chain associated with the policy; and the learning rate α_t is decayed according to the Robbins-Monro conditions in stochastic approximation theory: $\sum_t \alpha_t = \infty, \sum_t \alpha_t^2 < \infty$ [BT96]. When the set of states S is large, it is often necessary to approximate the value function V using a set of handcrafted basis functions (e.g., polynomials, radial basis functions, wavelets etc.) or automatically generated basis functions [Mah09]. In linear value function approximation, the value function is assumed to lie in the linear span of the basis function matrix Φ of dimension $|S| \times p$, where it is assumed that $p \ll |S|$. Hence, $V^\pi \approx \hat{V}^\pi = \Phi w$. The equivalent TD(0) rule for linear function approximated value functions is given as:

$$w_{t+1} = \alpha_t \left(r_t + \gamma \phi(s_{t+1})^T w_t - \phi(s_t)^T w_t\right) \phi(s_t) \quad (3)$$

where the quantity in the parenthesis is the TD error. TD can be shown to converge to the fixed point of the composition of the projector Π^Φ onto the column space of Φ and the Bellman operator T^π.

l_1 regularized least-squares methods for solving MDPs attempt to find a fixed point of the l_1 penalized Bellman equation:[1] [KN09, PTPZ10, JPWP10]

$$w = f(w) = \text{argmin}_u \left(\|(R^\pi + \gamma P^\pi \Phi w - \Phi u)\|^2 + \beta \|u\|_1\right) \quad (4)$$

Unfortunately, the above l_1 regularized fixed point is not a convex optimization problem. Another way to introduce l_1 regularization is to penalize the projected Bellman residual [GS11], which yields a convex optimization problem:

$$\begin{aligned} w_\theta &= \text{argmin}_w \|R^\pi + \gamma P^\pi \Phi\theta - \Phi w\|^2 \\ \theta^* &= \text{argmin}_\theta \|\Phi w_\theta - \Phi\theta\|_2^2 + \beta\|\theta\|_1 \end{aligned} \quad (5)$$

where the first step is the projection step and the second is the fixed point step. Note that in the on-policy setting, algorithms derived from the motivation of minimizing projected Bellman residual asymptotically converge to the solution of conventional TD-learning [SMP+09]. Recent l_1-regularized RL methods, such as LARS-TD and LCP-TD, involve matrix inversion, requiring at least cubic complexity in the number of (active) features. In contrast, mirror-descent based RL methods can provide similar performance guarantees involving only linear complexity in the number of features.

1.2 Online Convex Optimization

Online convex optimization [Zin03] explores the use of first-order gradient methods for solving convex optimization problems. In this framework, at each step, the learner picks an element w_t of a convex set, in response to which an adversary picks a convex loss function $f_t(w_t)$. The aim of the learner is to select elements in such a way as to minimize its long-term regret

$$\sum_{t=1}^T f_t(w_t) - \min_w \sum_{t=1}^T f_t(w)$$

with respect to the choice it would have made in hindsight.

A fundamental problem addressed in this paper is to minimize a *sum* of two functions, as in Equation 4 and Equation 5:

$$w^* = \text{argmin}_{w \in X} \left(f(w) + g(w)\right) \quad (6)$$

where $f(w)$ is a smooth differentiable convex function, whereas g is a (possibly non-smooth) convex function that is subdifferentiable over its domain. A common example is l_1 regularized classification or regression:

$$w^* = \text{argmin}_{w \in \mathbb{R}^d} \sum_{t=1}^m L(\langle w, x_t\rangle, y_t) + \beta\|w\|_1 \quad (7)$$

[1] In practice, the full Φ matrix is never constructed, and only the p-dimensional embedding $\phi(s)$ of sampled states are explicitly formed. Also, R^π, Φ, and $P^\pi\Phi$ are approximated by $\tilde{R}$, $\tilde{\Phi}$, and $\tilde{\Phi}'$ over a given set of samples.

where $L(a, b)$ is a convex loss function, and β is a sparsity-controlling parameter. The simplest online convex algorithm is based on the classic gradient descent procedure for minimizing a function, given as:

$$w_0 \in X, w_t = \Pi_X \left(w_{t-1} - \alpha_t \nabla f(w_{t-1}) \right) : t \geq 1 \quad (8)$$

where $\Pi_X(x) = \text{argmin}_{y \in X} \|x - y\|^2$ is the projector onto set X, and α_t is a stepsize. If f is not differentiable, then the subgradient ∂f can be substituted instead, resulting in the well-known projected subgradient method, a workhorse of nonlinear programming [Ber99]. We discuss a general framework for minimizing Equation 6 next.

1.3 Proximal Mappings and Mirror Descent

The proximal mapping associated with a convex function h is defined as:

$$\text{prox}_h(x) = \text{argmin}_u \left(h(u) + \|u - x\|_2^2 \right)$$

If $h(x) = 0$, then $\text{prox}_h(x) = x$, the identity function. If $h(x) = I_C(x)$, the indicator function for a convex set C, then $\text{prox}_{I_C}(x) = \Pi_C(x)$, the projector onto set C. For learning sparse representations, the case when $h(w) = \beta \|w\|_1$ is particularly important. In this case, the entry-wise proximal operator is:

$$\text{prox}_h(w)_i = \begin{cases} w_i - \beta, & \text{if } w_i > \beta \\ 0, & \text{if } |w_i| \leq \beta \\ w_i + \beta, & \text{otherwise} \end{cases} \quad (9)$$

An interesting observation follows from noting that the projected subgradient method (Equation 8) can be written equivalently using the proximal mapping as:

$$w_{t+1} = \text{argmin}_{w \in X} \left(\langle w, \partial f(w_t) \rangle + \frac{1}{2\alpha_t} \|w - w_t\|_2^2 \right) \quad (10)$$

An intuitive way to understand this equation is to view the first term as requiring the next iterate w_{t+1} to move in the direction of the (sub) gradient of f at w_t, whereas the second term requires that the next iterate w_{t+1} not move too far away from the current iterate w_t. Note that the (sub)gradient descent is a special case of Equation (10) with Euclidean distance setup.

With this introduction, we can now introduce the main concept of *mirror descent* [NY83]. We follow the treatment in [BT03] in presenting the mirror descent algorithm as a nonlinear proximal method based on a distance generating function that is a Bregman divergence [Bre67].

Definition 1: A distance generating function $\psi(x)$ is defined as a continuously differentiable strongly convex function (with modulus σ) which satisfies:

$$\langle x' - x, \nabla \psi(x') - \nabla \psi(x) \rangle \geq \sigma \|x' - x\|^2 \quad (11)$$

Given such a function ψ, the Bregman divergence associated with it is defined as:

$$D_\psi(x, y) = \psi(x) - \psi(y) - \langle \nabla \psi(y), x - y \rangle \quad (12)$$

Intuitively, the Bregman divergence measures the difference between the value of a strongly convex function $\psi(x)$ and the estimate derived from the first-order Taylor series expansion at $\psi(y)$. Many widely used distance measures turn out to be special cases of Bregman divergences, such as Euclidean distance (where $\psi(x) = \frac{1}{2}\|x\|_2^2$) and Kullback Liebler divergence (where $\psi(x) = \sum_i x_i \log_2 x_i$, the positive entropy function). In general, Bregman divergences are non-symmetric, but projections onto a convex set with respect to a Bregman divergence is well-defined.

The general mirror descent procedure can be written as:

$$w_{t+1} = \text{argmin}_{w \in X} \left(\langle w, \partial f(w_t) \rangle + \frac{1}{\alpha_t} D_\psi(w, w_t) \right) \quad (13)$$

Notice that the squared distance term in Equation 10 has been generalized to a Bregman divergence. The solution to this optimization problem can be stated succinctly as the following generalized gradient descent algorithm, which forms the core procedure in mirror descent:

$$w_{t+1} = \nabla \psi^* \left(\nabla \psi(w_t) - \alpha_t \partial f(w_t) \right) \quad (14)$$

Here, ψ^* is the Legendre transform of the strongly convex function ψ, which is defined as

$$\psi^*(y) = \sup_{x \in X} \left(\langle x, y \rangle - \psi(x) \right)$$

It can be shown that $\nabla \psi^* = (\nabla \psi)^{-1}$ [BT03]. Mirror descent is a powerful first-order optimization method that been shown to be "universal" in that if a problem is online learnable, it leads to a low-regret solution using mirror descent [SST11b]. It is shown in [BTMN01] that the mirror descent procedure specified in Equation 14 with the Bregman divergence defined by the *p-norm* function [Gen03], defined below, can outperform regular projected subgradient method by a factor $\frac{n}{\log n}$ where n is the dimensionality of the space. For high-dimensional spaces, this ratio can be quite large.

2 Proposed Framework: Mirror Descent RL

Algorithm 1 describes the proposed mirror-descent TD(λ) method.[2] Unlike regular TD, the weights are updated using the TD error in the dual space by mapping the primal weights w using a gradient of a strongly convex function ψ. Subsequently, the updated dual weights are converted

[2] All the algorithms described extend to the action-value case where $\phi(s)$ is replaced by $\phi(s, a)$.

Algorithm 1 Adaptive Mirror Descent TD(λ)

Let π be some fixed policy for an MDP M, and s_0 be the initial state. Let Φ be some fixed or automatically generated basis.

1: **repeat**
2: Do action $\pi(s_t)$ and observe next state s_{t+1} and reward r_t.
3: Update the eligibility trace $e_t \leftarrow e_t + \lambda\gamma\phi(s_t)$
4: Update the dual weights θ_t for a linear function approximator:

$$\theta_{t+1} = \nabla\psi_t(w_t) + \alpha_t(r_t + \gamma\phi(s_{t+1})^T w_t - \phi(s_t)^T w_t)e_t$$

where ψ is a distance generating function.
5: Set $w_{t+1} = \nabla\psi_t^*(\theta_{t+1})$ where ψ^* is the Legendre transform of ψ.
6: Set $t \leftarrow t+1$.
7: **until done**.
Return $\hat{V}^\pi \approx \Phi w_t$ as the value function associated with policy π for MDP M.

back into the primal space using the gradient of the Legendre transform of ψ, namely $\nabla\psi^*$. Algorithm 1 specifies the mirror descent TD(λ) algorithm wherein each weight w_i is associated with an eligibility trace $e(i)$. For $\lambda = 0$, this is just the features of the current state $\phi(s_t)$, but for nonzero λ, this corresponds to a decayed set of features proportional to the recency of state visitations. Note that the distance generating function ψ_t is a function of time.

2.1 Choice of Bregman Divergence

We now discuss various choices for the distance generating function in Algorithm 1. In the simplest case, suppose $\psi(w) = \frac{1}{2}\|w\|_2^2$, the Euclidean length of w. In this case, it is easy to see that mirror descent TD(λ) corresponds to regular TD(λ), since the gradients $\nabla\psi$ and $\nabla\psi^*$ correspond to the identity function. A much more interesting choice of ψ is $\psi(w) = \frac{1}{2}\|w\|_q^2$, and its conjugate Legendre transform $\psi^*(w) = \frac{1}{2}\|w\|_p^2$. Here, $\|w\|_q = \left(\sum_j |w_j|^q\right)^{\frac{1}{q}}$, and p and q are conjugate numbers such that $\frac{1}{p} + \frac{1}{q} = 1$. This $\psi(w)$ leads to the p-norm link function $\theta = f(w)$ where $f : \mathbb{R}^d \to \mathbb{R}^d$ [Gen03]:

$$f_j(w) = \frac{\text{sign}(w_j)|w_j|^{q-1}}{\|w\|_q^{q-2}}, \quad f_j^{-1}(\theta) = \frac{\text{sign}(\theta_j)|\theta_j|^{p-1}}{\|\theta\|_p^{p-2}} \tag{15}$$

The p-norm function has been extensively studied in the literature on online learning [Gen03], and it is well-known that for large p, the corresponding classification or regression method behaves like a multiplicative method (e.g., the p-norm regression method for large p behaves like an exponentiated gradient method (EG) [KW95, Lit88]).

Another distance generating function is the negative entropy function $\psi(w) = \sum_i w_i \log w_i$, which leads to the entropic mirror descent algorithm [BT03]. Interestingly, this special case has been previously explored [PS95] as the exponentiated-gradient TD method, although the connection to mirror descent and Bregman divergences were not made in this previous study, and EG does not generate sparse solutions [SST11a]. We discuss EG methods vs. p-norm methods in Section 6.

2.2 Sparse Learning with Mirror Descent TD

Algorithm 2 Sparse Mirror Descent TD(λ)

1: **repeat**
2: Do action $\pi(s_t)$ and observe next state s_{t+1} and reward r_t.
3: Update the eligibility trace $e_t \leftarrow e_t + \lambda\gamma\phi(s_t)$
4: Update the dual weights θ_t:

$$\tilde{\theta}_{t+1} = \nabla\psi_t(w_t) + \alpha_t\left(r_t + \gamma\phi(s_{t+1})^T w_t - \phi(s_t)^T w_t\right)e_t$$

(e.g., $\psi(w) = \frac{1}{2}\|w\|_q^2$ is the p-norm link function).
5: Truncate weights:

$$\forall j, \;\; \theta_j^{t+1} = \text{sign}(\tilde{\theta}_j^{t+1})\max(0, |\tilde{\theta}_j^{t+1}| - \alpha_t\beta)$$

6: $w_{t+1} = \nabla\psi_t^*(\theta_{t+1})$ (e.g., $\psi^*(\theta) = \frac{1}{2}\|\theta\|_p^2$ and p and q are dual norms such that $\frac{1}{p} + \frac{1}{q} = 1$).
7: Set $t \leftarrow t+1$.
8: **until done**.
Return $\hat{V}^\pi \approx \Phi w_t$ as the l_1 penalized sparse value function associated with policy π for MDP M.

Algorithm 2 describes a modification to obtain sparse value functions resulting in a sparse mirror-descent TD(λ) algorithm. The main difference is that the dual weights θ are truncated according to Equation 9 to satisfy the l_1 penalty on the weights. Here, β is the sparsity parameter defined in Equation 7. An analogous approach was suggested in [SST11a] for l_1 penalized classification and regression.

2.3 Composite Mirror Descent TD

Another possible mirror-descent TD algorithm uses as the distance-generating function a Mahalanobis distance derived from the subgradients generated during actual trials. We base our derivation on the composite mirror-descent approach proposed in [DHS11] for classification and regression. The composite mirror-descent solves the following optimization problem at each step:

$$w_{t+1} = \text{argmin}_{x \in X}\left(\alpha_t\langle x, \partial f_t\rangle + \alpha_t\mu(x) + D_{\psi_t}(x, w_t)\right) \tag{16}$$

Here, μ serves as a fixed regularization function, such as the l_1 penalty, and ψ_t is the time-dependent distance generating function as in mirror descent. We now describe a dif-

ferent Bregman divergence to be used as the distance generating function in this method. Given a positive definite matrix A, the Mahalanobis norm of a vector x is defined as $\|x\|_A = \sqrt{\langle x, Ax\rangle}$. Let $g_t = \partial f(s_t)$ be the subgradient of the function being minimized at time t, and $G_t = \sum_t g_t g_t^T$ be the covariance matrix of outer products of the subgradients. It is computationally more efficient to use the diagonal matrix $H_t = \sqrt{\text{diag}(G_t)}$ instead of the full covariance matrix, which can be expensive to estimate. Algorithm 3 describes the adaptive subgradient mirror descent TD method.

Algorithm 3 Composite Mirror Descent TD(λ)

1: **repeat**
2: Do action $\pi(s_t)$ and observe next state s_{t+1} and reward r_t.
3: Set TD error $\delta_t = r_t + \gamma\phi(s_{t+1})^T w_t - \phi(s_t)^T w_t$
4: Update the eligibility trace $e_t \leftarrow e_t + \lambda\gamma\phi(s_t)$
5: Compute TD update $\xi_t = \delta_t e_t$.
6: Update feature covariance

$$G_t = G_{t-1} + \phi(s_t)\phi(s_t)^T$$

7: Compute Mahalanobis matrix $H_t = \sqrt{\text{diag}(G_t)}$.
8: Update the weights w:

$$w_{t+1,i} = \text{sign}(w_{t,i} - \frac{\alpha_t \xi_{t,i}}{H_{tt,i}})(|w_{t,i} - \frac{\alpha_t \xi_{t,i}}{H_{tt,i}}| - \frac{\alpha_t \beta}{H_{tt,i}})$$

9: Set $t \leftarrow t + 1$.
10: **until done**.
Return $\hat{V}^\pi \approx \Phi w_t$ as the l_1 penalized sparse value function associated with policy π for MDP M.

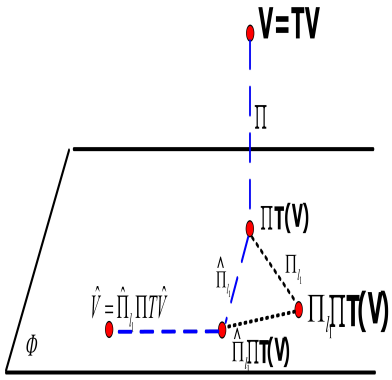
3 Convergence Analysis

Definition 2 [GLMH11]: Π_{l_1} is the l_1-regularized projection defined as: $\Pi_{l_1} y = \Phi\alpha$ such that $\alpha = \arg\min_w \|y - \Phi w\|^2 + \beta\|w\|_1$, which is a non-expansive mapping w.r.t weighted l_2 norm induced by the on-policy sample distribution setting, as proven in [GLMH11]. Let the approximation error $f(y, \beta) = \|y - \Pi_{l_1} y\|^2$.

Definition 3 (Empirical l_1-regularized projection): $\hat{\Pi}_{l_1}$ is the empirical l_1-regularized projection with a specific l_1 regularization solver, and satisfies the non-expansive mapping property. It can be shown using a direct derivation that $\hat{\Pi}_{l_1}\Pi T$ is a γ-contraction mapping. Any unbiased l_1 solver which generates intermediate sparse solution before convergence, e.g., SMIDAS solver after t-th iteration, comprises an empirical l_1-regularized projection.

Theorem 1 The approximation error $||V - \hat{V}||$ of Algorithm 2 is bounded by (ignoring dependence on π for simplicity):

Figure 1: Error Bound and Decomposition



$$||V - \hat{V}|| \leq \frac{1}{1-\gamma} \times \left(\|V - \Pi V\| + f(\Pi V, \beta) + (M-1)P(0) + \|w^*\|_1^2 \frac{M}{\alpha_t N}\right) \quad (17)$$

where $\hat{V}$ is the approximated value function after N-th iteration, i.e., $\hat{V} = \Phi w_N$, $M = \frac{2}{2 - 4\alpha_t(p-1)e}$, α_t is the step-size, $P(0) = \frac{1}{N}\sum_{i=1}^{N} \|\Pi V(s_i)\|_2^2$, s_i is the state of i-th sample, $e = d^{\frac{p}{2}}$, d is the number of features, and finally, w^* is l_1-regularized projection of ΠV such that $\Phi w^* = \Pi_{l_1}\Pi V$.

Proof: In the on-policy setting, the solution given by Algorithm 2 is the fixed point of $\hat{V} = \hat{\Pi}_{l_1}\Pi T\hat{V}$ and the error decomposition is illustrated in Figure 1. The error can be bounded by the triangle inequality

$$||V - \hat{V}|| = ||V - \Pi TV|| + ||\Pi TV - \hat{\Pi}_{l_1}\Pi TV|| + ||\hat{\Pi}_{l_1}\Pi TV - \hat{V}|| \quad (18)$$

Since $\hat{\Pi}_{l_1}\Pi T$ is a γ-contraction mapping, and $\hat{V} = \hat{\Pi}_{l_1}\Pi T\hat{V}$, we have

$$||\hat{\Pi}_{l_1}\Pi TV - \hat{V}|| = ||\hat{\Pi}_{l_1}\Pi TV - \hat{\Pi}_{l_1}\Pi T\hat{V}|| \leq \gamma||V - \hat{V}|| \quad (19)$$

So we have

$$(1-\gamma)||V - \hat{V}|| \leq ||V - \Pi TV|| + ||\Pi TV - \hat{\Pi}_{l_1}\Pi TV||$$

$\|V - \Pi TV\|$ depends on the expressiveness of the basis Φ, where if V lies in $span(\Phi)$, this error term is zero. $||\Pi TV - \Pi_{l_1}\hat{\Pi}TV||$ is further bounded by the triangle inequality

$$||\Pi TV - \hat{\Pi}_{l_1}\Pi TV|| \leq ||\Pi TV - \Pi_{l_1}\Pi TV|| + ||\Pi_{l_1}\Pi TV - \hat{\Pi}_{l_1}\Pi TV||$$

where $\|\Pi TV - \Pi_{l_1}\Pi TV\|$ is controlled by the sparsity parameter β, i.e., $f(\Pi TV, \beta) = ||\Pi TV - \Pi_{l_1}\Pi TV||$, where $\varepsilon = ||\hat{\Pi}_{l_1}\Pi TV - \Pi_{l_1}\Pi TV||$ is the approximation error depending on the quality of the l_1 solver employed. In Algorithm 2, the l_1 solver is related to the SMIDAS l_1 regularized mirror-descent method for regression and classification [SST11a]. Note that for a squared loss function

$L(\langle w, x_i \rangle, y_i) = ||\langle w, x_i \rangle - y_i||_2^2$, we have $|L'|^2 \leq 4L$. Employing the result of Theorem 3 in [SST11a], after the N-th iteration, the l_1 approximation error is bounded by

$$\varepsilon \leq (M-1)P(0) + ||w^*||_1^2 \frac{M}{\alpha_t N}, M = \frac{2}{2 - 4\alpha_t(p-1)e}$$

By rearranging the terms and applying $V = TV$, Equation (17) can be deduced.

4 Experimental Results: Discrete MDPs

Figure 2 shows that mirror-descent TD converges more quickly with far smaller Bellman errors than LARS-TD [KN09] on a discrete "two-room" MDP [MM07]. The basis matrix Φ was automatically generated as 50 proto-value functions by diagonalizing the graph Laplacian of the discrete state space connectivity graph[MM07]. The figure also shows that Algorithm 2 (sparse mirror-descent TD) scales more gracefully than LARS-TD. Note LARS-TD is unstable for $\gamma = 0.9$. It should be noted that the computation cost of LARS-TD is $O(Ndm^3)$, whereas that for Algorithm 2 is $O(Nd)$, where N is the number of samples, d is the number of basis functions, and m is the number of active basis functions. If p is linear or sublinear w.r.t d, Algorithm 2 has a significant advantage over LARS-TD.

Figure 3 shows the result of another experiment conducted to test the noise immunity of Algorithm 2 using a discrete 10×10 grid world domain with the goal set at the upper left hand corner. For this problem, 50 proto-value basis functions were automatically generated, and 450 random Gaussian mean 0 noise features were added. The sparse mirror descent TD algorithm was able to generate a very good approximation to the optimal value function despite the large number of irrelevant noisy features, and took a fraction of the time required by LARS-TD.

Figure 4 compares the performance of mirror-descent Q-learning with a fixed p-norm link function vs. a decaying p-norm link function for a 10×10 discrete grid world domain with the goal state in the upper left-hand corner. Initially, $p = O(\log d)$ where d is the number of features, and subsequently p is decayed to a minimum of $p = 2$. Varying p-norm interpolates between additive and multiplicative updates. Different values of p yield an interpolation between the truncated gradient method [LLZ09] and SMIDAS [SsT09].

Figure 5 illustrates the performance of Algorithm 3 on the two-room discrete grid world navigation task.

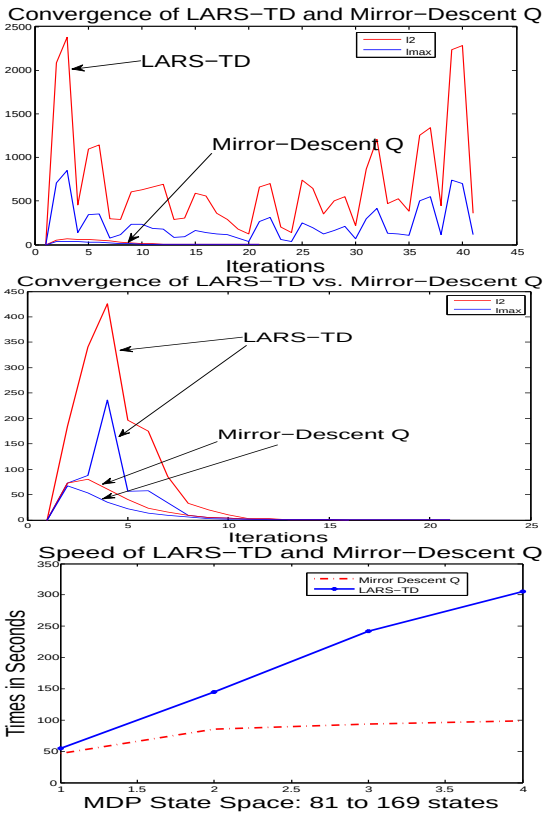

Figure 2: Mirror-descent Q-learning converges significantly faster than LARS-TD on a "two-room" grid world MDP for $\gamma = 0.9$ (top left) and $\gamma = 0.8$ (top right). The y-axis measures the l_2 (red curve) and l_∞ (blue curve) norm difference between successive weights during policy iteration. Bottom: running times for LARS-TD (blue solid) and mirror-descent Q (red dashed). Regularization $\beta = 0.01$.

lower variance. Figure 7 shows that mirror-descent Q-learning with learned diffusion wavelet bases converges quickly on the 4-dimensional Acrobot task. We found in our experiments that LARS-TD did not converge within 20 episodes (its curve, not shown in Figure 6, would be flat on the vertical axis at 1000 steps). Finally, we tested the mirror-descent approach on a more complex 8-dimensional continuous MDP. The triple-link inverted pendulum [SW01] is a highly nonlinear time-variant underactuated system, which is a standard benchmark testbed in the control community. We base our simulation using the system parameters described in [SW01], except that the action space is discretized because the algorithms described here are restricted to policies with discrete actions. There are three actions, namely $\{0, 5\text{Newton}, -5\text{Newton}\}$. The state space is 8-dimensional, consisting of the angles made to the horizontal of the three links in the arm as well as their angular velocities, the position and velocity of the cart used to balance the pendulum. The goal is to learn a policy that can balance the system with the minimum num-

ber of episodes. A run is successful if it balances the inverted pendulum for the specified number of steps within 300 episodes, resulting in a reward of 0. Otherwise, this run is considered as a failure and yields a negative reward -1. The first action is chosen randomly to push the pendulum away from initial state. Two experiments were conducted on the triple-link pendulum domain with 20 runs for each experiment. As Table 1 shows, Mirror Descent Q-learning is able to learn the policy with fewer episodes and usually with reduced variance compared with regular Q-learning.

The experiment settings are Experiment 1: Zero initial state and the system receives a reward 1 if it is able to balance 10,000 steps. Experiment 2: Zero initial state and the system receives a reward 1 if it is able to balance 100,000 steps. Table 1 shows the comparison result between regular Q-learning and Mirror Descent Q-learning.

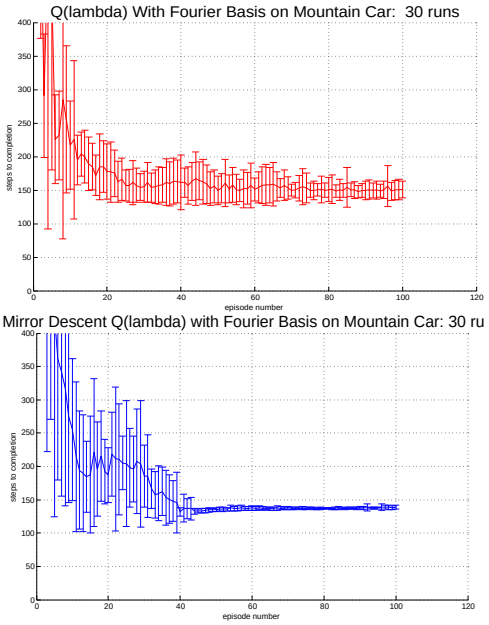

Figure 6: Top: Q-learning; Bottom: mirror-descent Q-learning with p-norm link function, both with 25 fixed Fourier bases [KOT08] for the mountain car task.

6 Comparison of Link Functions

The two most widely used link functions in mirror descent are the p-norm link function [BT03] and the relative entropy function for exponentiated gradient (EG) [KW95]. Both of these link functions offer a multiplicative update rule compared with regular additive gradient methods. The differences between these two are discussed here. Firstly, the loss function for EG is the relative entropy whereas that of the p-norm link function is the square l_2-norm function. Second and more importantly, EG does not produce sparse solutions since it must maintain the weights away from zero, or else its potential (the relative entropy) becomes unbounded at the boundary.

Another advantage of p-norm link functions over EG is that

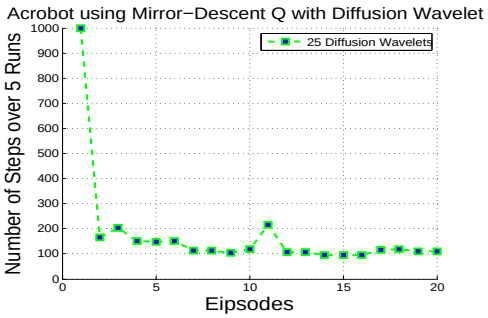

Figure 7: Mirror-descent Q-learning on the Acrobot task using automatically generated diffusion wavelet bases averaged over 5 trials.

Table 1: Results on Triple-Link Inverted Pendulum Task.

# of Episodes\Experiment	1	2
Q-learning	6.1 ± 5.67	15.4 ± 11.33
Mirror Descent Q-learning	5.7 ± 9.70	11.8 ± 6.86

the p-norm link function offers a flexible interpolation between additive and multiplicative gradient updates. It has been shown that when the features are dense and the optimal coefficients θ^* are sparse, EG converges faster than the regular additive gradient methods [KW95]. However, according to our experience, a significant drawback of EG is the overflow of the coefficients due to the exponential operator. To prevent overflow, the most commonly used technique is rescaling: the weights are re-normalized to sum to a constant. However, it seems that this approach does not always work. It has been pointed out [PS95] that in the EG-Sarsa algorithm, rescaling can fail, and replacing eligible traces instead of regular additive eligible traces is used to prevent overflow. EG-Sarsa usually poses restrictions on the basis as well. Thanks to the flexible interpolation capability between multiplicative and additive gradient updates, the p-norm link function is more robust and applicable to various basis functions, such as polynomial, radial basis function (RBF), Fourier basis [KOT08], proto-value functions (PVFs), etc.

7 Summary and Future Work

We proposed a novel framework for reinforcement learning using mirror-descent online convex optimization. Mirror Descent Q-learning demonstrates the following advantage over regular Q learning: faster convergence rate and reduced variance due to larger stepsizes with theoretical convergence guarantees [NJLS09]. Compared with existing sparse reinforcement learning algorithms such as LARS-TD, Algorithm 2 has lower sample complexity and lower computation cost, advantages accrued from the first-order mirror descent framework combined with proximal mapping [SST11a]. There are many promising future research topics along this direction. We are currently exploring a mirror-descent fast-gradient RL method, which is both convergent off-policy and quicker than fast gradient TD methods such as GTD and TDC [SMP$^+$09]. To scale to large MDPs, we are investigating hierarchical mirror-descent RL methods, in particular extending SMDP Q-learning. We are also undertaking a more detailed theoretical analysis of the mirror-descent RL framework, building on existing analysis of mirror-descent methods [DHS11, SST11a]. Two types of theoretical investigations are being explored: regret bounds of mirror-descent TD methods, extending previous results [SW94] and convergence analysis combining robust stochastic approximation [NJLS09] and RL theory [BT96, Bor08].

Abstract

We describe multi-objective influence diagrams, based on a set of p objectives, where utility values are vectors in $\mathbb{R}^p$, and are typically only partially ordered. These can still be solved by a variable elimination algorithm, leading to a set of maximal values of expected utility. If the Pareto ordering is used this set can often be prohibitively large. We consider approximate representations of the Pareto set based on ϵ-coverings, allowing much larger problems to be solved. In addition, we define a method for incorporating user tradeoffs, which also greatly improves the efficiency.

1 INTRODUCTION

Influence diagrams [1] are a powerful formalism for reasoning with sequential decision making problems under uncertainty. They involve both chance variables, where the outcome is determined randomly based on the values assigned to other variables, and decision variables, which the decision maker can choose the value of, based on observations of some other variables. Uncertainty is represented (like in a Bayesian network) by a collection of conditional probability distributions, one for each chance variable. The overall value of an outcome is represented as the sum of a collection of utility functions.

In many situations, a decision maker has more than one objective, and mapping several objectives to a single utility scale can be problematic, since the decision maker may be unwilling or unable to provide precise tradeoffs between objectives [2, 3, 4]. We consider multi-objective influence diagrams, where utility values are now vectors in $\mathbb{R}^p$, with p being the number of objectives. Since utility values are now only partially ordered (for instance by the Pareto ordering) we no longer have a unique maximal value of expected utility, but a set of them.

The Pareto ordering on multi-objective utility is a rather weak one; the effect of this is that the set of maximal values of expected utility can often become huge. We discuss how the notion of ϵ-covering, which approximates the Pareto set, can be applied for the case of multi-objective influence diagrams. As we demonstrate experimentally, this has a major effect on the size of the undominated utility vector sets and hence on the computational efficiency and feasibility for larger problems.

We also define a simple formalism for imprecise tradeoffs; this allows the decision maker, during the elicitation stage, to specify a preference for one multi-objective utility vector over another, and uses such inputs to infer other preferences. The induced preference relation then is used to eliminate dominated utility vectors during the computation. Our experimental results indicate that the presence of even a few such imprecise tradeoffs greatly reduces the undominated set of expected utility values.

The paper is organized as follows. We first discuss the related work. Then Section 2 describes standard influence diagrams and multi-objective utility values. Section 3 defines multi-objective influence diagrams, and how variable elimination can be used to compute the set of maximal values of expected utility, up to a form of equivalence. Section 4 describes the use of the ϵ-covering of the Pareto set. Section 5 defines the formalism for tradeoffs and how the induced notion of preference dominance can be computed. Section 6 describes our experimental testing of multi-objective influence diagrams, based on the Pareto ordering, on the ϵ-covering approximation, and based on the dominance relation induced by the user tradeoffs. Section 7 concludes.

RELATED WORK: Our approach to multi-objective influence diagram computation is based on our general framework [5].

Diehl and Haimes [6] describe a computational technique for influence diagrams with multiple objectives, with the

restriction of just a single value node (utility function). The solution method is based on influence diagram transformations [7]. Pareto dominance is used to prune sub-optimal utility vectors during the computation (with tradeoffs being taken into account at the end of the computation).

Papadimitriou and Yannakakis [8] proposed the use of the logarithmic grid in $(1+\epsilon)$ to generate an ϵ-covering of the Pareto set. Dubus et al. [9] also developed a variable elimination algorithm that uses ϵ-dominance over a graphical model (GAI network) that represents a (multi-objective) generalized decomposable additive utility function.

Zhou et al. [10] consider influence diagrams (with a unique value node) based on interval-valued utility, which is similar to bi-objective utility. They adapt Cooper's approach for solving influence diagrams based on Bayesian network algorithms [11]. Other extensions of influence diagrams include work in [12, 13, 14] which allow interval probability (but precise single-objective utility), and in [15] which considers generalized influence diagrams based on fuzzy random variables.

Maua et al. [16] proposed a variable elimination algorithm for solving Limited Memory Influence Diagrams (LIMIDs). Although they consider standard totally ordered utilities, their algorithm also manipulates partially ordered sets: in their case, sets of functions that are used to represent the effect of different undominated policies.

Our method for incorporating tradeoffs relates to *convex cones*, as shown by Theorem 3. A general approach to multi-objective preferences based on cones has been developed by Yu and others [17, 18].

2 BACKGROUND

2.1 INFLUENCE DIAGRAMS

An *influence diagram* (ID) [1] is defined by a tuple $\langle \mathbf{X}, \mathbf{D}, \mathbf{P}, \mathbf{U} \rangle$, where $\mathbf{X} = \{X_1, \ldots, X_n\}$ is a set of *chance variables* which specify the uncertain decision environment and $\mathbf{D} = \{D_1, \ldots, D_m\}$ is a set of *decision variables* which specify the possible decisions to be made in the domain. The chance variables are further divided into *observable* meaning they will be observed during execution, or *unobservable*. As in Bayesian networks [19], each chance variable $X_i \in \mathbf{X}$ is associated with a *conditional probability table* (CPT) $P_i = P(X_i | pa(X_i))$, where $P_i \in \mathbf{P}$ and $pa(X_i) \subseteq \mathbf{X} \cup \mathbf{D} \setminus \{X_i\}$. Each decision variable $D_k \in \mathbf{D}$ has a parent set $pa(D_k) \subseteq \mathbf{X} \cup \mathbf{D} \setminus \{D_k\}$, denoting the variables whose values will be known at the time of the decision and may affect directly the decision. *Non-forgetting* is typically assumed for an influence diagram, meaning that a decision node and its parents are parents to all subsequent decisions. The *utility* (or *reward*) *functions* $\mathbf{U} = \{U_1, \ldots, U_r\}$ are defined over subsets of

Figure 1: A simple influence diagram with two decisions.

variables $Q = \{Q_1, \ldots, Q_r\}$, $Q_i \subseteq \mathbf{X} \cup \mathbf{D}$, called *scopes*, and represent the preferences of the decision maker.

The graph of an ID contains nodes for chance variables (circled), decision variables (boxed) and for the utility components (diamond). For each chance or decision node there is an arc directed from each of its parent variables toward it, and there is a directed arc from each variable in the scope of a utility function toward its utility node.

The decision variables in an influence diagram are typically assumed to be temporally ordered (also known as *regularity*). Let $D_1, D_2, ..., D_m$ be the order in which the decisions are to be made. The chance variables can be partitioned into a collection of disjoint sets $\mathbf{I}_0, \mathbf{I}_1, \ldots, \mathbf{I}_m$. For each k, where $0 < k < m$, $\mathbf{I}_k$ is the set of chance variables that are observed between D_k and D_{k+1}. $\mathbf{I}_0$ is the set of initial evidence variables that are observed before D_1. $\mathbf{I}_m$ is the set of chance variables left unobserved when the last decision D_m is made. This induces a strict partial order $\prec$ over $\mathbf{X} \cup \mathbf{D}$, given by: $\mathbf{I}_0 \prec D_1 \prec \mathbf{I}_1 \prec \cdots \prec D_m \prec \mathbf{I}_m$ [20].

A *policy* (or *strategy*) for an influence diagram is a list of decision rules $\Delta = (\delta_1, \ldots, \delta_m)$ consisting of one rule for each decision variable. A *decision rule* for the decision $D_k \in \mathbf{D}$ is a mapping $\delta_k : \Omega_{pa(D_k)} \rightarrow \Omega_{D_k}$, where for a set $S \subseteq \mathbf{X} \cup \mathbf{D}$, Ω_S is the Cartesian product of the individual domains of the variables in S. Therefore, a policy Δ determines a value for each decision variable D_i (which depends on the parents set $pa(D_i)$). Given a utility function U, a policy Δ yields a utility function $[U]_\Delta$ that involves no decision variables, by assigning their values using Δ. The expected utility given policy Δ is $EU_\Delta = \sum_{\mathbf{X}} [(\prod_{i=1}^{n} P_i \times \sum_{j=1}^{r} U_j)]_\Delta$. Solving an influence diagram means finding an *optimal policy* that maximizes the expected utility, i.e., to find $\arg\max_\Delta EU_\Delta$. The maximum expected utility can be shown to be equal to:

$$\sum_{\mathbf{I}_0} \max_{D_1} \cdots \sum_{\mathbf{I}_{m-1}} \max_{D_m} \sum_{\mathbf{I}_m} \left(\prod_{i=1}^{n} P_i \times \sum_{j=1}^{r} U_j \right) \quad (1)$$

Example 1 *Figure 1 shows the influence diagram of the oil wildcatter problem (adapted from [21]). An oil wildcatter must decide either to* drill *or* not to drill *for oil at a*

specific site. Before drilling, a seismic test *could help determine the geological structure of the site. The test results can show a* closed *reflection pattern (indication of significant oil), an* open *pattern (indication of some oil), or a* diffuse *pattern (almost no hope of oil). The special value* notest *is used if no seismic test is performed. There are therefore two decision variables, T (Test) and D (Drill), and two chance variables S (Seismic results) and O (Oil contents). The probabilistic knowledge consists of the conditional probability tables $P(O)$ and $P(S|O,T)$, while the utility function is the sum of $U_1(T)$ and $U_2(O,D)$. The optimal policy is to perform the test and to drill only if the test results show an open or a closed pattern. The expected utility of this policy is 22.5.*

Several exact methods have been proposed over the past decades for solving influence diagrams using local computations [7, 22, 23, 20, 24, 25]. These methods adapted classical *variable elimination* techniques, which compute a type of marginalization over a combination of local functions, in order to handle the multiple types of information (probabilities and utilities), marginalization ($\sum$ and $\max$) and combination ($\times$ for probabilities, $+$ for utilities) involved in influence diagrams. Since the alternation of $\sum$ and $\max$ in Equation 1 does not commute in general, it prevents the solution technique from eliminating variables in any ordering. Therefore, the computation dictated by Equation 1 must be performed along a *legal elimination ordering* that respects $\prec$, namely the reverse of the elimination ordering is some extension of $\prec$ to a total order [20, 24].

2.2 MULTI-OBJECTIVE UTILITY VALUES

In many real-world situations it may not be possible for the decision maker to map the various possible consequences of a set of actions to the same scale of utility in a way that avoids essentially arbitrary decisions. Hence, it is natural to consider multi-objective or multi-attribute utility functions to cope with multiple and non-commensurate utility scales on which the decision maker's preferences are expressed.

Consider a situation with p objectives (or attributes). A *multi-objective utility value* is characterized by a vector $\vec{u} = (u_1, \ldots, u_p) \in \mathbb{R}^p$, where u_i represents the utility with respect to objective $i \in \{1, \ldots, p\}$. We assume the standard pointwise arithmetic operations, namely $\vec{u} + \vec{v} = (u_1 + v_1, \ldots, u_p + v_p)$ and $q \times \vec{u} = (q \times u_1, \ldots, q \times u_p)$, where $q \in \mathbb{R}$. The comparison of utility values reduces to that of their corresponding p-dimensional vectors.

We are interested in partial orders $\succcurlyeq$ on $\mathbb{R}^p$ satisfying the following two monotonicity properties, where $\vec{u}, \vec{v}, \vec{w} \in \mathbb{R}^p$ are arbitrary vectors.

[Independence:] If $\vec{u} \succcurlyeq \vec{v}$ then $\vec{u} + \vec{w} \succcurlyeq \vec{v} + \vec{w}$

[Scale-Invariance:] If $\vec{u} \succcurlyeq \vec{v}$ and $q \in \mathbb{R}$, $q \geq 0$ then $q \times \vec{u} \succcurlyeq q \times \vec{v}$.

An important example of such a partial order is the weak Pareto order.

DEFINITION **1 (weak Pareto ordering)** *Let $\vec{u}, \vec{v} \in \mathbb{R}^p$ such that $\vec{u} = (u_1, \ldots, u_p)$ and $\vec{v} = (v_1, \ldots, v_p)$. We define the binary relation $\geq$ on $\mathbb{R}^p$ by $\vec{u} \geq \vec{v} \iff \forall i \in \{1, \ldots, p\}\ u_i \geq v_i$.*

Given $\vec{u}, \vec{v} \in \mathbb{R}^p$, if $\vec{u} \succcurlyeq \vec{v}$ then we say that $\vec{u}$ *dominates* $\vec{v}$. As usual, the symbol $\succ$ refers to the asymmetric part of $\succcurlyeq$, namely $\vec{u} \succ \vec{v}$ if and only if $\vec{u} \succcurlyeq \vec{v}$ and it is not the case that $\vec{v} \succcurlyeq \vec{u}$. In particular, relation $\geq$ (resp. $>$) is also called *weak Pareto dominance* (resp. *Pareto dominance*).

DEFINITION **2 (maximal/Pareto set)** *Given a partial order $\succcurlyeq$ and a finite set of utility vectors $\mathcal{U} \subseteq \mathbb{R}^p$, we define the* maximal set, *denoted by $\max_{\succcurlyeq}(\mathcal{U})$, to be the set consisting of the undominated elements in $\mathcal{U}$, i.e., $\max_{\succcurlyeq}(\mathcal{U}) = \{\vec{v} \in \mathcal{U} \mid \nexists \vec{v} \in \mathcal{U}, \vec{v} \succ \vec{u}\}$. When $\succcurlyeq$ is the weak Pareto ordering $\geq$, we call $\max_{\succcurlyeq}(\mathcal{U})$ the* Pareto set.

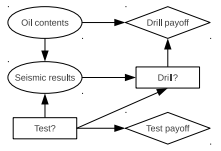
3 MULTI-OBJECTIVE INFLUENCE DIAGRAMS

In this section, we introduce the extension of the standard influence diagram model to include multiple objectives. Towards this goal we consider a multi-objective utility function that is additively decomposable [26]. For simplicity and without loss of generality we assume that all objectives are to be maximized. We next define formally the graphical model and then derive a sequential variable elimination algorithm for evaluating the model.

3.1 THE GRAPHICAL MODEL

A *multi-objective influence diagram* (MOID) extends the standard influence diagram by allowing a multi-objective utility function defined on $p > 1$ objectives. The graphical structure of a MOID is identical to that of a standard ID, namely it is a directed acyclic graph containing *chance nodes* (drawn as circles) for the random discrete variables $\mathbf{X}$, *decision nodes* (drawn as rectangles) for the decision variables $\mathbf{D}$, and *utility nodes* (drawn as diamonds) for the local utility functions $\mathbf{U}$ of the decision maker. The directed arcs in the MOID represent the same dependencies between the variables as in the standard model. Each chance node $X_i \in \mathbf{X}$ is associated with a conditional probability table $P(X_i|pa(X_i)) : \Omega_{X_i \cup pa(X_i)} \rightarrow [0, 1]$. The utility functions $U_j \in \mathbf{U}$ represent the decision maker's preferences with respect to each of the p objectives, namely $U_j : \Omega_{Q_j} \rightarrow \mathbb{R}^p$, where Q_j is the scope of U_j.

A *policy* for a MOID is a sequence $\Delta = (\delta_1, \ldots, \delta_m)$, where each δ_i is a function from $\Omega_{pa(D_i)} \rightarrow \Omega_{D_i}$. Clearly, given a policy Δ we have that $EU_\Delta \subseteq \mathbb{R}^p$. Solving a multi-objective influence diagram means finding the set of



Oil contents	P(O)		
	dry	wet	soak
	0,5	0,3	0,2

Test payoff	U_1(T)
Test?	
yes	{(-10,10)}
no	{(0,0)}

soak	no	{(0,0)}

Figure 2: A bi-objective influence diagram.

policies that generate maximal values of expected utility, i.e., values of utility in the set $\max_{\succcurlyeq}\{EU_\Delta \mid \text{policies } \Delta\}$. We say that a policy Δ is *optimal* if the corresponding expected utility EU_Δ is undominated.

Example 2 *Figure 2 displays a bi-objective influence diagram for the decision problem from Example 1. We consider a utility function with two attributes representing the testing/drilling* payoff *and* damage *to the environment, respectively. The utility of testing is* $(-10, 10)$*, whereas the utility of drilling is* $(-70, 18)$*,* $(50, 12)$*,* $(200, 8)$ *for a dry, wet and soaking hole, respectively. The aim is to find optimal policies that maximize the payoff and minimize the damage to environment. The dominance relation is defined in this case by* $\vec{u} \geq \vec{v} \Leftrightarrow u_1 \geq v_1$ *and* $u_2 \leq v_2$ *(e.g.,* $(10, 2) \geq (8, 4)$ *and* $(10, 2) \not\geq (8, 1)$*). The Pareto set* $\max_{\geq}\{EU_\Delta \mid$ *policies* $\Delta\}$ *contains 4 elements, i.e.,* $\{(22.5, 17.56),\ (20, 14.2),\ (11, 12.78),\ (0, 0)\}$*, corresponding to the four optimal policies shown below (we show how to obtain these in Section 3.4):*

	Δ_1	Δ_2	Δ_3	Δ_4
δ_T	*yes*	*no*	*yes*	*no*
δ_D	*yes (S = closed)* *yes (S = open)* *no (S = diffuse)*	*yes (S = notest)*	*yes (S = closed)* *no (S = open)* *no (S = diffuse)*	*no (S = notest)*
EU_{Δ_i}	$\{(22.5, 17.56)\}$	$\{(20, 14.2)\}$	$\{(11, 12.78)\}$	$\{(0, 0)\}$

Because we are considering partially ordered utilities, the $\max$ operator does not necessarily lead to a unique element. This means that we need to extend the arithmetic operations, addition, multiplication and $\max$, to finite sets of utility values.

3.2 ARITHMETIC OPERATIONS AND DISTRIBUTIVITY PROPERTIES

In this section we assume a partial order $\succcurlyeq$ on $\mathbb{R}^p$ that satisfies Independence and Scale-Invariance. In particular, $\succcurlyeq$ can be the weak Pareto ordering.

Given two finite sets $\mathcal{U}, \mathcal{V} \subseteq \mathbb{R}^p$ and $q \geq 0$, we define the summation and multiplication operations as $\mathcal{U} + \mathcal{V} = \{\vec{u} + \vec{v} \mid \vec{u} \in \mathcal{U}, \vec{v} \in \mathcal{V}\}$ and $q \times \mathcal{U} = \{q \times \vec{u} \mid \vec{u} \in \mathcal{U}\}$, respectively. The maximization operation is defined as $\max(\mathcal{U}, \mathcal{V}) = \max_{\succcurlyeq}(\mathcal{U} \cup \mathcal{V})$. It is easy to see that $+$, $\times$ and $\max$ are commutative and associative.

To ensure the correctness of a variable elimination computation (such as the one in Algorithm 1) we need some distributivity properties. However, the important property $(q_1 + q_2) \times \mathcal{U} = q_1 \times \mathcal{U} + q_2 \times \mathcal{U}$ does not always hold. As a simple example, let $q_1 = q_2 = 0.5$ and consider a set of bi-objective utility vectors $\mathcal{U} = \{(1, 0), (0, 1)\}$. Using the point-wise operations on pairs of real numbers we have that $(q_1 + q_2) \times \mathcal{U}$ yields the set $\{(1, 0), (0, 1)\}$, whereas $(q_1 \times \mathcal{U}) + (q_2 \times \mathcal{U}) = \{(0.5, 0), (0, 0.5)\} + \{(0.5, 0), (0, 0.5)\} = \{(1, 0), (0.5, 0.5), (0, 1)\}$. We will see next that this distributivity property does hold if we restrict to convex sets.

3.3 EQUIVALENT SETS OF UTILITY VALUES

For $\mathcal{U}, \mathcal{V} \subseteq \mathbb{R}^p$, we say that $\mathcal{U} \succcurlyeq \mathcal{V}$ if every element of $\mathcal{V}$ is (weakly) dominated by some element of $\mathcal{U}$ (so that $\mathcal{U}$ contains as least as large elements as $\mathcal{V}$), namely if for all $\vec{v} \in \mathcal{V}$ there exists $\vec{u} \in \mathcal{U}$ with $\vec{u} \succcurlyeq \vec{v}$. We also define an equivalence relation $\approx$ between two finite sets $\mathcal{U}, \mathcal{V} \subseteq \mathbb{R}^p$ by $\mathcal{U} \approx \mathcal{V}$ if and only if $\mathcal{U} \succcurlyeq \mathcal{V}$ and $\mathcal{V} \succcurlyeq \mathcal{U}$.

Given a set $\mathcal{U} \subseteq \mathbb{R}^p$, we define its *convex closure* $\mathcal{C}(\mathcal{U})$ to consist of every element of the form $\sum_{j=1}^{k}(q_j \times \vec{u}^j)$, where k is an arbitrary natural number, each $\vec{u}^j \in \mathcal{U}$, each $q_j \geq 0$ and $\sum_{j=1}^{k} q_j = 1$, respectively.

Given $\mathcal{U}, \mathcal{V} \subseteq \mathbb{R}^p$, we define the equivalence relation $\equiv$ by $\mathcal{U} \equiv \mathcal{V}$ if and only if $\mathcal{C}(\mathcal{U}) \approx \mathcal{C}(\mathcal{V})$. Therefore, two sets of utility vectors are considered equivalent if, for every convex combination of elements of one, there is a convex combination of elements of the other which is at least as good (with respect to the partial order $\succcurlyeq$ on $\mathbb{R}^p$). The following result shows, in particular, that the operations on sets of utility values respects the equivalence relation.

PROPOSITION **1** *Let* $\mathcal{U}, \mathcal{V}, \mathcal{W} \subseteq \mathbb{R}^p$ *be finite sets and let* $q \geq 0$*. The following properties hold: (1)* $\mathcal{U} \equiv \max_{\succcurlyeq}(\mathcal{U})$*; (2) if* $\mathcal{U} \equiv \mathcal{V}$ *then* $q \times \mathcal{U} \equiv q \times \mathcal{V}$*,* $\mathcal{U} + \mathcal{W} \equiv \mathcal{V} + \mathcal{W}$ *and* $\max(\mathcal{U}, \mathcal{W}) \equiv \max(\mathcal{V}, \mathcal{W})$*.*

We can show now that the distributivity, and other properties we require, hold with respect to the $\equiv$ relation between finite sets of partially ordered utility values.

THEOREM **1** *Let* $\succcurlyeq$ *be a partial order on* $\mathbb{R}^p$ *satisfying Independence and Scale-Invariance. Then, for all* $q, q_1, q_2 \geq 0$ *and for all finite sets* $\mathcal{U}, \mathcal{V}, \mathcal{W} \subseteq \mathbb{R}^p$*, we have that:*
(i) $q \times (\mathcal{U} + \mathcal{V}) = q \times \mathcal{U} + q \times \mathcal{V}$*;*
(ii) $(q_1 + q_2) \times \mathcal{U} \equiv (q_1 \times \mathcal{U}) + (q_2 \times \mathcal{U})$*;*
(iii) $q_1 \times (q_2 \times \mathcal{U}) = (q_1 \times q_2) \times \mathcal{U}$*;*
(iv) $\max(q \times \mathcal{U}, q \times \mathcal{V}) = q \times \max(\mathcal{U}, \mathcal{V})$*;*
(v) $\max(\mathcal{U} + \mathcal{W}, \mathcal{V} + \mathcal{W}) \equiv \max(\mathcal{U}, \mathcal{V}) + \mathcal{W}$*.*

This implies that variable elimination can be used to gen-

Algorithm 1: ELIM-MOID

15 $\Delta \leftarrow \Delta \cup \delta_l$
16 **return** Δ

erate the set of maximal values of expected utility, up to equivalence (see also [5] for more details).

3.4 VARIABLE ELIMINATION

As well as operation $+$ on sets of utilities, we define operation $+'$ on finite sets of utility values by $\mathcal{U} +' \mathcal{V} = \max_{\succcurlyeq}(\mathcal{U} + \mathcal{V})$. Theorem 1 allows us to apply an iterative variable elimination procedure along a legal elimination ordering where chance variables are eliminated by $+'$, decision variables by $\max$, and the probability and (set-valued) utility functions are combined by $\times$ and $+$, respectively. The set of maximal expected utility values is equivalent to $\sum'_{\mathbf{I}_0} \max_{D_1} \cdots \max_{D_m} \sum'_{\mathbf{I}_m} \left(\prod_{i=1}^{n} P_i \times \sum_{j=1}^{r} U_j \right)$.

The variable elimination algorithm, called ELIM-MOID, is described by Algorithm 1. It is based on Dechter's bucket elimination framework [24] and computes the maximal set $\max_{\succcurlyeq}\{EU_\Delta | \text{ policies } \Delta\}$ as well as an optimal policy (the algorithm can be easily instrumented to produce the entire set of optimal policies). Given a legal elimination ordering $\tau = Y_1, \ldots, Y_t$, the input functions are partitioned into a bucket structure, called *buckets*, such that each bucket is associated with a single variable Y_l and contains all input probability and utility functions whose highest variable in their scope is Y_l.

ELIM-MOID processes each bucket, top-down from the last to the first, by a variable elimination procedure that computes new probability (denoted by ϕ) and utility (denoted by ψ) components which are then placed in corresponding lower buckets (lines 3-11). For a chance variable Y_l, the ϕ-message is generated by multiplying all probability components in that bucket and eliminating Y_l by summation. The ψ-message is computed as the average utility in that bucket, normalized by the bucket's compiled ϕ (here Y_l is eliminated by $\sum'$). For a decision variable Y_l, we compute the ϕ and ψ components in a similar manner and eliminate Y_l by maximization. In this case, the product of probability components in the bucket is a constant when viewed as a function of the bucket's decision variable and therefore the compiled ϕ-message is a constant as well [20, 5].

In the second, bottom-up step, the algorithm generates an optimal policy (lines 12-16). The decision buckets are processed in reversed order, from the first variable to the last. Each decision rule is generated by taking the argument of the maximization operator applied over the combination of probability and utility components in the respective bucket, for each combination of the variables in the bucket's scope (i.e., the union of the scopes of all functions in the bucket minus Y_l) while remembering the values assigned to earlier decisions. Ties are broken uniformly at random.

As is usually the case with bucket elimination algorithms, the complexity of ELIM-MOID can be bounded exponentially (time and space) by the width of the ordered induced graph that reflects the execution of the algorithm (i.e., induced width of the legal elimination ordering) [24]. Since the utility values are vectors in $\mathbb{R}^p$, it is not easy to predict the size of the undominated set of expected utility values.

4 APPROXIMATING THE PARETO SET

In this section, we assume without loss of generality a weak Pareto ordering on $\mathbb{R}^p_+$ because the proposed approximation method relies on a log transformation of the solution space as we will see next. The cardinality of the Pareto set $\max_{\geq}\{EU_\Delta : \text{ policies } \Delta\}$ (and also the number of optimal policies) can often get very large. What would then be desirable for the decision maker is an approximation of the Pareto set that *approximately* dominates (or covers) all elements in $\{EU_\Delta : \text{ policies } \Delta\}$ and is of considerably smaller size. This can be achieved by considering the notion of ϵ-covering of the Pareto set which is based on ϵ-*dominance* between utility values [8].

DEFINITION **3 (ϵ-dominance)** *For any finite $\epsilon > 0$, the* ϵ-dominance *relation is defined on positive vectors of $\mathbb{R}^p_+$ by $\vec{u} \geq_\epsilon \vec{v} \Leftrightarrow (1 + \epsilon) \cdot \vec{u} \geq \vec{v}$.*

DEFINITION **4 (ϵ-covering)** *Let $\mathcal{U} \subseteq \mathbb{R}^p_+$ and $\epsilon > 0$. Then a set $\mathcal{U}_\epsilon \subseteq \mathcal{U}$ is called an* ϵ-approximate Pareto set *or an* ϵ-covering*, if any vector $\vec{v} \in \mathcal{U}$ is ϵ-dominated by at least one vector $\vec{u} \in \mathcal{U}_\epsilon$, i.e., $\forall \vec{v} \in \mathcal{U}\ \exists \vec{u} \in \mathcal{U}_\epsilon$ such that $\vec{u} \geq_\epsilon \vec{v}$.*

Algorithm 2: $(\epsilon, \lambda)-$COVERING($\mathcal{U}$)

$\Gamma \leftarrow \emptyset$; $\mathcal{V} \leftarrow \emptyset$;
foreach $\vec{u} \in \mathcal{U}$ **do**
  if $\varphi_\lambda(\vec{u}) \notin \Gamma$ **then**
    remove from Γ all $\varphi_\lambda(\vec{v})$ such that $\varphi_\lambda(\vec{u}) \geq \varphi_\lambda(\vec{v})$;
    $\Gamma \leftarrow \Gamma \cup \{\varphi_\lambda(\vec{u})\}$;
foreach $\varphi_\lambda(\vec{u}) \in \Gamma$ **do** $\mathcal{V} \leftarrow \mathcal{V} \cup \{\vec{u}\}$;
return $\mathcal{V}$;

The set $\mathcal{U}_\epsilon$ is not unique. However, it is possible to compute an ϵ-covering of a finite set $\mathcal{U} \subseteq \mathbb{R}^p_+$ by mapping each vector $\vec{u} \in \mathcal{U}$ onto a hyper-grid using the log transformation $\varphi : \mathbb{R}^p_+ \rightarrow \mathbb{Z}^p_+$, defined by $\varphi(\vec{u}) = (\varphi(u_1), \ldots, \varphi(u_p))$ where $\forall i$, $\varphi(u_i) = \lceil \log u_i / \log(1+\epsilon) \rceil$ [8]. By definition, we have that:

PROPOSITION **2** $\forall \vec{u}, \vec{v} \in \mathbb{R}^p_+$, $\varphi(\vec{u}) \geq \varphi(\vec{v}) \Rightarrow \vec{u} \geq_\epsilon \vec{v}$.

It is easy to see that any cell of the grid represents a different class of vectors having the same image through φ. Based on Proposition 2, any vector belonging to a given cell ϵ-dominates any other vector of that cell. Therefore, for any finite ϵ, we can obtain a valid ϵ-covering of $\mathcal{U}$ by choosing one representative element in each cell and by keeping only undominated cells occupied. For example, if we restrict the vectors in $\mathcal{U}$ to be bounded by: $1 \leq u_i \leq B$ for all $i \in \{1, \ldots, p\}$, then the size of $\mathcal{U}_\epsilon$ is polynomial in $\log B$ and $1/\epsilon$ (see also [8] for more details).

Example 3 *Let $\mathcal{U} = \{\vec{u}, \vec{v}\}$ such that $\vec{u} = (3.1, 2.9)$ and $\vec{v} = (3, 3.05)$. Clearly, $\vec{u} \not\geq \vec{v}$ and $\vec{v} \not\geq \vec{u}$. Set $\epsilon = 0.1$. We have that $\varphi(\vec{u}) = \varphi(\vec{v}) = (12, 12)$, and it is easy to verify that $\vec{u} \geq_\epsilon \vec{v}$ and $\vec{v} \geq_\epsilon \vec{u}$. Therefore, $\mathcal{U}_\epsilon = \{\vec{u}\}$ is a valid ϵ-covering of $\mathcal{U}$, as is $\{\vec{v}\}$.*

We next extend algorithm ELIM-MOID to compute an ϵ-covering of the expected utility set $\{EU_\Delta : \text{ policies } \Delta\}$. However, it is not possible to just replace Pareto dominance with ϵ-dominance at each variable elimination step and still guarantee a valid ϵ-covering because ϵ-dominance is not a transitive relation (e.g., if $\vec{u} \geq_\epsilon \vec{v}$ and $\vec{v} \geq_\epsilon \vec{w}$, we only have that $\vec{u} \geq (1+\epsilon)^2 \cdot \vec{w}$). To overcome this difficulty, we use a finer dominance relation, defined as follows [9].

DEFINITION **5 (**(ϵ, λ)**-dominance)** *For any finite $\epsilon > 0$ and $\lambda \in (0, 1)$, the* (ϵ, λ)-dominance *relation is defined on positive vectors of $\mathbb{R}^p_+$ by $\vec{u} \geq^\lambda_\epsilon \vec{v} \Leftrightarrow (1+\epsilon)^\lambda \cdot \vec{u} \geq \vec{v}$. Given a set $\mathcal{U} \subseteq \mathbb{R}^p_+$, a subset $\mathcal{U}_{(\epsilon,\lambda)} \subseteq \mathcal{U}$ is called an (ϵ, λ)-covering, if $\forall \vec{v} \in \mathcal{U}$ $\exists \vec{u} \in \mathcal{U}_{(\epsilon,\lambda)}$ such that $\vec{u} \geq^\lambda_\epsilon \vec{v}$.*

Algorithm 2 computes an (ϵ, λ)-covering of a finite set $\mathcal{U} \subseteq \mathbb{R}^p_+$ by using the log grid mapping $\varphi_\lambda : \mathbb{R}^p_+ \rightarrow \mathbb{Z}^p_+$ defined by $\varphi_\lambda(\vec{u}) = (\varphi_\lambda(u_1), \ldots, \varphi_\lambda(u_p))$ where $\forall i$, $\varphi_\lambda(u_i) = \lceil \log u_i / \log(1+\epsilon)^\lambda \rceil$. It is easy to see that:

PROPOSITION **3** $\forall \vec{u}, \vec{v} \in \mathbb{R}^p_+$, $\varphi_\lambda(\vec{u}) \geq \varphi_\lambda(\vec{v}) \Rightarrow \vec{u} \geq^\lambda_\epsilon \vec{v}$.

PROPOSITION **4** *Let $\vec{u}, \vec{v}, \vec{w} \in \mathbb{R}^p_+$ and $\lambda, \lambda' \in (0, 1)$. The following properties hold: (i) if $\vec{u} \geq^\lambda_\epsilon \vec{v}$ then $\vec{u} + \vec{w} \geq^\lambda_\epsilon \vec{v} + \vec{w}$, and if $\vec{u} \geq^\lambda_\epsilon \vec{v}$ and $q \geq 0$ then $q \cdot \vec{u} \geq^\lambda_\epsilon q \cdot \vec{v}$; (ii) if $\vec{u} \geq^\lambda_\epsilon \vec{v}$ and $\vec{v} \geq^{\lambda'}_\epsilon \vec{w}$ then $\vec{u} \geq^{\lambda+\lambda'}_\epsilon \vec{w}$.*

We define operations $\max^*$ and $+^*$ on finite sets of utility values by $\max^*(\mathcal{U}, \mathcal{V}) = \max_{\geq^\lambda_\epsilon}(\mathcal{U} \cup \mathcal{V})$ and $\mathcal{U} +^* \mathcal{V} = \max_{\geq^\lambda_\epsilon}(\mathcal{U} + \mathcal{V})$, where $\max_{\geq^\lambda_\epsilon}(\mathcal{U})$ is an (ϵ, λ)-covering of the finite set $\mathcal{U} \subseteq \mathbb{R}^p_+$ (computed using Algorithm 2).

The algorithm called ELIM-MOID$_\epsilon$, which computes an ϵ-covering of the expected utility set, is obtained from Algorithm 1 by replacing $\max$ and $\sum'$ by $\max^*$ and $\sum^*$, respectively. Since the top-down phase of the algorithm consists of t elimination steps, one for each variable, and therefore requires computing t (ϵ, λ_i)-coverings via $\max_{\geq^\lambda_\epsilon}$, $i = 1, \ldots, t$, a sufficient condition to obtain a valid ϵ-covering is to choose the λ_i values summing to 1, specifically $\lambda_i = 1/t$, where t is the number of variables. Thus:

THEOREM **2** *Given a MOID instance $\langle \mathbf{X}, \mathbf{D}, \mathbf{P}, \mathbf{U} \rangle$ with t variables, $p > 1$ objectives and any finite $\epsilon > 0$, algorithm* ELIM-MOID$_\epsilon$ *computes an ϵ-covering.*

The time and space complexity of ELIM-MOID$_\epsilon$ is also bounded exponentially by the induced width of the legal elimination ordering. However, the size of ϵ-covering generated can be in many cases significantly smaller than the corresponding Pareto set, as we will see in Section 6.

5 HANDLING IMPRECISE TRADEOFFS

The Pareto ordering is rather weak (often leading to very large Pareto optimal sets, as mentioned above in Section 4, and illustrated by the experiments in Section 6). Very often the decision maker will be happy to allow some trade-offs between objectives. For example, in a two-objective situation, they may tell us that are happy to gain 3 units of the first objective at the cost of losing one unit of the second, and hence prefer $(3, -1)$ to $(0, 0)$. Such tradeoffs may be elicited using some structured method, or in a more *ad hoc* way. For instance, in Example 1, the decision maker may be asked to imagine a scenario where it was known that the oil content was "wet", and whether they would then have a preference for drilling. To do so would imply a preference of $(50, 12)$ over $(0, 0)$.

We thus consider some set Θ of vector pairs of the form $(\vec{u}, \vec{v})$, where $\vec{u}, \vec{v} \in \mathbb{R}^p$. The idea is that this consists of elicited preferences of the decision maker. We say that binary relation $\succcurlyeq$ on $\mathbb{R}^p$ *extends* Θ if $\vec{u} \succcurlyeq \vec{v}$ for all $(\vec{u}, \vec{v}) \in \Theta$. Similarly, we say that $\succcurlyeq$ extends Pareto if $\vec{u} \geq \vec{v} \Rightarrow \vec{u} \succcurlyeq \vec{v}$.

We consider that the decision maker has a partial order $\succcurlyeq$ over $\mathbb{R}^p$, and that they specify a set of preferences Θ. We assume the Scale-Invariance and Independence properties hold (see Section 2), and, naturally, assume that $\succcurlyeq$ extends

Pareto. The input preferences Θ could contradict the other assumptions we make. We say that Θ *is consistent* if there exists some partial order $\succcurlyeq$ that extends Θ, extends Pareto, and satisfies Scale-Invariance and Independence.

The input preferences Θ (if consistent) give rise to a relation $\succeq_\Theta$ which specifies the deduced preferences. We say that $(\vec{u}, \vec{v})$ *can be deduced from* Θ if $\vec{u} \succcurlyeq \vec{v}$ holds for all partial orders $\succcurlyeq$ that extend Θ, extend Pareto, and satisfy Scale-Invariance and Independence. In this case we write $\vec{u} \succeq_\Theta \vec{v}$. The definition easily implies the following.

PROPOSITION **5** *If Θ is consistent then $\succeq_\Theta$ is a partial order extending Θ and Pareto, and satisfying Scale-Invariance and Independence.*

Proposition 5 shows that this dominance relation $\succeq_\Theta$ satisfies Scale-Invariance and Independence, giving the properties (Theorem 1) we need for the variable elimination algorithm to be correct (up to equivalence).

In Example 1, suppose now we have the additional user preference of $(50, 12)$ over $(0, 0)$, and hence include the pair $((50, 12), (0, 0))$ in Θ. This would then imply that $(11, 12.78)$ is dominated w.r.t. $\succeq_\Theta$ by $(20, 14.2)$.

Theorem 3 below gives a characterization of the partial order $\succeq_\Theta$, which we use as the basis of our implemented algorithm for testing this kind of dominance. Let W be some subset of $\mathbb{R}^p$. Define $\mathbf{C}(W)$, *the convex cone generated by* W, to be the set consisting of all vectors $\vec{u}$ such that there exists $k \geq 0$ and non-negative real scalars $q_1, \ldots, q_k$ and $\vec{w_i} \in W$ with $\vec{u} \geq \sum_{i=1}^{k} q_i \vec{w_i}$, where $\geq$ is the weak Pareto relation (and an empty summation is taken to be equal to 0). $\mathbf{C}(W)$ is the set of vectors that weakly-Pareto dominate some (finite) positive linear combination of elements of W.

THEOREM **3** *Let Θ be a consistent set of pairs of vectors in $\mathbb{R}^p$. Then $\vec{u} \succeq_\Theta \vec{v}$ if and only if $\vec{u} - \vec{v} \in \mathbf{C}(\vec{u_i} - \vec{v_i} : (\vec{u_i}, \vec{v_i}) \in \Theta)$.*

Write finite set of input preferences Θ as $\{(\vec{u_i}, \vec{v_i}) : i = 1, \ldots, k\}$. Theorem 3 shows that, to perform the dominance test $\vec{u} \succeq_\Theta \vec{v}$, it sufficient to check if there exist, for $i = 1, \ldots, k$, non-negative real scalars q_i such that $\vec{u} - \vec{v} \geq \sum_{i=1}^{k} q_i(\vec{u_i} - \vec{v_i})$. This can be determined using a linear programming solver, since it amounts to testing if a finite set of linear inequalities is satisfiable.

Example 4 *Consider $\Theta = \{(-1, 2, -1), (4, -3, 0)\}$ and vectors $\vec{u} = (1, -1, 0)$ and $\vec{v} = (0, -2, 1)$. Then $\vec{u} \succeq_\Theta \vec{v}$ iff $\vec{u} - \vec{v}$ weak Pareto-dominates a non-negative combination of elements of Θ, i.e., $\exists q_1 \geq 0, q_2 \geq 0$ such that $\vec{u} - \vec{v} \geq q_1(-1, 2, -1) + q_2(4, -3, 0)$, which is iff there exists a solution for the linear system defined by: $1 \geq -q_1 + 4q_2$ and $1 \geq 2q_1 - 3q_2$, and $-1 \geq -q_1$. Since this is the case (e.g., $q_1 = 1$; $q_2 = 0.5$) we have $\vec{u} \succeq_\Theta \vec{v}$.*

Alternatively, we can use the fact that the dominance test corresponds to checking whether $\vec{u} - \vec{v}$ is in the convex cone generated by $\{\vec{u_i} - \vec{v_i} : i = 1, \ldots, k\}$ plus the p unit vectors in $\mathbb{R}^p$. We made use of an (incomplete) algorithm [27] for this purpose (which computes the distance of a vector from a cone).

Therefore, the algorithm called ELIM-MOID-TOF that exploits tradeoffs is obtained from Algorithm 1, by replacing the $+'$ and $\max$ operators with $+^\Theta$ and $\max^\Theta$, respectively, where $\max^\Theta(\mathcal{U}, \mathcal{V}) = \max_{\succeq_\Theta}(\mathcal{U} \cup \mathcal{V})$, $\mathcal{U} +^\Theta \mathcal{V} = \max_{\succeq_\Theta}(\mathcal{U} + \mathcal{V})$, and $\max_{\succeq_\Theta}(\mathcal{U})$ is the set of undominated elements of finite set $\mathcal{U} \subseteq \mathbb{R}^p$ with respect to $\succeq_\Theta$.

Instead of eliminating $\succeq_\Theta$-dominated utility values during the computation, one could generate the Pareto optimal set of expected utility values, and only then eliminate $\succeq_\Theta$-dominated values. However, the experimental results in Section 6 (Table 2) indicate that this will typically be much less computationally efficient.

6 EXPERIMENTS

In this section, we evaluate empirically the performance of the proposed variable elimination algorithms on random multi-objective influence diagrams. All experiments were run on a 2.6GHz quad-core processor with 4GB of RAM.

The algorithms considered were implemented in C++ (32-bit) and are denoted by ELIM-MOID (Section 3), ELIM-MOID$_\epsilon$ (Section 4) and ELIM-MOID-TOF (Section 5), respectively. We implemented both methods for performing the $\succeq_\Theta$-dominance, namely the linear programming and the distance from a cone based one, and report only on the former because their performance was comparable overall.

We experimented with a class of random influence diagrams described by the parameters $\langle C, D, k, p, r, a, O \rangle$, where C is the number of chance variables, D is the number of decision variables, k is the maximum domain size, p is the number of parents in the graph for each variable, r is the number of root nodes, a is the arity of the utility functions and O is the number of objectives. The structure of the influence diagram is created by randomly picking $C + D - r$ variables out of $C + D$ and, for each, selecting p parents from their preceding variables, relative to some ordering, whilst ensuring that the decision variables are connected by a directed path. We then added to the graph D utility nodes, each one having a parents picked randomly from the chance and decision variables.

We generated random problems with parameters $k = 2$, $p = 2$, $r = 5$, $a = 3$ and varied $C \in \{15, 25, 35, 45, 55\}$, $D \in \{5, 10\}$ and $O \in \{2, 3, 5\}$, respectively. In each case, 25% of the chance nodes were assigned deterministic CPTs (containing 0 and 1 entries). The remaining CPTs were randomly filled using a uniform distribution. The utility vectors were generated randomly, each objective value being

drawn uniformly at random between 1 and 30.

We report the average CPU time (in seconds) as well as the average size (together with standard deviation and median) of the maximal expected utility sets generated. In addition, we also record the average induced width (w^*) of the problems obtained using a minfill elimination ordering [24].

Impact of the ϵ-covering Table 1 summarizes the results obtained with algorithms ELIM-MOID and ELIM-MOID$_\epsilon$ with $\epsilon \in \{0.01, 0.1, 0.3\}$ on problems with 5 and 10 decisions. The number shown in column (#) indicates how many instances out of 20 were solved within the time or memory limit. We see that ELIM-MOID can solve only relatively small instances and runs out of time/memory on the larger ones. For example, on problem size $\langle 25, 5, 2\rangle$, ELIM-MOID solved 60% of the instances in about 17 seconds and generated Pareto sets containing about 3,600 vectors on average (with a standard deviation of about 6,900). On the other hand, algorithm ELIM-MOID$_\epsilon$ scales up and solves larger problems while generating significantly smaller ϵ-coverings, especially as ϵ increases. For example, on problem class $(25, 5, 2)$, the average size of the ϵ-covering for $\epsilon = 0.3$ is about 2 orders of magnitude smaller than the corresponding Pareto optimal set. The reason is that as ϵ increases, the corresponding logarithmic grid gets coarser (i.e., fewer cells) and therefore the number of representative vectors needed to cover the optimal Pareto set is smaller.

Figure 3 plots the distribution (mean and standard deviation) of the size of the ϵ-coverings generated for problem class $\langle 35, 5, 5\rangle$, as a function of ϵ. We can see that as ϵ increases the size of the ϵ-covering decreases considerably.

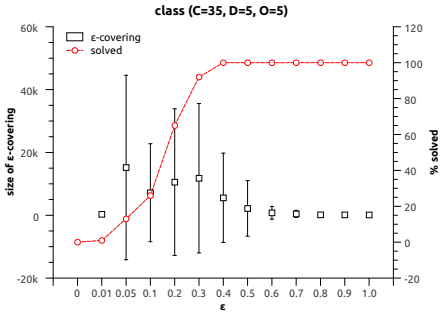

Figure 3: Distribution (mean and stdev) of the ϵ-covering size as a function of the ϵ value. We also plot the number of instances solved out of 100. Time limit 20 minutes.

Impact of imprecise tradeoffs For the purpose of this evaluation, we generated consistent random tradeoffs between the objectives of a given problem instance, as follows. Let (i, j) be a pair of objectives picked randomly out of p objectives. We generate two tradeoffs $a\vec{e}_i - b\vec{e}_j$ and $b\vec{e}_j - ac\vec{e}_i$, where $\vec{e}_i$ and $\vec{e}_j$ are the i-th and j-th unit vectors. Intuitively, one of the tradeoffs indicates how much of objective i one is willing to sacrifice to gain a unit of objective j, and the other is vice versa. In addition, we also generate a 3-way tradeoff between three objectives (i, j, k) picked randomly as well in the form of the tradeoff vector $a\vec{e}_i + b\vec{e}_j - c\vec{e}_k$. Therefore, our random tradeoffs generator is characterized by parameters (K, T, a, b, c), where K is the number of pairs of objectives, T is the number of triplets (and thus a total of $2K + T$ tradeoffs in Θ), and randomly chosen $a, b, c \in [0, 1)$ are used to construct the tradeoff vectors. Notice that parameter c can be used to control the strength of the two-way tradeoffs. Specifically,

if we were to set $c = 1$ then the two objectives i and j would essentially collapse into a single one (we'd have precise rates of exchange between objectives i and j). If $c = 0$ then the second tradeoff for the pair (i, j) is irrelevant.

Table 3: Impact of the quality of the random tradeoffs on bi-objective influence diagrams. Time limit 20 minutes.

Table 2 reports the results obtained with algorithms ELIM-MOID and ELIM-MOID-TOF, respectively. For each problem class $\langle C, D, O\rangle$ we generated 10 random instances, and for each problem instance we generated 10 sets of random tradeoff vectors using the parameters K, T, a, b, c indicated in the header of each horizontal block. As before, the columns labeled by # show how many problems out of 10 (respectively, out of 100) were solved by ELIM-MOID (respectively, ELIM-MOID-TOF). Overall, we notice that the expected utility sets computed by ELIM-MOID-TOF are orders of magnitude smaller than the corresponding Pareto optimal ones generated by ELIM-MOID. We also see that the median size is even smaller, in some cases being actually 1 indicating that the tradeoffs generated were strong enough to make $\succeq_\Theta$ fairly close to being a total order.

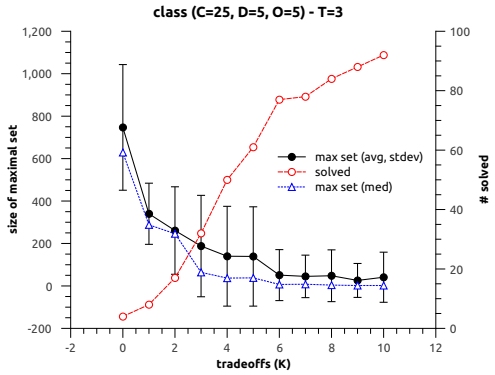

Figure 4: Distribution (mean, stdev, median) of the size of maximal utility sets as a function of pairwise tradeoffs K and fixed 3-way tradeoffs ($T = 3$). We also plot the number of instances solved out of 100. Time limit 20 minutes.

In Table 3 we take a closer look at the impact of the tradeoffs strength for bi-objective problems with 5 decisions. We see that even exploiting a single tradeoff (i.e., using $c = 0$ for two objective case) has a dramatic impact on the size of the maximal expected utility set. For example, on problem class $\langle 55, 5, 2\rangle$, the undominated set of expected utility values computed by ELIM-MOID-TOF contains on average 38 times fewer utility values than the corresponding Pareto optimal set generated by ELIM-MOID.

Figure 4 shows the distribution (mean, standard deviation and median) of the size of the maximal sets generated by ELIM-MOID-TOF on problems from class $\langle 25, 5, 5\rangle$ as a function of the number of pairwise tradeoffs K. As more tradeoffs become available the number of problem instances solved increases because the $\succeq_\Theta$-dominance gets stronger and therefore it reduces the undominated utility sets significantly.

7 CONCLUSION

In this paper, we describe how a variable elimination solution method for influence diagrams is extended to the case of multi-objective utility. A general problem with using the Pareto ordering for multi-objective utility is that the set of maximal expected utility values will often become extremely large. We show how the use of ϵ-coverings can lead to a much more practical computational approach than the exact computation.

We also define a natural way of taking imprecise tradeoffs into account, and give a computational method for checking the resulting dominance condition. Our experimental results indicate that the resulting maximal (multi-objective) values of expected utility can be very much reduced by the adding of (even a small number of) tradeoffs.

Unsupervised Joint Alignment and Clustering using Bayesian Nonparametrics

Marwan A. Mattar **Allen R. Hanson** **Erik G. Learned-Miller**

Abstract

Joint alignment of a collection of functions is the process of independently transforming the functions so that they appear more similar to each other. Typically, such unsupervised alignment algorithms fail when presented with complex data sets arising from multiple modalities or make restrictive assumptions about the form of the functions or transformations, limiting their generality. We present a transformed Bayesian infinite mixture model that can simultaneously align and cluster a data set. Our model and associated learning scheme offer two key advantages: the optimal number of clusters is determined in a data-driven fashion through the use of a Dirichlet process prior, and it can accommodate any transformation function parameterized by a continuous parameter vector. As a result, it is applicable to a wide range of data types, and transformation functions. We present positive results on synthetic two-dimensional data, on a set of one-dimensional curves, and on various image data sets, showing large improvements over previous work. We discuss several variations of the model and conclude with directions for future work.

1 Introduction

Joint alignment is the process in which data points are transformed to appear more similar to each other, based on a criterion of joint similarity. The purpose of alignment is typically to remove unwanted variability in a data set, by allowing the transformations that reduce that variability. This process is widely applicable in a variety of domains. For example, removing temporal variability in event related potentials allows psychologists to better localize brain responses [32], removing bias in magnetic resonance images [21] provides doctors with cleaner images for their analyses, and removing (affine) spatial variability in images of objects can improve the performance of joint compression [9] and recognition [15] algorithms. Specifically, it has been found that using an aligned version of the Labeled Faces in the Wild [16] data set significantly increases recognition performance [5], even for algorithms that explicitly handle misalignments. Aside from bringing data into correspondence, the process of alignment can be used for other scenarios. For example, if the data are similar up to known transformations, joint alignment can remove this variability and, in the process, recover the underlying latent data [23]. Also, the resulting transformations from alignment have been used to build classifiers using a single training example [21] and learn sprites in videos [17].

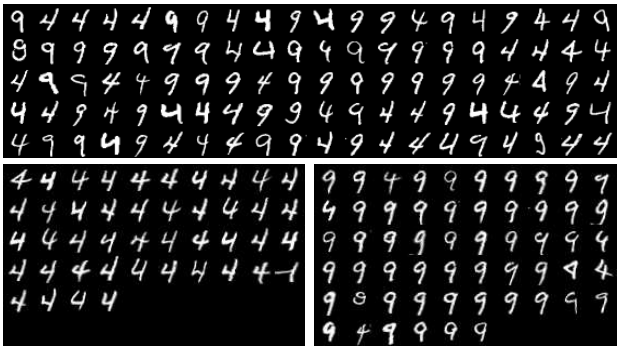

Figure 1: Joint alignment and clustering: given 100 unlabeled images (top), without any other information, our algorithm (§ 3) chooses to represent the data with two clusters, *aligns* the images and *clusters* them as shown (bottom). Our clustering accuracy is 94%, compared to 54% with K-means using two clusters (using the minimum error across 200 random restarts). Our model is not limited to affine transformations or images.

1.1 Previous Work

Typically what distinguishes joint alignment algorithms are the assumptions they make about the data to be aligned

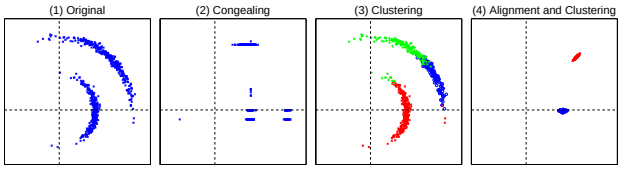

Figure 2: Illustrative example. (1) shows a data set of 2D points. The set of allowable transformations is rotations around the origin. (2) shows the result of the congealing algorithm which transforms points to minimize the sum of the marginal entropies. This independence assumption in the entropy computation causes the points to be squeezed into axis aligned groups. (3) highlights that clustering alone with an infinite mixture model may result in a larger number of clusters. (4) shows the result of the model presented in this paper. It discovers two clusters and aligns the points in each cluster correctly. This result is very close to the ideal one, which would have created tighter clusters.

and the transformations they can incur along with the level of supervision needed. Supervision takes several forms and can range from manually selecting landmarks to be aligned [5] to providing examples of data transformations [28]. In this paper we focus on unsupervised joint alignment which is helpful in scenarios where supervision is not practical or available. Several such algorithms exist.

In the curve domain, the *continuous profile model* [23] uses a variant of the hidden Markov model to locally transform each observation, while a mixture of regression model appended with global scale and translation transformations can simultaneously align and cluster [12]. Mattar *et al*. [25] adapted the *congealing* framework [21] to one dimensional curves. Congealing is an alignment framework that makes few assumptions about the data and allows the use of continuous transformations. It is a gradient-descent optimization procedure that searches for the transformations parameters that maximize the probability of the data under a kernel density estimate. Maximizing the likelihood is achieved by minimizing the entropy of the transformed data. It was initially applied to binary images of digits, but has since also been extended to grayscale images of complex objects [15] and 3D brain volumes [33]. Additionally, several congealing variants [31, 30, 6] have been presented that can improve its performance on binary images of digits and simple grayscale images of faces. Also in the image domain, the transformed mixture of Gaussians [11] and the work of Lui *et al*. [24] are used to align and cluster.

One of the attractive properties of congealing is a clear separation between the transformation operator and optimization procedure. This has allowed congealing to be applied to a wide range of data types and transformation functions [1, 15, 21, 22, 25, 33]. Its main drawback is its inability to handle complex data sets that may contain multiple modes (i.e. images of the digits 1 and 7). While congealing's use of an entropy-based objective function can in theory allow it to align multiple modes, in practice the independence assumption (temporally for curves and spatially for images) can cause it to collapse modes (see Figure 2 for an illustration). Additionally, its method for regularizing parameters to avoid excessive transformations is *ad hoc* and does not prevent it from annihilating the data (shrinking to size zero) in some scenarios.

1.2 Our Approach

The problem we address here is joint alignment of a data set that may contain multiple groups or clusters. Previous nonparametric alignment algorithms (e.g. congealing [21]) typically fail to acknowledge the multi-modality of the data set resulting in poor performance on complex data sets. We address this by simultaneously aligning and clustering [11, 12, 24] the data set. As we will show (and illustrated in Figure 2), solving both alignment and clustering together offers many advantages over clustering the data set first and then aligning the points in each cluster.

To this end, we developed a nonparametric[1] Bayesian joint alignment and clustering model that is a generalization of the standard Bayesian infinite mixture model. Our model possesses many of the favorable characteristics of congealing, while overcoming its drawbacks. More specifically, it:

- Explicitly clusters the data which provides a mechanism for handling complex data sets. Furthermore, the use of a Dirichlet process prior enables learning the number of clusters in a data-driven fashion.
- Can use any generic transformation function parameterized by a vector. This decouples our model from the specific transformations which allows us to plug in different functions for different data types.
- Enables the encoding of prior beliefs regarding the degree of variability in the data set, as well as regularizes the transformation parameters in a principled way by treating them as random variables.

We first present a Bayesian joint alignment model (§ 2) that assumes a unimodal data set (i.e. only one cluster). This model is a special case of our proposed joint alignment and clustering model that we introduce in § 3. We then discuss several variations of our model in § 4 and conclude in § 5 with directions for future work.

1.3 Problem Definition

We are provided with a data set $\mathbf{x} = \{x_i\}_{i=1}^{N}$ of N items and a transformation function, $x_i = \tau(y_i, \rho_i)$ parameter-

[1]Here, we use the term nonparametric to imply that the number of model parameters can grow (a property of the infinite mixtures), and not that the distributions are not parametric.

ized by ρ_i. Our objective is to recover the set of transformation parameters $\{\rho_i\}_{i=1}^N$, such that the aligned data set $\{y_i = \tau(x_i, \rho_i^{-1})\}_{i=1}^N$ is more coherent. In the process, we also learn a clustering assignment $\{z_i\}_{i=1}^N$ of the data points. Here ρ_i^{-1} is defined as the parameter vector generating the inverse of the transformation that would be generated by the parameter vector ρ (i.e. $x_i = \tau(\tau(x_i, \rho_i^{-1}), \rho_i)$).

2 Bayesian Joint Alignment

The Bayesian alignment (BA) model assumes a unimodal data set (in § 3 this assumption is relaxed). Consequently there is a single set of parameters (θ and ρ) that generate the entire data set (see Figure 3). Under this model, every observed data item, x_i, is generated by transforming a canonical data item, y_i, with transformation, ρ_i. More formally, $x_i = \tau(y_i, \rho_i)$, where $y_i \sim F_D(\theta)$ and $\rho_i \sim F_T(\varphi)$. The auxiliary variable y_i is not shown in the graphical model for simplicity. Given the Bayesian setting, the parameters θ and φ are random variables, with their respective prior distributions, $H_D(\lambda)$ and $H_T(\alpha)$.[2]

The model does not assume that there exists a single perfect canonical example that explains all the data, but uses a parametric distribution $F_D(\theta)$ to generate a slightly different canonical example, y_i, for each data item, x_i. This enables it to explain variability in the data set that may not be captured with the transformation function alone. The model treats the transformation function as a black-box operation, making it applicable to a wide range of data types (e.g. curves, images, and 3D MRI scans), as long as an appropriate transformation function is specified.

For both this model and the full joint alignment and clustering model introduced in the next section we use exponential family distributions for $F_D(\theta)$ and $F_T(\varphi)$ and their respective conjugate priors for $H_T(\alpha)$ and $H_D(\lambda)$. This allows us to use Rao-Blackwellized sampling schemes [4] by analytically integrating out the model parameters and caching sufficient statistics for efficient likelihood computations. Furthermore, the hyperparameters now play intuitive roles where they act as a pseudo data set and are easier to set or learn from data.

2.1 Learning

Given a data set $\{x_i\}_{i=1}^N$ we wish to learn the parameters of this model ($\{\rho_i\}_{i=1}^N$, θ, φ). We use a Rao-Blackwellized Gibbs sampler that integrates out the model parameters, θ and φ, and only samples the hidden variables, $\{\rho_i\}_{i=1}^N$. Such samplers typically speed-up convergence. The intuition is that the model parameters are implicitly updated with the sampling of every transformation parameter instead of once per Gibbs iteration. The resulting Gibbs sampler only iterates over the transformation parameters:

$$\begin{aligned}
\forall_{i=1:N}\ \rho_i^{(t)} &\sim p(\rho_i|\mathbf{x}, \boldsymbol{\rho}_{-i}^{(t)}, \alpha, \lambda) \\
&\propto p(\rho_i, x_i|\mathbf{x}_{-i}, \boldsymbol{\rho}_{-i}^{(t)}, \alpha, \lambda) \\
&= p(x_i|\rho_i, \mathbf{x}_{-i}, \boldsymbol{\rho}_{-i}^{(t)}, \lambda) p(\rho_i|\boldsymbol{\rho}_{-i}^{(t)}, \alpha) \\
&= p(y_i|\mathbf{y}_{-i}^{(t)}, \lambda) p(\rho_i|\boldsymbol{\rho}_{-i}^{(t)}, \alpha),
\end{aligned}$$

where $y_i = \tau(x_i, \rho_i^{-1})$. The t superscript in the above equations refers to the Gibbs iteration number.

Sampling ρ_i is complicated by the fact that $p(y_i|\mathbf{y}_{-i}^{(t)}, \lambda)$ depends on the transformation function. Previous alignment research [21, 24], has shown that the gradient of an alignment objective function with respect to the transformations provides a strong indicator for how alignment should proceed. One option would be Hamiltonian Monte Carlo sampling [26] which uses the gradient as a drift factor to influence sampling. However, instead of relying on direct sampling techniques, we use approximations based on the posterior mode [13]. Such an approach is more direct since it is expected that the distribution will be tightly concentrated around the mode. Thus, at each iteration the transformation parameter is updated as follows:

$$\rho_i = \arg\max_{\rho_i} p(y_i|\mathbf{y}_{-i}^{(t)}, \lambda) p(\rho_i|\boldsymbol{\rho}_{-i}^{(t)}, \alpha).$$

Interestingly, the same learning scheme can be derived using the incremental variant [27] of hard-EM.

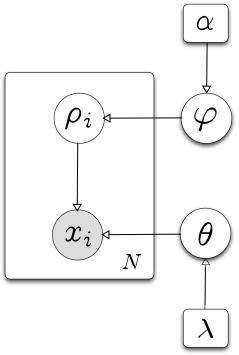

Figure 3: Graphical representation for our proposed Bayesian alignment model (§ 2).

2.2 Model Characteristics

The objective function optimized in our model contains two key terms, a data term, $p(\mathbf{x}|\boldsymbol{\rho}, \theta)$, and a transformation term, $p(\boldsymbol{\rho}|\varphi)$. The latter acts as a regularizer to penalize large transformations and prevent the data from being annihilated. One advantage of our model is that large transformations are penalized in a principled fashion. More specifically, the cost of a transformation, ρ_i is based on the

[2] Here we assume that the hyperparameters α and λ are fixed, but they can be learned or sampled if necessary.

Figure 4: Top row. Means before alignment. Bottom row. Means after alignment with BA. The averages of pixelwise entropies are as follows. Before: 0.3 (top), with congealing: 0.23 (not shown), and with BA: 0.21 (bottom).

learned parameter φ which depends on the transformations of all the other data items, $\boldsymbol{\rho}_{-i}$, and the hyperparameters, α. Learning φ from the data is a more effective means for assigning costs than handpicking them.

The model has several other favorable qualities. It is efficient, can operate on large data sets while maintaining a low memory footprint, allows continuous transformations, regularizes transformations in a principled way, is applicable to a large variety of data types, and its hyperparameters are intuitive to set. Its main drawback is the assumption of a unimodal data set, which we remedy in § 3. We first evaluate this model on digit and curve alignment.

2.3 Experiments

Digits. We selected 50 images of every digit from the MNIST data set and performed alignment on each digit class independently. The mean images before and after alignment are presented in Figure 4. We allowed 7 affine image transformations: scaling, shearing, rotating and translation. $F_D(\theta)$ is the product of independent Bernoulli distributions, one for each pixel location, and $F_T(\varphi)$ is a $7-$D zero mean diagonal Gaussian. For comparison, we also ran the congealing algorithm (see Figure 4).

Curves. We generated 85 curve data sets in a manner similar to curve congealing [25], where we took five original curves from the UCR repository [18] and for each one generated 17 data sets, each containing 50 random variations of the original curve. We used the same transformation function in curve congealing [25], which allows non-linear time warping (4 parameters), non-linear amplitude scaling (8 parameters), linear amplitude scaling (1 parameter), and amplitude translation (1 parameter). $F_D(\theta)$ was set to a diagonal Gaussian distribution (i.e. we treat the raw curves as a random vector), and $F_T(\varphi)$ was a $14-$D zero mean diagonal Gaussian. Again, we compared against the curve congealing algorithm. We computed a standard deviation score by summing the standard deviation at each time step of the final alignment produced by both algorithms. Figure 5 shows a scatter plot of these scores obtained by congealing and BA for all 85 data sets, as well as sample alignment results on two difficult cases. As the figure shows, the curve data sets can be quiet complex.

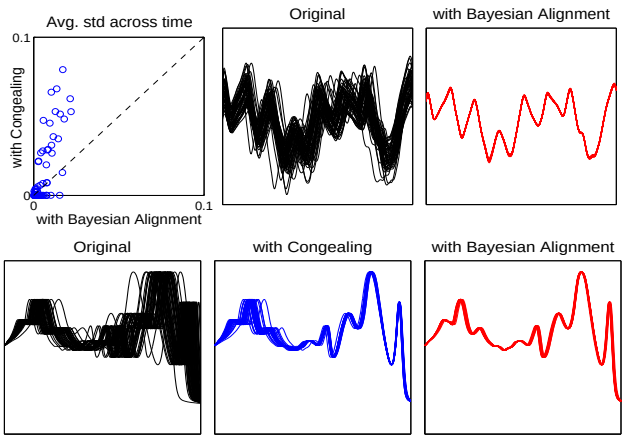

Figure 5: Top row. Left: scatter plot of the standard deviation score (see text) of congealing and the Bayesian alignment algorithm across the 85 synthetic curve data sets. Middle: An example of a difficult data set. Right: The alignment result of the difficult data set. The bottom row shows an example where BA outperformed congealing.

Discussion. On the digits data sets, BA performed at least as well as congealing for every digit class and on average performed better. On the curves data sets, BA does substantially better than congealing in many cases, but in some cases congealing does slightly better. In all the experiments, both congealing and BA converged. BA's advantage is largely due to its explicit regularization of transformations which enables it to perform a maximization at each iteration. Congealing's lack of such regularization requires it to take small steps at each iteration making it more susceptible to local optima. Furthermore, congealing typically requires five times the number of iterations to converge.

3 Clustering with Dirichlet Processes

We now extend the BA model introduced in the previous section to explicitly cluster the data points. This provides a mechanism for handling complex data sets that may contain multiple groups.

The major drawback of the BA model is that a single pair of data and transformation parameters (θ and φ, respectively) generate the entire data set. One natural extension to this generative process is to assume that we have several such parameter pairs (finite but unknown a priori) and each data point samples its parameter pair. By virtue of points sampling the same parameter pair, they are assigned to the same group or cluster. A Dirichlet process (DP) provides precisely this construction and serves as the prior for the data and transformation parameter pairs.

A DP essentially provides a distribution over distributions, or, more formally, a distribution on random probability

measures. It is parameterized by a base measure and a concentration parameter. A draw from a DP generates a finite set of samples from the base measure (the concentration parameter controls the number of samples). A key advantage of DP's is that the number of unique parameters (i.e. clusters) can grow and adapt to each data set depending on its size and characteristics. Under this new probability model, data points are generated in the following way:

1. Sample from the DP, $G \sim DP(\gamma, H_\alpha \times H_\lambda)$. γ is the concentration parameter, and H_α and H_λ are the base measures for $F_T(\varphi)$ and $F_D(\theta)$ respectively.

2. For each data point, x_i, sample a data and transformation parameter pair, $(\theta_i, \varphi_i) \sim G$.

3. Sample a transformation and canonical data item from their distributions, $y_i \sim F_D(\theta_i)$ and $\rho_i \sim F_T(\varphi_i)$.

4. Transform the canonical data item to generate the observed sample, $x_i = \tau(y_i, \rho_i)$.

Figure 6 depicts the generative process as described above (distributional form, right) and in the more traditional graphical representation with the cluster random variable, z, and mixture weights, π, made explicit (left).

Our model can thus be seen as an extension of the standard Bayesian infinite mixture model where we introduced an additional latent variable, ρ_i, for each data point to represent its transformation. Several existing alignment models [11, 12, 21, 23] can be viewed as similar extensions to other standard generative models. Sometimes the transformations are applied to other model parameters instead of data points as in the case of transformed Dirichlet processes (TDP) [29]. TDP is an extension of *hierarchical Dirichlet processes* where global mixture components are transformed before being reused in each group. The challenge in introducing additional latent variables is in designing efficient learning schemes that can accommodate this increase in model complexity.

3.1 Learning

We consider two different learning schemes for this model. The **first** is a blocked, Rao-Blackwellized Gibbs sampler, where we sample both the cluster assignment z_i, and transformation parameters ρ_i, simultaneously:

$$\begin{aligned}(z_i^{(t)}, \rho_i^{(t)}) &\sim p(z_i, \rho_i | \mathbf{z}_{-i}^{(t)}, \boldsymbol{\rho}_{-i}^{(t)}, \mathbf{x}, \gamma, \alpha, \lambda) \\ &\propto p(z_i | \mathbf{z}_{-i}^{(t)}, \gamma) p(\rho_i | \boldsymbol{\rho}_{-i}^{(t)}, \alpha) p(y_i | \mathbf{y}_{-i}^{(t)}, \lambda).\end{aligned}$$

As with the BA model, we approximate $p(\rho_i | \boldsymbol{\rho}_{-i}^{(t)}, \alpha) p(y_i | \mathbf{y}_{-i}^{(t)}, \lambda)$ with a point estimate based on its mode. Consequently this learning scheme is a direct generalization of the one derived for the BA model. Note

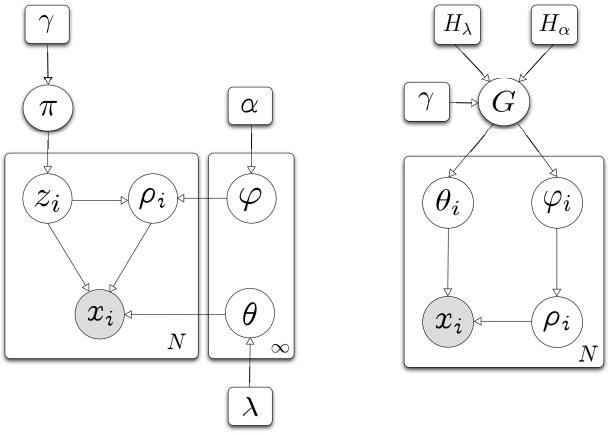

Figure 6: Graphical representation for our proposed nonparametric Bayesian joint alignment and clustering model (left) and its corresponding distributional form (right).

that $p(z_i | \mathbf{z}_{-i}^{(t)}, \gamma)$ is the cluster predictive distribution based on the Chinese restaurant process (CRP) [2].

While this sampler is effective (it produced the positive result in Figure 1) it scales linearly with the number of clusters and computing the most likely transformation for a cluster is an expensive operation. We designed an alternative sampling scheme that does not require the expensive mode computation and whose running time is independent of the number of clusters.

The **second** sampler further integrates out the transformation parameter, and only samples the cluster assignment. We now derive an implementation for this sampler.

$$\begin{aligned}\forall_{i=1:N} \; z_i^{(t)} &\sim p(z_i \,|\, \mathbf{z}_{-i}^{(t)}, \mathbf{x}, \gamma, \alpha, \lambda) \\ &\propto p(z_i, x_i \,|\, \mathbf{z}_{-i}^{(t)}, \mathbf{x}_{-i}, \gamma, \alpha, \lambda) \\ &= p(z_i \,|\, \mathbf{z}_{-i}^{(t)}, \gamma) p(x_i \,|\, \mathbf{z}^{(t)}, \mathbf{x}_{-i}, \alpha, \lambda).\end{aligned}$$

$$\begin{aligned}&p(x_i \,|\, \mathbf{z}, \mathbf{x}_{-i}, \alpha, \lambda) \\ &= \int_{\boldsymbol{\theta}} \int_{\boldsymbol{\varphi}} \int_{\rho_i} p(x_i, \rho_i, \boldsymbol{\theta}, \boldsymbol{\varphi} \,|\, \mathbf{z}, \mathbf{x}_{-i}, \alpha, \lambda) \; d\rho_i \; d\boldsymbol{\varphi} \; d\boldsymbol{\theta} \\ &= \int_{\boldsymbol{\theta}} \int_{\boldsymbol{\varphi}} \left(\int_{\rho_i} p(x_i, \rho_i \,|\, z_i, \boldsymbol{\theta}, \boldsymbol{\varphi}, \alpha, \lambda) \; d\rho_i \right) \cdots \\ &\quad p(\boldsymbol{\theta}, \boldsymbol{\varphi} \,|\, \mathbf{z}_{-i}, \mathbf{x}_{-i}, \alpha, \lambda) \; d\boldsymbol{\varphi} \; d\boldsymbol{\theta} \\ &\overset{(1)}{\approx} \int_{\rho_i} p(x_i, \rho_i \,|\, z_i, \hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\varphi}}, \alpha, \lambda) \; d\rho_i, \\ &\quad \textit{s.t.} \;\; (\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\varphi}}) = \arg\max_{\boldsymbol{\theta}, \boldsymbol{\varphi}} p(\boldsymbol{\theta}, \boldsymbol{\varphi} \,|\, \mathbf{z}_{-i}, \mathbf{x}_{-i}, \alpha, \lambda) \\ &= \int_{\rho_i} p(\rho_i \,|\, \hat{\boldsymbol{\varphi}}, z_i, \alpha) p(x_i \,|\, \rho_i, z_i, \hat{\boldsymbol{\theta}}, \lambda) \; d\rho_i \\ &= \int_{\rho_i} p(\rho_i \,|\, \hat{\varphi}_{z_i}, \alpha) p(x_i \,|\, \rho_i, \hat{\theta}_{z_i}, \lambda) \; d\rho_i\end{aligned}$$

$$\overset{(2)}{\approx} \quad \frac{\sum_{l=1}^{L} w_i \cdot p(x_i \mid \hat{\rho_i}^l, \hat{\theta}_{z_i}, \lambda)}{\sum_{l=1}^{L} w_i}$$

$$\text{s.t. } \{\hat{\rho_i}^l\}_{l=1}^{L} \sim q(\rho), \qquad w_i = \frac{p(\hat{\rho_i}^l \mid \hat{\varphi}_{z_i}, \alpha)}{q(\hat{\rho_i}^l)}$$

(1) approximates the posterior distribution of the parameters by its mode. The mode is computed using incremental hard-EM. Furthermore, the mode can be computed for each cluster's parameters independently. For every other data point j, perform an EM update:

$$\text{E:} \quad \hat{\rho}_j = \arg\max_{\rho_j} p(\rho_j \mid x_j, \hat{\theta}_{z_j}, \hat{\varphi}_{z_j}) = \arg\max_{\rho_j} p(\rho_j \mid \hat{\varphi}_{z_j}) p(x_j \mid \rho_j, \hat{\theta}_{z_j})$$

$$\text{M:} \quad \hat{\theta}_{z_j} = \arg\max_{\theta} p(\theta, \mid \{x_k, \rho_k \mid z_k = z_j\}, \lambda)$$
$$\hat{\varphi}_{z_j} = \arg\max_{\varphi} p(\varphi \mid \{\rho_k \mid z_k = z_j\}, \alpha)$$

(2) uses importance sampling in order to reduce the number of data transformations that need to be performed. Computing $p(x_i \mid \hat{\rho_i}^l, \hat{\theta}_{z_i}, \lambda)$ requires transforming the data point, which is the most computationally expensive single operation for this sampler. Thus it would be wise to reuse the samples, $\{\hat{\rho_i}^l\}_{l=1}^{L}$, across different clusters. We achieve this through importance sampling, which proceeds by sampling a set of transformation parameters from a proposal distribution, $q(\rho)$ and using those samples for all the clusters by reweighting them differently for each cluster. This is a large computational saving since the number of data transformation operations performed in a single iteration of this sampler is now independent of the number of clusters. Furthermore, the quality of approximation is controlled by the number of samples, L, generated.

To further increase the efficiency of the sampler, we approximate the maximization in the E-step by reusing the samples and selecting the one that maximizes $p(\rho_j \mid x_j, \hat{\theta}_{z_j}, \hat{\varphi}_{z_j})$. This avoids the direct maximization operation in the E-step which can be expensive. While not adopted in this work, further computational gains might be achieved at the expense of memory by storing and reusing samples (i.e. transformed data points) across iterations and reweighting them accordingly.

Thus our sampler iterates over every point in the data set, samples a cluster assignment and then updates $\hat{\theta}$ and $\hat{\varphi}$ for the sampled cluster. It also updates its own transformation parameter, $\hat{\rho}_i$ in the process.

Summary. We presented two samplers for our joint alignment and clustering model. Both samplers work well in practice, but the second is more efficient. For both samplers, every iteration begins by randomly permuting the order of the points and the DP concentration parameter is resampled using auxiliary variable methods [10]. As in the BA model, we cache the sufficient statistics for every cluster which can be updated efficiently as points are reassigned to clusters to allow for efficient likelihood and mode computation.

3.2 Incorporating Labelled Examples

The model presented in the previous section was used without any supervision. Supervision here refers to the ground-truth labels for some of the data points or the correct number of clusters. However, there are many scenarios where this information is available and would be advantageous to incorporate.

It is straightforward to modify the joint alignment and clustering model to accommodate such labelled examples. Lets assume we have positive examples for each cluster as well as a large data set of unlabeled examples. Before attempting to align and cluster the unlabeled examples, we would initialize several clusters and assign the positive examples to their respective clusters. By assigning these examples to their clusters and updating the sufficient statistics accordingly, the cluster parameters have incorporated the positive examples. Depending on the strength of the priors (i.e. the hyperparameters) and the number of positive examples per cluster it may be necessary to add the positive examples several times. The stronger the prior, the more times the positive examples need to be replicated. Note that replicating the positive examples does not increase memory usage since we only store the sufficient statistics for each cluster.

If the labelled portion contains positive examples for all the clusters, then setting the concentration parameter of the DP to 0 would prevent additional, potentially unnecessary, clusters from being created.

3.3 Experiment: Alignment and Clustering of Digits

We evaluated our unsupervised and semi-supervised models on two challenging data sets. The first contains 100 images of the digits "4" and "9", which are the two most similar and confusing digit classes (the performance of KMeans on this data set is close to random guessing). The second contains the 200 images of all 10 digit classes used by Liu *et al*. [24].[3] For the second data set we used the Histogram of Oriented Gradients (HOG) feature representation [7] used by Liu *et al*. to enable a fair comparison.

For both digit data sets we compared several algorithms using the same two metrics reported by Lui *et al*.: *alignment*

[3] Liu *et al*. also evaluated their model on 6 Caltech-256 categories and the CEAS face data set. For both data sets they randomly selected 20 images from each category. We found that the difficulty of a data set varied greatly from one sample to another, so we reached out to the authors. Unfortunately, they were only able to provide us with the digits data set which we do use. The digits data set was the most difficult of the three.

Algorithm	Digits 4 and 9 (Fig 1)		All 10 digits (Fig 7)	
	Alignment	Clustering	Alignment	Clustering
KMeans	$4.18\ (1.57) \pm 0.031$	54.0%	$4.88\ (1.61) \pm 0.033$	62.5%
Infinite mixture model [10]	$3.64\ (1.34) \pm 0.036$	$86.0\%, 4$	$4.87\ (1.64) \pm 0.037$	$69.5\%, 13$
Congealing [21]	$2.11\ (0.93) \pm 0.019$	83.0%	$3.51\ (1.34) \pm 0.029$	70.5%
TIC [11]	–	–	$6.00\ (1.1)$	35.5%
Unsupervised SAC [24]	–	–	$3.80\ (0.9)$	56.5%
Semi-supervised SAC [24]	–	–	not reported	73.7%

Table 1: Joint alignment and clustering of images. The left subtable refers to the first digit data set comprising 100 images containing the digits "4" and "9" (Figure 1), while the right subtable refers to the second data set comprising 200 images containing all 10 digits (the same data set used by Liu *et al*. [24], Figure 7). The alignment score columns contain three metrics that adhere to the following template: mean (standard deviation) $\pm$ standard error. The number following the clustering accuracy in the "Infinite mixture model" and "Unsupervised JAC" rows is the number of clusters that the model discovered (i.e. chose to represent the data with). On both data sets, our models significantly outperforms previous nonparametric alignment [21], joint alignment and clustering [11, 24], and nonparametric Bayesian clustering [10] models.

score measures the distance between pairs of aligned images assigned to the same cluster (we report the mean and standard deviation of all the distances, and the standard error[4]), and *clustering accuracy* is the Rand index with respect to the correct labels.

Table 1 summarizes the results on the models we evaluated:

- KMeans: we clustered the digits into the correct number of ground-truth classes (2 for the first data set, and 10 for the second) using the best of 200 KMeans runs.
- Infinite mixture model: removing the transformation/alignment component of our model reduces it to a standard Bayesian infinite mixture model. We ran this model to evaluate the advantage of joint alignment and clustering.
- Congealing: we ran congealing on all the images simultaneously and after alignment converged, clustered the aligned images using KMeans (with the correct number of ground-truth clusters). This allows us to evaluate the advantages of simultaneous alignment and clustering over alignment followed by clustering.
- TIC, USAC and SSAC results are listed exactly as reported by Liu *et al*.
- Unsupervised JAC refers to our full nonparametric Bayesian alignment and clustering model (§ 3.1).
- Semi-supervised JAC refers to the semi-supervised variant of our alignment and clustering model (§ 3.2). We used a *single* positive example for each digit and set the DP concentration parameter to 0.

[4]The standard error here is defined as the sample standard deviation divided by the square root of the number of pairs.

Note that the alignment scores for KMeans and the infinite mixture model are not relevant since no alignment takes place in either of these two algorithms. They are only included to offer a reference for the alignment score when the data is not transformed.

As the results show, our models outperform previous work with respect to both alignment and clustering quality. We make three observations about these results:

1. Our unsupervised model outperformed the unsupervised model of Liu *et al*. by 30.5%, and our semi-supervised model outperformed their semi-supervised model by 8.8%. This is in addition to the significant improvement in alignment quality.
2. Our unsupervised model improved upon the standard infinite mixture model in terms of alignment quality, clustering accuracy, and correctness of the discovered number of clusters.
3. The number of clusters discovered by our unsupervised model is quite accurate. For the first data set the model discovered the correct number of clusters (see Figure 1), and for the second it needed two additional clusters (see Figure 7).

These positive results validate our joint alignment and clustering models and associated learning schemes. Furthermore, it provides evidence for the advantage of solving both alignment and clustering problems simultaneously instead of independently.

3.4 Experiment: Alignment and Clustering of Curves

We now present joint alignment and clustering results on a challenging curve data set of ECG heart data [19] that is

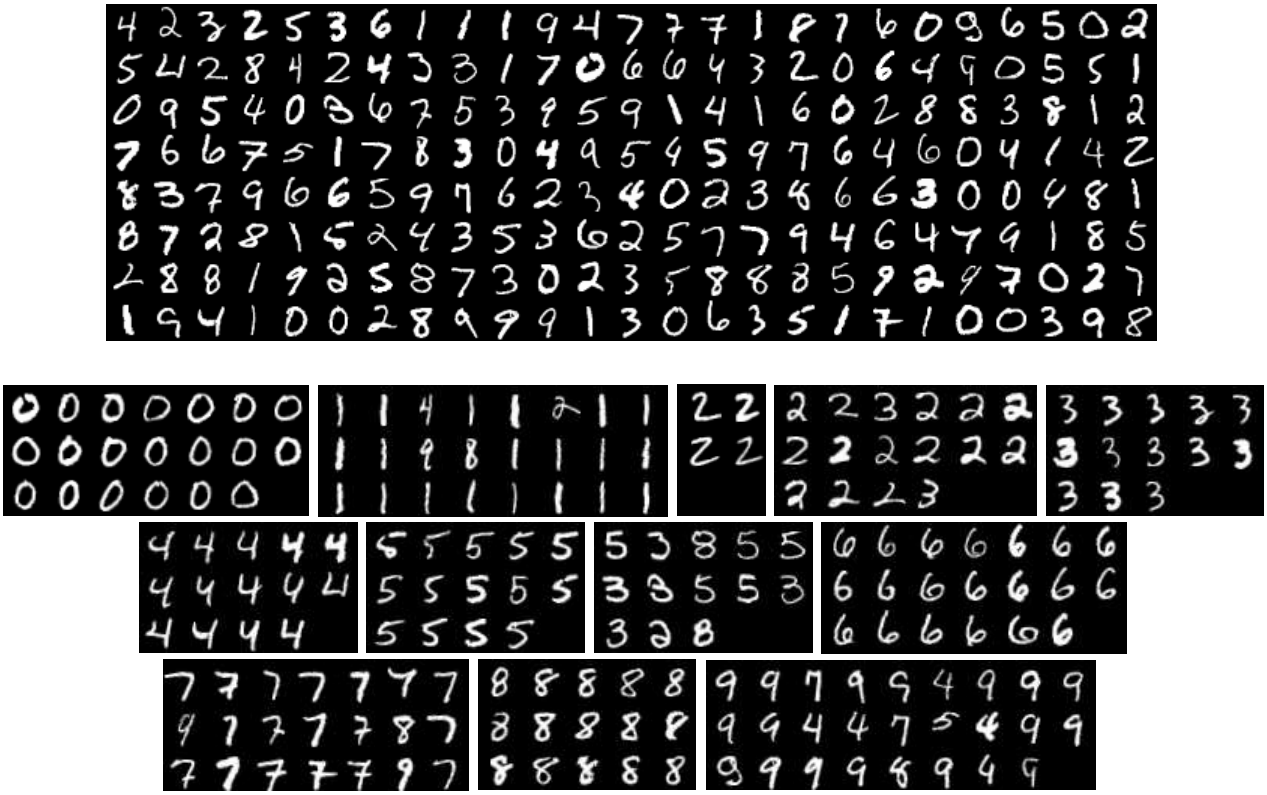

Figure 7: Unsupervised joint alignment and clustering of 200 images of all 10 digits. (Top) All 200 images provided to our model. (Bottom) The 12 clusters discovered and their alignments.

helpful in identifying the heart condition of patients. This data set contains 46 curves. 24 represent a normal heartbeat, and 22 represent an abnormal heartbeat. We ran both congealing and our nonparametric Bayesian joint alignment and clustering model. In both cases we excluded the non-linear scaling in amplitude transformation since the amplitudes of the curves are helpful in classifying whether the curve is normal or abnormal.

Our model discovered 5 clusters in the data set resulting in a clustering accuracy of 84.8%. Inspecting the clusters discovered by our model in Figure 8 highlights the fact that although the data set represents two groups (normal and abnormal), the curves do not naturally fall into two clusters and more are needed to explain the data appropriately. Figure 8 also displays the result of congealing the curves. Clustering the congealed curves into 2 clusters using the best of 200 KMeans runs results in a clustering accuracy of 71.7%. Clustering the congealed curves into 5 clusters in a similar manner results in a clustering accuracy of 76.1%.

The large improvement in clustering accuracy over congealing in addition to a much cleaner alignment result (Figure 8) highlights the importance of explicit clustering when presented with a complex data set. Furthermore it showcases our models ability to perform equally well on both image and curve data sets.

4 Discussions

In this section we discuss the adaptation of our joint alignment and clustering model to both online (when the data arrives at intervals) and distributed (when multiple processors are available) settings. Both of these adaptations are applicable to the unsupervised and semi-supervised settings.

4.1 Online Learning

There are several scenarios where online alignment and clustering may be helpful. Consider for instance a very large data set that cannot fit in memory or the case where the data set is not available up front but arrives over an extended period of time (such as in a tracking application).

An advantage of our model that has not yet been raised is its ability to easily adapt to an online setting where only a portion of the data set is available in the beginning. This is due to our use of conjugate priors and distributions in the exponential family which enable us to efficiently summarize an entire cluster through its sufficient statistics. Consequently, we can align/cluster the initial portion of the data set and save out the sufficient statistics for every cluster after each iteration (for both the data and transformations). Then as new data arrives, we can load in the sufficient statistics and use them to guide the alignment and clustering of the new

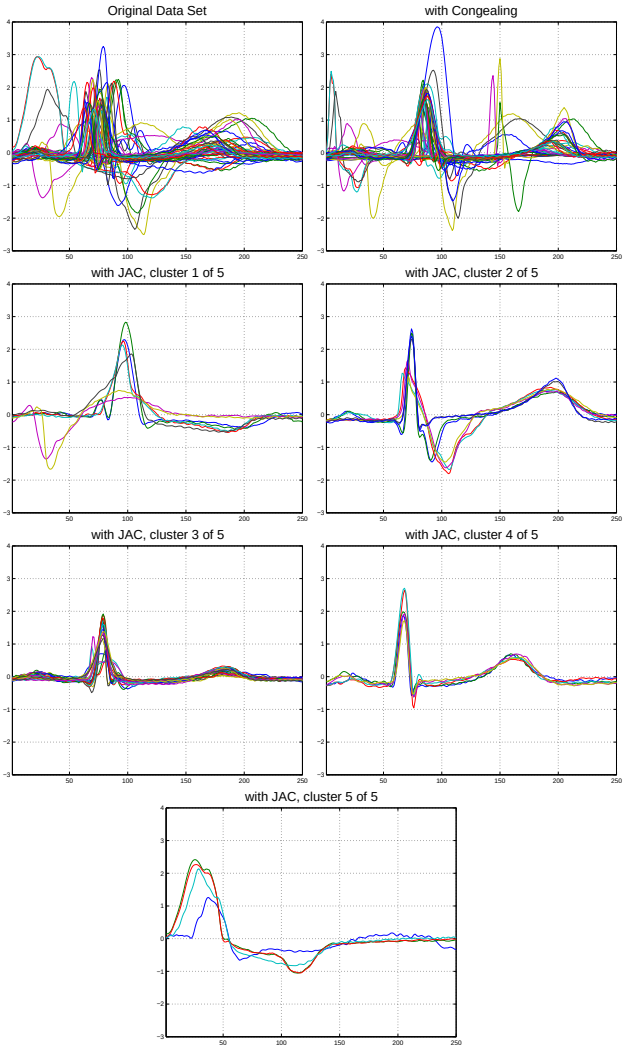

Figure 8: Joint alignment and clustering of ECG heart data. The first row displays the original data set (left) and the result of congealing (right). The last three rows display the 5 clusters discovered by our model.

data in lieu of the original data set which can now be discarded.

Given a sufficiently large initial data set, the alignment of a new data point using the procedure described above would be nearly identical to the result had that data point been included in the original set. This is true since the addition of a single point to an already large data set would have a negligible effect on the sufficient statistics. This process is also applicable to the Bayesian alignment model.

4.2 Distributed Learning

We now describe how to adapt our sampling scheme to a distributed setting using the MapReduce [8] framework. This facilitates scaling our model to large data sets in the presence of many processors. The key difference between the MapReduce implementation and the one described in § 3.1 is that the cluster parameters are updated once per sampling iteration instead of after each point's reassignment (i.e. using a standard sampler instead of a Rao-Blackwellized sampler).

A MapReduce framework involves two key steps, Map and Reduce. For our model the mapper would handle updating the transformation parameter and clustering assignment of a single data point, while the reducer would handle updating the parameters of a single cluster. More specifically, the input to each Map operation would be a data point along with a snapshot of the model parameters (the set of sufficient statistics that summarize the data set). The Map would output the updated cluster assignment and transformation parameter for that data point. The input to the Reduce step would then be all the data points that were assigned to a specific cluster (i.e. we would have a Reduce operation for every cluster created). The Reducer would then update the cluster parameters. Thus each sampling iteration is composed of a Map and Reduce stage.

5 Conclusion

We presented a nonparametric Bayesian joint alignment and clustering model that has been successfully applied to curve and image data sets. The model outperforms congealing and yields impressive gains in clustering accuracy over infinite mixture models. These results highlight the advantage of solving both alignment and clustering tasks simultaneously.

A strength of our model is the separation of the transformation function and sampling scheme, which makes it applicable to a wide range of data types, feature representations, and transformation functions. In this paper we presented results on three data types (2D points, 1D curves, and images), three transformation functions (point rotations, nonlinear curve transformations and affine image transformations), and two feature representations (identity and HOG).

In the future we foresee our model applied to a wide array of problems. Since curves are a natural representation for object boundaries [18], one of our goals is to apply our model to shape matching. We also intend to explore alternative parameter learning schemes based on variational inference [3, 20, 14].

Abstract

We describe 北斎 Hokusai, a real time system which is able to capture frequency information for streams of arbitrary sequences of symbols. The algorithm uses the Count-Min sketch as its basis and exploits the fact that sketching is linear. It provides real time statistics of arbitrary events, e.g. streams of queries as a function of time. We use a factorizing approximation to provide point estimates at arbitrary (time, item) combinations. Queries can be answered in constant time.

1 Introduction

Obtaining frequency information of data streams is an important problem in the analysis of sequence data. Much work exists describing how to obtain highly efficient frequency counts of sequences at any given time. For instance, the Count-Min [6] sketch is capable of providing ϵ accuracy with failure probability δ in $O(\log \delta/\epsilon)$ space. Even better guarantees are possible for the space-saver sketch [12], albeit at the expense of having to keep a dictionary of tokens and a considerably more computationally expensive data structure (we need an ordered list rather than just a flat array in memory). The key point is that sketching algorithms can be queried at any time to return the total number of symbols of any given type seen so far.

While highly desirable in its own right it does not solve the following: we would like to know how many symbols were observed at some time in the past. For instance, we may want to know how many queries of "Britney Spears" were carried out, say at noontime last year on Easter Sunday. Clearly we could address this problem by brute force, that is by pre-processing the logfiles. Query languages such as Pig [14] are well suited to generating such summary statistics, albeit unable to retrieve it in *real time*.

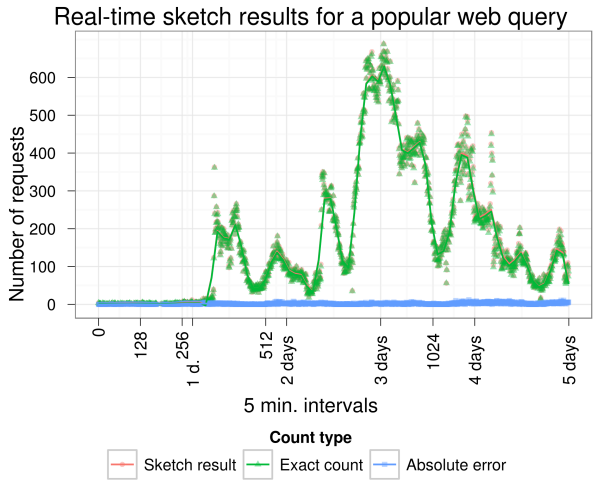

Figure 1: Real-time results for the item aggregation sketch and web query (*"gigi goyette"*) that was popular at the time of our study. Points represent actual results; lines are LOESS smoothed with span 0.1. The plot shows the exact time query started to gain popularity and peaked, as well as daily fluctuations of search traffic. Estimate and real traffic are virtually indistinguishable and the error is minimal.

It is the latter that we focus on in this paper. We present an algorithm capable of retrieving *approximate* count statistics in real time for any given point or interval in time without the need to peruse the original data. We will see that the work required for retrieving such statistics is $O(\log t)$ for lookup and $O(t)$ for decoding (here t is the length of the requested sequence) and moreover that the answers are exact under the assumption of statistical independence. Experiments show that even if this assumption is violated, as it typically is in practice, the statistics still match closely the exact data. We use a number of blocks:

- The Count-Min sketch serves as the basic data aggregator. This is desirable since it has the property of being linear in the data stream. That is, if we sketch time periods T and T', then the sketch

of $T \cup T'$ is given by the sum over the two individual sketches. This makes it easy to aggregate time intervals which are powers of 2.
- We exploit the fact that the Count-Min sketch is linear in the resolution of the hash function. That is, a sketch using a lower resolution hash function is obtained by aggregating adjacent bins.
- We use the fact that for independent random variables the joint distribution can be characterized exactly by retaining only the marginals.
- We use a Markovian approximation for sequences.

Our implementation stores Count-Min sketches of both increasing time intervals in powers of 2, e.g. 1, 2, 4, 8, ... minutes length. Moreover we also store sketches of decreasing bit resolution. Finally, in order to accelerate computation, we store sketches which have both decreasing time and bit resolution. This provides a suitable normalization.

Outline. We begin by giving a brief overview over the Count-Min sketch [6] and how it can be parallelized and made fault tolerant. In Section 3 we describe the data structures used to aggregate the data in a linear fashion and show how reduction in the bit resolution of the hash function allows us to compute both time and keyspace marginals. Using approximate independence assumptions we can recover higher (time, item) resolution of the sketch over time. In Section 4 we apply sketches to $O(1)$ probability estimates in the context of probabilistic graphical models. Section 5 contains experimental results.

2 Count-Min Sketch

Algorithms for sketches of data streams aim at obtaining count statistics for observed items as they keep on arriving in an online fashion. That is, such algorithms typically allow one to assess how many items of a given kind are contained in the data stream. One of the most exciting algorithms for this purpose is the Count-Min sketch of [6], a generalization of the Bloom filter [3] and the count sketch [5], which generates linear data summaries *without* requiring storage of the keys. That is, the maximum amount of memory is allocated for storing count statistics rather than an auxiliary index.

Denote by $\mathcal{X}$ the domain of symbols in the data stream. The Count-Min sketch allocates a matrix of counters $M \in \mathbb{R}^{d \times n}$ initially all set to zero. Moreover, we require d pairwise independent hash functions $h_1, \ldots, h_d : \mathcal{X} \to \{0, \ldots n-1\}$. For each item insertion d counters, as determined by the hash functions and the key, are incremented. Retrieval works by taking the minimum of the associated counts (this mitigates errors due to collisions). Algorithm 1 comes with surprisingly strong guarantees. In particular [6] proves:

Algorithm 1 Count-Min Sketch

insert(x)**:**
for $i = 1$ **to** d **do**
  $M[i, h_i(x)] \leftarrow M[i, h_i(x)] + 1$
end for

query(x)**:**
$c = \min \{M[i, h_i(x)] \text{ for all } 1 \le i \le d\}$
return c

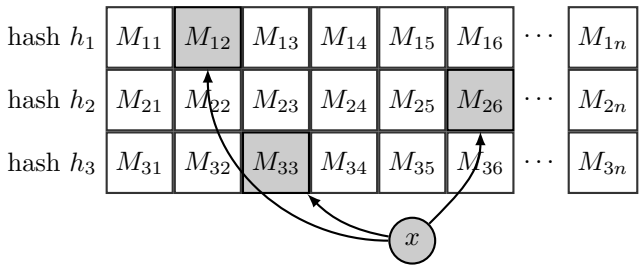

Figure 2: Item x is inserted into each row of the Count-Min sketch (positions 2, 6, and 3 respectively).

Theorem 1 *Assume that* $n = \lceil \frac{e}{\epsilon} \rceil$ *and* $d = \lceil \log \frac{1}{\delta} \rceil$. *Then with probability at least* $1 - \delta$ *the Count-Min sketch returns at any time an estimate* c_x *of the true count* n_x *for any* x *which satisfies*

$$n_x \le c_x \le n_x + \epsilon \sum_{x'} n_{x'}. \tag{1}$$

That is, the guarantee (1) is simply an additive bound on the deviation of counts. Tighter estimates can be obtained from M by using an iterative procedure which goes beyond Algorithm 1. In particular, the Counter Braid iteration [11] provides guarantees of exact reconstruction with high probability provided that the number of stored symbols is sufficiently small and sufficiently well distributed. Note that reconstruction using [11] requires linear time, hence it is not applicable to our scenario of high throughput sketches. Furthermore, whenever the item distribution follows a power law, a tighter bound is available [7]. The following two corollaries are immediate consequences of the fact that the Count-Min sketch is *linear* in the amount of data and in the amount of memory available.

Corollary 2 *Denote by* M_T *and* $M_{T'}$ *the Count-Min sketches for the data stream observed at time intervals* T *and* T'. *Then whenever* $T \cap T' = \emptyset$ *we have that* $M_{T \cup T'} = M_T + M_{T'}$.

This is analogous to Bloom filter hashes of the union of two sets — one simply takes the OR of both hashes. In our case the Boolean semiring is replaced by the semiring of integers (or real numbers) [4].

Corollary 3 *Assume that $n = 2^b$ for $b \in \mathbb{N}$ and let M_b be the summary obtained by the Count-Min sketch. In this case the summary M_{b-1} obtained by a sketch $M_{b-1}[i,j] = M_b[i,j] + M_b[i, j+2^{b-1}]$ using hash functions $h_i^{b-1}(x) := h_i^b(x) \mod 2^{b-1}$.*

This is simply 'folding over' the first and second half of the Count-Min sketch on itself. These two corollaries mean that it is possible to increase the time intervals simply by aggregating sketches over shorter sub-intervals. Likewise, we may reduce the accuracy *after the fact* simply by dropping the most significant bits of h. This will become valuable when compressing the Count-Min sketch by reducing either temporal resolution or accuracy. Obviously as a consequence of this compression we double the error incurred by the sketch. The following chapters present algorithms to counteract this effect.

3 Aggregation

We want to obtain information regarding item frequency over an extended period of time. Assume that we are interested in this data at a resolution of 1 minute (the time scale is arbitrary — we just use 1 minute for the sake of concreteness). Even in the case where M might be relatively small (in the order of 1 MB) we would suffer from memory overflow if we wanted to store 2 years (approximately 2^{20} minutes and hence 1 TB of data) in RAM to allow for fast retrieval.[1] Consequently we need to compress data.

3.1 Time Aggregation

One strategy is to perform binary aggregation on the time axis. That is, rather than retaining a 1 minute resolution for 2 years, we only retain a 2^m minute resolution for the last 2^m minutes. The rationale is that old observations have an exponentially decreasing value and consequently it is sufficient to store them at a concomitantly decreased precision. This is achieved by Algorithm 2. The basic idea is to keep aggregates M^i for time intervals of length $\{1, 1, 2, 4, 8, \ldots, 2^m\}$ available. Note that the sequence contains its own cumulative sum, since $1 + \sum_{i=1}^{n-1} 2^i = 2^n$. To update M^i whenever it covers the time span $[2^{i-1}, 2^i - 1]$ it suffices to sum over the terms covering the smaller segments.

Theorem 4 *At t, the sketch M^j contains statistics for the period $[t - \delta, t - \delta - 2^j]$ where $\delta = t \mod 2^j$.*

[1] We could store this data on disk. Many tools exist for offline parallel analytics which complement our approach. However, we are interested in online instant access.

Algorithm 2 Time Aggregation

```
for all m do do
    Initialize Count-Min sketch M^m = 0
end for
Initialize t = 0 and M̄ = 0
while data arrives do
    Aggregate data into sketch M̄ for unit interval
    t ← t + 1 (increment counter)
    for j = 0 to argmax {l where i mod 2^l = 0} do
        T ← M̄ (back up temporary storage)
        M̄ ← M̄ + M^j (increment cumulative sum)
        M^j ← T (new value for M^j)
    end for
    M̄ ← 0 (reset aggregator)
end while
```

Proof The proof proceeds by induction. At time $t = 0$ this condition clearly holds since all counters are empty. Now assume that it holds for time $t > 0$. Denote by $j^* := \operatorname{argmax}\{l \text{ where } i \mod 2^l = 0\}$ the largest exponent of 2 for which t is divisible by 2^{j^*}. This is the last index which will become aggregated.

- For all M^j with $j > j^*$ the condition holds if we increment $t \leftarrow t+1$ since the intervals are shifted by one time step without crossing any power of 2.
- For all M^j with $j \leq j^*$ note that in the `for` loop we update all such counters by cumulative sums covering a consecutive contiguous sequence of shorter intervals via the cumulative sum counter S. In other words, all these intervals start from $t - \delta = 0$ again. ∎

Lemma 5 *The amortized time required to update the statistics is $O(1)$ per time period regardless of T.*

Proof This follows from the fact in 2^{-i} of all time periods we need to do i work. Hence the total amortized workload is $\sum_{i=1}^{\infty} i \cdot 2^{-i} = 2$. ∎

One of the nice side-effects of this procedure is that an "expensive" aggregation step which can involve up to $\log t$ many additions is always followed by a cheap update requiring only a single update (see Figure 3). This means that the update operations may be carried out as background threads in parallel to new updates, as long as they complete their first step within the update time period (this is trivially the case).

3.2 Item Aggregation

An alternative means of aggregating count statistics over time is to retain the full time resolution while

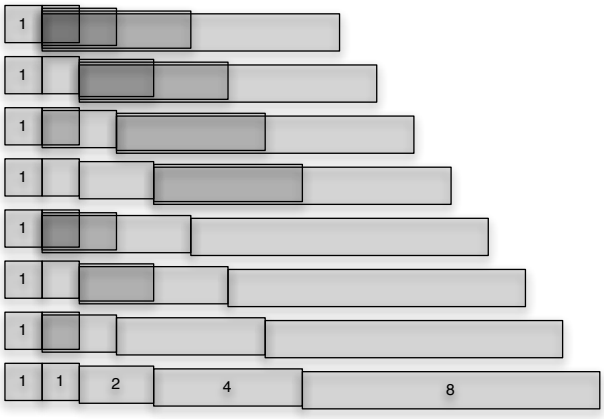

Figure 3: Time aggregation. We always insert into the leftmost aggregation interval. As time proceeds (top to bottom), new intervals are inserted from the left. Whenever an interval of length 2^n is 2^n steps old, it aggregates all data in $[0, 2^n]$ as its new value. The more shaded bins are contained in more than one interval.

sacrificing accuracy. That is, we can shrink the number of bins n over time but we retain the unit time intervals. More specifically, we can halve the resolution each time the Count-Min sketch ages 2^n time steps. One of the advantages of this strategy is that the work required for aggregation is directly proportional to the remaining size of the bins (see Figure 3). We invoke Corollary 3 to halve the amount of space required successively. This yields Algorithm 3.

Algorithm 3 Item Aggregation

$t \leftarrow 0$ (initialize counter)
while data arrives **do**
  Receive aggregated data sketch $\bar{M}$ for unit interval
  $t \leftarrow t + 1$ (increment counter)
  $A^t \leftarrow \bar{M}$
  for $k = 1$ **to** $\lfloor \log_2 t \rfloor$ **do**
    for all i, j **do** (reduce item resolution)
    $A^{t-2^k}[i,j] \leftarrow A^{t-2^k}[i,j] + A^{t-2^k}[i, j + 2^{m-k}]$
    Shrink A^{t-2^k} to length 2^{m-k}
  end for
end while

Note that as before this algorithm requires only $O(1)$ computational cost. Even better than before, this cost is now $O(1)$ for all steps rather than being an amortized (i.e. average) cost: at each time step there is one intervals of size 2^i with $2^i \leq n$ for each i that needs halving. The cost of doing so is bounded by $\sum_{i=0}^{l} 2^i = 2^{l+1} - 1 < 2n$.

Moreover, the amount of storage required per time interval $[t - 2^i, t - 2^{i-1}]$ is constant since for every doubling of the interval size we halve the amount of storage required per sketch. This means that we can retain full temporal resolution, albeit at the expense of increasingly lose bounds on the item counts. In the extreme case where $2^m = n$ we end up with a sketch which tells us simply how many tokens we received at a given point in time but no information whatsoever regarding the type of the tokens.

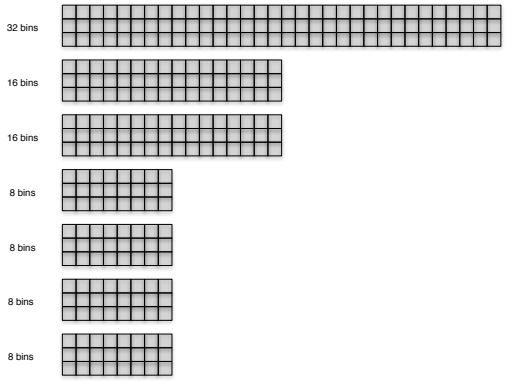

Figure 4: Item aggregation. Every 2^n with $n \in \mathbb{N}$ we halve the amount of bits used in the sketch. This allows us to sketch T time steps in $O(\log T)$ space. Obviously having fewer storage bins means that we have less space available to store fine-grained information regarding the observed keys. However, for heavy hitters this is sufficient.

Note that by default the absolute error also doubles at every aggregation step (the scaling is slightly different for power law distributions). This means that after several iterations the accuracy of the sketch becomes very poor for low-frequency items while still providing good quality for the heavy hitters. We will exploit this as follows — for low frequency items we will use an interpolation estimate whereas for high frequency items we will use the aggregate sketch directly.

3.3 Resolution Extrapolation

We can take advantage of the following observation to improve our estimates: at some point in time we would like to obtain to-the-minute resolution of observations for arbitrary objects. In the extreme case we may have to-the-minute counts for *all* events and simultaneously highly specific counts for a *long* period of time. The basic idea in extrapolating counts is to use the fact that a joint distribution $p(x, t)$ over time and events can be recovered using its marginals $p(x)$ and $p(t)$ whenever x and t are independent of each other. In terms of counts this means that we estimate

$$\hat{n}_{xt} = \frac{n_x \cdot n_t}{n} \text{ where } n = \sum_t n_t = \sum_x n_x. \quad (2)$$

The quantities n_x and n_t are available (as upper bounds) via the Count-Min sketches M^i and A^j respectively. Finally, n *could* be obtained at runtime by carrying out the summation over t or x respectively. However, this is too costly as it requires summing over $O(T)$ bins at time T. Instead, we compute a third set of aggregate statistics simultaneously to Algorithms 2 and 3 which performs both time and item aggregation.

Algorithm 4 Item and Time Aggregation

```
t ← 0 (initialize counter)
while data arrives do
  Wait until item and time aggregation complete
  t ← t + 1 (increment counter)
  S = M^2 (we only start combining at time 2)
  for j = 1 to argmax{l where i mod 2^l = 0} do
    S[i, j] ← S[i, j] + S[i, j + 2^{m−j}]
    Shrink S to length 2^{m−j}
    T ← S (back up temporary storage)
    S ← S + B^j (increment cumulative sum)
    B^j ← T (new value for B^j)
  end for
end while
```

While individual estimates on n_t and n_x would allow for upper bounds via Theorem 1, and likewise a lower bound on n, we only obtain an approximation (we take a ratio between two upper bounds): we use (2) for each hash function separately and perform the `min` operation subsequently. At time T the query for $n(x,t)$ requires:

$$\hat{n}(x,t) := \min_i \frac{M^{\jmath^*}[i, h_i(x)] A^t[i, h_i^{m-\jmath^*}(x)]}{B^{\jmath^*}[i, h_i^{m-\jmath^*}(x)]} \quad (3)$$

$$\text{where } \jmath^* := \lfloor \log_2(T-t) \rfloor$$

We compute $\jmath^*$ as the indicator for the most recent interval containing information pertaining t after we have seen T instants of data. The use of $h^{m-\jmath^*}$ is needed to restrict the key range to the available array. As a consequence we obtain *estimates* of counts at full time and token resolution, albeit at decreasing accuracy as we look further into the past.

Since (3) is only an approximation of the true counts we use it only whenever the Count-Min estimate with reduced bit resolution is not accurate enough. Given that the accuracy decreases with $e2^{-b}$ where 2^b is the number of bins used in the sketch, we have the following variant of the sketching algorithm for queries: use the simplified item aggregate whenever the error is small enough. Otherwise switch to interpolation. Since we know that the absolute error of the Count-Min sketch is well controlled, we know that this strategy is self consistent for frequent items. See Algorithm 5 for details.

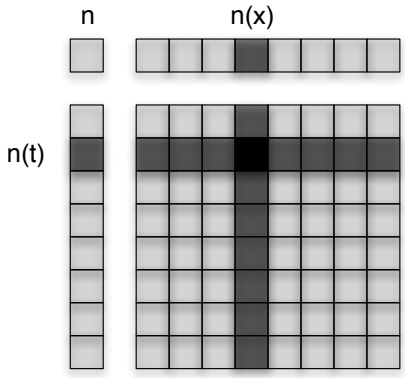

Figure 5: Resolution interpolation. We approximate $n(x,t)$ by $\frac{n(t)n(x)}{n}$ assuming independence, i.e. by approximating $p(a,b) \approx p(a) \cdot p(b)$. This is analogous to density estimation via copulas [13].

Algorithm 5 Improved Interpolating Sketch

```
query(x, t):
Obtain ñ(x, t) := min_i A^t[i, h_i^{m−j*(x)}]
if ñ(x, t) > et/2^b then
  return ñ(x, t) (heavy hitter)
else
  Compute n̂(x, t) using (3).
  return n̂(x, t) (interpolate)
end if
```

4 Beyond Sketches

Often we want to estimate the likelihood of a sequence of symbols, e.g. *probabilistic graphical models*. Unfortunately it is undesirable to insert long sequences directly into the Count-Min sketch. The reason for this is that, as stated in Theorem 1, the error in approximating the counts is an *absolute* error rather than being relative to the key frequency. While this is not a problem for relatively frequently occurring terms (provided that we know that they are frequent), the error may not be acceptable for low probability (and hence infrequently occurring) keys. We resort to tools from undirected graphical models to obtain $O(1)$ estimates for item frequencies of more complex objects.

Cliques For sequences we use a Markovian approximation. That is, we model e.g. trigrams in terms of a product of unigrams or in terms of a chain of bigrams. For concreteness consider modeling the string 'abc':

$$p(abc) \approx p(a) \cdot p(b) \cdot p(c) \quad \text{Unigrams} \quad (4)$$

$$p(abc) \approx p(a,b)p(c|b) = \frac{p(a,b)p(b,c)}{p(b)} \quad \text{Bigrams} \quad (5)$$

Clearly, whenever (4) is exact, it is included in (5) as a special case, since the bigram model subsumes the

unigram representation as a special case. In general we may use the Markov model (4) and (5) as a frequency estimate for items that are too rare to track.

Since we only have access to the item frequencies rather than the true probabilities of occurrence it is advisable to use hierarchical smoothing. While it would be most desirable to use a Dirichlet-process style smoothing along the lines of [16], the latter is too costly to apply in real time as it requires considerably more than $O(1)$ computation. Instead we may resort to a simplified approach like backoff smoothing:

$$\hat{p}(a) = \frac{n_a + n_0}{n + Ln_0} \text{ and } \hat{p}(ab) = \frac{n_{ab} + n_1 \hat{p}(a)\hat{p}(b)}{n + n_1}. \quad (6)$$

Here n_0 and n_1 are parameters which describe the amount of backoff smoothing we employ to estimate the joint as a product of the marginals. More generally, we may use Good-Turing or Kneser-Ney [10] smoothing. Eq. (5) can be extended as follows:

Theorem 6 *Assume that x has an independence structure that can be expressed as an undirected graph $G(V, E)$ in the sense of an undirected graphical model (here V denotes the vertices associated with the coordinates of x and E denotes the edges in the sense of an undirected graphical model). Moreover denote by T a junction tree containing $G(V, E)$ as subgraph with a set of cliques $\mathcal{C}$ and a set of separator sets $\mathcal{S}$, then it suffices if we obtain counts for x_C and x_S with $C \in \mathcal{C}$ and $S \in \mathcal{S}$ to generate frequency estimates via*

$$\hat{p}(x) = n^{|\mathcal{S}|-|\mathcal{C}|} \prod_{C \in \mathcal{C}} n_{x_C} \prod_{S \in \mathcal{S}} n_{x_S}^{-1} \quad (7)$$

Proof This follows immediately from the Hammersley-Clifford Theorem [2], the fact that a junction tree contains the maximum cliques of an undirected graph, and the fact that empirical frequencies converge to their probabilities. ∎

In this view (4) and (5) are simple applications of a Markov chain. It also provides us with a recipe for selecting and generating extrapolation formulae for more complex structures.

Maximum Entropy Estimation A natural choice for estimating joint probabilities from marginals would be to perform a (smoothed) maximum entropy estimate which is then guaranteed to be consistent. However, this is too costly, as it requires at least $O(m)$ operations, where m is the size of the support of the distribution. Such an estimate will lead to

$$p(x|\theta) = \exp\left(\sum_{i=1}^{d} \theta[i, h_i(x)] - g(\theta)\right) \quad (8)$$

This follows directly, e.g. from [8, 1]. The advantage is that after significant computation to obtain θ we can provide more accurate frequency estimates at the same cost as the original Count-Min sketch. Note that the likelihood of the data stream is given by

$$\prod_t p(x_t|\theta) = \exp\left(\operatorname{tr} M^\top \theta - n g(\theta)\right). \quad (9)$$

Unfortunately computing $g(\theta)$ is very costly — it requires that we have access to the support of the distribution, which would require an auxiliary data structure in its own right, thus obviating the advantages afforded by sketches. This is why we do not pursue this avenue further in the present paper.

5 Experiments

5.1 Setup

Code We implemented the Count-Min sketch algorithms 2, 3 and 4 in the client-server setting, using C++ and ICE (http://www.zeroc.com) middleware. The experiments were run on quad core 2GHz Linux x86 servers with 16GB RAM and Gigabit network connection, and used sketches with 4 hash functions, 2^{23} bins, and 2^{11} aggregation intervals (amounting to 7 days in 5 minute intervals). For trigram interpolation, we load Wikipedia into a single 12GB sketch with 3 hash functions, 2^{30} bins, and no time aggregation.

Data We use two datasets for our research. One is a proprietary dataset containing a subset of search queries of five days in May 2011. The second dataset contains the entire textual dump of the English version of Wikipedia as per January 4, 2012 (we removed the XML markup as a preprocessing step). In all cases full statistics of the data were computed using Hadoop. These counts serve as the gold standard for any sketches and allow us to obtain a proper evaluation of the estimated frequency counts.

Our choice of data (see Figure 6) was guided by both the need to build algorithms applicable in an industrial context and by the need to provide reproducible experimental descriptions. Furthermore, both datasets are quite different in terms of the size of their long tail. The smaller query dataset has a very significant component of infrequent terms whereas Wikipedia, largely prose, displays a much lighter tail with a support of only 4.5 Million unique terms.

5.2 Performance

In our experiments all three types of sketches were able to consistently handle over 50k inserts per second. For read requests we measured on average 22k requests per

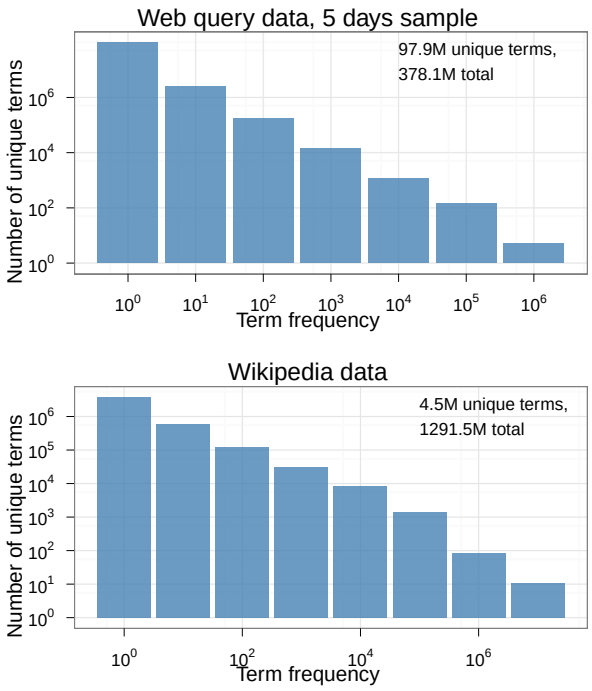

Figure 6: (Top) web query data from 5 days in May 2011; (Bottom) English text in Wikipedia as per January 4, 2012. While both datasets exhibit power-law behavior they differ quite a bit in size and support.

second for time aggregation sketch, and 8,5k requests per second for item aggregation and resolution interpolation. Performance is proportional to the network bandwidth: inserts are one-way, asynchronous, and use very short messages, whereas queries require two-way communication and response messages are larger.

5.3 Accuracy

The first set of experiments is to evaluate the accuracy of the sketches under temporal aggregation. Since the Wikipedia dataset constitutes a snapshot in time we only study the accuracy for the query dataset. The Wikipedia dataset is only used to study interpolation. The experimental protocol is as follows:

Gold Standard For all experiments we computed the true counts using a batch algorithm on Hadoop. It serves as reference for our estimates.
Time aggregation as described in Section 3.1.
Key aggregation as described in Section 3.2.
Interpolation as described in Section 3.3.
Absolute deviation is given by the absolute amount that the sketch deviates from the true counts. In the case of item aggregation sketching estimates are always an overestimate. In all other cases this is not necessarily true. We compute it using $\sum_x |\hat{n}_x - n_x|$.
Relative deviation is given by the ratio between the deviation and the estimate, i.e. $\sum_x \frac{|\hat{n}_x - n_x|}{\hat{n}_x}$. Note that this quantity may exceed 1 since we aggregate over all keys.

We are not aware of any sketching algorithm addressing the problem of providing aggregates for arbitrary time intervals. Hence we compare our results to the exact offline aggregation results. Furthermore, we compare to a naive aggregation per time slice and also to a piecewise constant model. One would expect the latter to perform well, given that we are dealing with time-series data which is unlikely to change dramatically in between intervals.

As can be seen in Figure 7, the interpolation algorithm is well competitive relative to algorithms that perform constant interpolation or that reduce item counts. As expected the error increases with the amount of time past. This is the case since we compress data every 2^n time steps by a factor of 2. The fact that the error of the 'item aggregation' variant is considerably higher than of the 'time aggregation' algorithm suggests that the item frequency does not vary strongly over time for most items, when compared to the variation between items. Hence the relative frequency of occurrence is generally a better estimate. That said, by using interpolation we combine the best of both worlds and obtain overall good estimates.

To obtain a more detailed estimate we stratify accuracy per item frequency interval, i.e. we stratify by the number of occurrences of the item, as depicted in Figure 8. Not very surprisingly for frequent items, reducing the bit resolution of the sketch is less damaging, as follows directly from Theorem 1, hence for heavy hitters interpolation is on par with item aggregation.

5.4 Multigram Interpolation

We show that the factorizing approximation of Section 4 can be used to obtain good estimates of multigrams in both textual documents and query streams. To show that this works for interpolating terms, we approximate trigrams by sketching unigrams and bigrams with a regular Count-Min sketch. We do that in three different ways:

Unigram approximation by consuming unigrams and using (4) to estimate trigram probabilities;
Bigram approximation by consuming bigrams and unigrams and using (5);
Trigram sketching by consuming and querying sketch for trigrams directly.

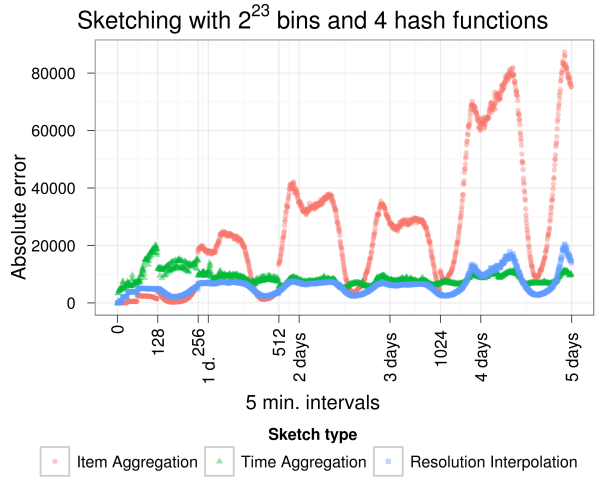

Figure 7: Absolute accuracy $\hat{n} - n$ of three different aggregation algorithms.

	Absolute error	Relative error
Unigram approximation	24977905.97	0.265740
Bigram approximation	1222160.44	0.013002
Trigram sketching	8352974.60	0.088867

Table 1: Absolute and relative deviation of trigram approximation models using Wikipedia data.

Table 1 compares the resulting estimates with exact trigram counts. Note that due to the lower number of collisions, our bigram approximation has less than 15% the error of direct aggregation. This is quite significant since it means that in order to store higher order terms direct sketching may not be quite so desirable (possibly with the exception of storing the heaviest hitters directly). It offers a very fast and cheap means of retrieving estimates relative to exact storage.

6 Discussion

Summary In this paper we presented an algorithm for aggregating statistics on data streams which *retains* temporal information of the items. At its heart we used the Count-Min sketch to obtain a simple yet effective compressed representation of the data. By using time and item aggregation we showed how it is possible to obtain sketches for a more extensive set of query types. Moreover, we showed how the theory of graphical models can be employed to obtain estimates of structured set of covariates.

Our system allows real-time data access in constant time without any need for expensive preprocessing. This makes it an attractive alternative to batch processing systems which, while accurate, are unable to respond to requests without latency and which are therefore less well suited to online data analysis. Experiments demonstrated the excellent performance of the proposed algorithms.

An alternative of our work is to use empirical Laplace transforms to aggregate data. That is, many sketches are amenable to weighted inserts over time. This allows us to obtain sketches of the Laplace-transform counts of a sequence. Decoding then occurs at the client issuing a frequency query to the server. Details of this are the subject of future work.

Extension to Delayed Updates In some cases data may arrive with some delay. Here the Count-Min sketch excels due to the fact that it is a *linear* statistic of the data: We can always insert data later into the appropriate (aged) records at a later stage.

A second (and much more significant) advantage is that the additive property of Corollary 2 also applies to sets. Denote by $S(\mathcal{X})$ the data sketch structure given by Algorithms 2, 3, and 4. In this case $S(\mathcal{X} \cup \mathcal{X}') = S(\mathcal{X}) + S(\mathcal{X}')$. Hence we may use MapReduce to carry out sketches on subsets of the data first and then aggregate the terms between mappers. Since everything is linear once the data has been inserted this exhibits perfect scaling properties.

Note that the issue might arise that different subsets of the data span slightly different time ranges. In this case it is important to ensure that all sketches are synchronized to the same time intervals since otherwise aliasing might occur (e.g. a summary of 1 week's data might start on different days on different machines).

Parallelization Note that the sketches discussed in the present paper are well amenable to parallelization. In fact, we may use consistent hashing [9] to distribute hash functions and keys over a range of workstations. Details of this strategy are described in [15]. In a nutshell the idea is to send keys to several machines, each of which compute only a single row of the matrix M, each of them using a different hash function. The combination of both ideas leads to a powerful enterprise framework for sketching data streams in real time.

Acknowledgments This work was supported by the Australian Research Council. We thank George Varghese for inspiring discussions.

Abstract

Influence diagrams allow for intuitive and yet precise description of complex situations involving decision making under uncertainty. Unfortunately, most of the problems described by influence diagrams are hard to solve. In this paper we discuss the complexity of approximately solving influence diagrams. We do not assume no-forgetting or regularity, which makes the class of problems we address very broad. Remarkably, we show that when both the treewidth and the cardinality of the variables are bounded the problem admits a fully polynomial-time approximation scheme.

1 INTRODUCTION

Influence diagrams are well-known graphical models of decision making under uncertainty which allow for compact and intuitive representation of complex situations, and relatively fast inference [7–9, 17].

Most of the algorithms for inference with influence diagrams require a total ordering over the decisions and unlimited memory. The first assumption is called *regularity* and is graphically equivalent to the existence of a directed path comprising all decision variables in the diagram. The second assumption, called *no-forgetting*, states that decisions are made in light of all previously disclosed information. Graphically, it implies that the parent set of a decision node contains all previous decision nodes and their parents. These conditions allow an optimal solution to be obtained by dynamic programming [19], but impose an inherent exponential worst-case complexity, since the output might include a decision function over exponentially many values (e.g., a table prescribing a value for the last decision for each one of the exponentially many assignments of the other decision variables).

There are two common approaches to avoid the exponential complexity. The first one is to insert arcs entering decision variables in a way that makes them insensitive to the previous decisions, thus decreasing the size needed to represent its corresponding solution [8, 14]. This, however, implies observing quantities that were initially deemed unobservable, which might be undesirable or even unfeasible. The second approach is to relax no-forgetting and work with a limited memory, that is, to assume that not all previous decisions and observations are known and considered when making a decision [10, 13, 20]. Graphically, it corresponds to dropping arcs until the maximum size of a decision function becomes manageable. The latter approach, which gives rise to limited memory influence diagrams [10], is additionally justified by situations where decisions have to be taken independently of one another, as in team decision analysis [1, 6]; for such cases, some of the no-forgetting arcs are inherently absent.

Removing arcs from the original graph can make the problem harder. This essentially occurs because the problem might no longer be solvable by standard dynamic programming approaches. Zhang, Qi, and Poole [21] and more recently Lauritzen and Nilsson [10] determined sufficient conditions under which even influence diagrams that violate no-forgetting can be solved exactly by dynamic programming. Any diagram of bounded treewidth meeting these conditions can be thus solved efficiently. As de Campos and Ji [4] showed, however, even structurally very simple cases can fail to meet these conditions and be hard to solve. In fact, we have recently shown that even singly connected diagrams of treewidth equal to two, with decision variables having no parents and variables taking on a bounded number of states are NP-hard to solve, and that the problem is inapproximable if the cardinality of the variables is unbounded [12].

In this paper, we resume our investigation and analyze the impact of the number of value nodes and

variable cardinality on the theoretical complexity of solving (limited memory) influence diagrams. We do not assume no-forgetting or regularity. We show that if the treewidth is bounded, the number of value variables do not affect the asymptotic complexity. Most importantly, we show that if the cardinalities of the variables are also bounded, the problem admits a fully polynomial-time approximation scheme.

2 INFLUENCE DIAGRAMS

To help introduce the notation and illustrate concepts, consider the following example of a decision problem where an agent first needs to select one among the actions $d_1^{(1)}, \ldots, d_1^{(i)}$, which causes one of $c_1^{(1)}, \ldots, c_1^{(j)}$ outcomes to obtain with probability $P(c_1|d_1)$, and generates a reward of $U(c_1)$. Then, without observing the value c_1, a second agent needs to select one among the actions $d_2^{(1)}, \ldots, d_2^{(k)}$, which generates one of the outcomes $c_2^{(1)}, \ldots, c_2^{(\ell)}$ with probability $P(c_2|c_1, d_2)$ and a reward of $U(c_2)$. The overall utility $U(d_1, c_1, d_2, c_2)$ of the agents' actions their corresponding outcomes is given by the sum of the intermediate rewards, that is, $U(d_1, c_1, d_2, c_2) = U(c_1) + U(c_2)$.

In the language of influence diagrams, the quantities and events of interest are represented by three distinct types of variables. *Chance variables* represent events on which the decision maker has no control, such as outcomes of tests or consequences of actions; *decision variables* represent the alternatives a decision maker has at each decision step; finally, *value variables* are used to represent immediate rewards. In the example, we can represent the decision of the first agent, its outcome, and the corresponding reward by a decision variable D_1, a chance variable C_1 and a value variable V_1, respectively. Similarly, we can represent the second decision, its outcome and the corresponding reward by a decision variable D_2, a chance variable C_2 and a value variable V_2. Regarding the notation, we denote variables by capital letters and identify them with the set of values they can assume; generic and particular values are denoted in lower case. For instance, a generic action of the first agent is represented as $d_1 \in D_1 = \{d_1^{(1)}, \ldots, d_1^{(i)}\}$, while the corresponding set of possible rewards (which depend on the outcome c_1) is given by $V_1 = \{U(c_1^{(1)}), \ldots, U(c_1^{(j)})\}$.

The functional dependencies between the variables in the model can be compactly represented by a directed acyclic graph (DAG) whose nodes are in a one-to-one correspondence to the (decision, chance and value) variables of the problem. For simplicity, we identify nodes with their associated variables. Hence, we can talk about the parents $\mathtt{Pa}(X)$ of a variable X, its children $\mathtt{Ch}(X)$, or yet its family $\mathtt{Fa}(X) = \mathtt{Pa}(X) \cup \{X\}$ of X. The arcs entering decision variables represent the set of variables whose values will be known by the time the corresponding decision is made, either because they are observed at this time (e.g., an outcome of a previous decision or an action taken by a different agent) or remembered (e.g., a previous decision or observation). The problem in the example can be depicted as a DAG in Figure 1 (as usual, chance, decision and value variables are represented by ovals, squares and diamonds, respectively). The existence of the dashed arc connecting D_1 to D_2 depends on whether the decision of the first agent is known by the second agent at the time the latter acts. It is present if the second agent knows (and takes into account) the decision of the first agent, and it is absent otherwise.

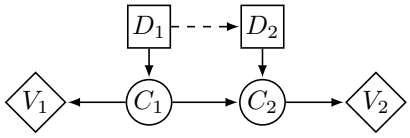

Figure 1: Influence diagram for the problem in the example.

An influence diagram is a tuple $(\mathcal{C}, \mathcal{D}, \mathcal{V}, \mathcal{G}, \mathcal{P}, \mathcal{U})$, where $\mathcal{C}$, $\mathcal{D}$ and $\mathcal{V}$ are the sets of chance, decision and value variables, respectively, $\mathcal{G}$ is a DAG over $\mathcal{C} \cup \mathcal{D} \cup \mathcal{V}$, $\mathcal{P}$ is a set containing one (conditional) probability distribution $P(C|\mathtt{Pa}(C))$ per chance variable C in $\mathcal{C}$, and $\mathcal{U}$ is a set containing one reward function $U(\mathtt{Pa}(V))$ per value variable V. Thus, an influence diagram specifies both a *joint probability distribution* $P(\mathcal{C}|\mathcal{D}) = \prod_{C \in \mathcal{C}} P(C|\mathtt{Pa}(C))$ of the outcomes conditional on the decisions, and a *utility* $U(\mathcal{C}, \mathcal{D}) = \sum_{V \in \mathcal{V}} U(\mathtt{Pa}(V))$ over outcomes and decisions.

2.1 The Strategy Selection Problem

For any decision variable $D \in \mathcal{D}$, a *policy* is a conditional probability distribution $P(D|\mathtt{Pa}(D))$ prescribing a (possibly randomized) action for each state of the parents. We say that a policy $P(D|\mathtt{Pa}(D))$ is *pure* if for every assignment to the parents it assigns all the mass to a single action $d \in D$. A *strategy* is a set $\mathcal{S} = \{P(D|\mathtt{Pa}(D)) : D \in \mathcal{D}\}$ containing a policy for each decision variable. A strategy $\mathcal{S}$ induces a(n unconditional) joint probability distribution over decisions and outcomes by

$$P_{\mathcal{S}}(\mathcal{C}, \mathcal{D}) = P(\mathcal{C}|\mathcal{D}) \prod_{D \in \mathcal{D}} P(D|\mathtt{Pa}(D)) \,,$$

and has an associated expected utility given by

$$\mathrm{E}_{\mathcal{S}} = \sum_{\mathcal{C}, \mathcal{D}} P_{\mathcal{S}}(\mathcal{C}, \mathcal{D}) U(\mathcal{C}, \mathcal{D}) \,.$$

The primary use of an influence diagram is the *strategy selection problem*, which consists in finding a strategy $\mathcal{S}^*$ that maximizes the expected utility, that is, to find $\mathcal{S}^*$ such that $\mathrm{E}_{\mathcal{S}^*} \geq \mathrm{E}_{\mathcal{S}}$ for all $\mathcal{S}$. The value $\mathrm{E}_{\mathcal{S}^*}$ is called the *maximum expected utility* and is denoted shortly by MEU. Most algorithms for finding optimal strategies have complexity at least exponential in the treewidth of the influence diagram, which is a measure of its resemblance to a tree and is better formalized by the notion of tree decomposition.

A *tree decomposition* of an influence diagram is a tree-shaped graph where each node is associated to a subset of the chance and decision variables in the diagram. The decomposition satisfies the *family preserving* and the *running intersection* properties, namely, that the family of each decision and chance variable, as well as the parent set of each value variable, is contained in at least one set associated to a node of the tree, and that the graph obtained by dropping nodes that do not contain any given chance or decision variable is still a tree. The treewidth of a tree decomposition is the maximum number of variables associated to a node minus one. The treewidth of an influence diagram is the minimum treewidth of a tree decomposition of it.

For a fixed integer k, Bodlaender [2] showed that for any diagram one can in linear time either obtain a tree decomposition of treewidth at most k or know that it does not exist. Hence, for any diagram of bounded treewidth we can obtain in linear time an optimal tree decomposition, that is, a tree decomposition whose treewidth equals the treewidth of the diagram. Moreover, any tree decomposition can be turned into a binary tree decomposition (i.e., one in which each node has at most three neighbors) of same treewidth in linear time [18]. Given a tree decomposition $\mathcal{T}$ with m nodes, we denote by $\mathcal{X}_1, \ldots, \mathcal{X}_m$ the sets of variables associated to nodes $1, \ldots, m$, respectively. Thus, $\mathcal{X}_1 \cup \cdots \cup \mathcal{X}_m = \mathcal{C} \cup \mathcal{D}$.

Given an influence diagram, we can evaluate the expected utility of any strategy $\mathcal{S}$ in time and space at most exponential in its treewidth. Hence, if a diagram has bounded treewidth, we can obtain $\mathrm{E}_{\mathcal{S}}$ for any strategy $\mathcal{S}$ in polynomial time [9, Chapter 23]. Obtaining the optimal strategy in this way is however unfeasible for any moderately large problem, as the number of strategies is too high. In fact, de Campos and Ji [4] showed that even in diagrams of bounded treewidth the strategy selection problem is NP-hard. We have recently [12] strengthened their result by showing that the problem is already NP-hard in singly connected diagrams of treewidth equal to two and variables assuming at most three values. The result uses a reduction from the partition problem to a influence diagram whose underlying graph is a tree and contains a single value variable. One might then wonder whether allowing more than one value variable affects the difficulty of the problem. The answer, as the following result shows, is no.

Theorem 1. *For any influence diagram $\mathcal{I}$, there is an influence diagram $\mathcal{I}'$ containing a single value variable such that any strategy $\mathcal{S}$ for $\mathcal{I}$ is also a strategy for $\mathcal{I}'$ and obtains the same expected utility. Moreover, the treewidth of $\mathcal{I}'$ is at most the treewidth of $\mathcal{I}$ plus three.*

Proof. Let $\mathcal{I} = (\mathcal{C}, \mathcal{D}, \mathcal{V}, \mathcal{G}, \mathcal{P}, \mathcal{U})$ be an arbitrary influence diagram and consider, without loss of generality, a binary tree decomposition $\mathcal{T}$ of $\mathcal{I}$ such that for every value variable V_i in $\mathcal{V}$ there is a leaf node in the tree whose associated set of variables is $\mathtt{Pa}(V_i)$.[1] Assume additionally that the tree is rooted at a node r and that the leaf nodes $\ell_1, \ell_2, \ldots, \ell_q$ associated to the sets $\mathtt{Pa}(V_1), \ldots, \mathtt{Pa}(V_q)$, respectively, where $q = |\mathcal{V}|$ denotes the number of value variables, are ordered in such a way that they agree with an *in-order tree traversal* of the tree decomposition, that is, in a depth-first tree traversal of $\mathcal{T}$ rooted at r, the node ℓ_1 precedes ℓ_2, which precedes ℓ_3, and so on. Let $\overline{U}$ and $\underline{U}$ be upper and lower bounds, respectively, on the reward functions in $\mathcal{U}$, with $\overline{U} > \underline{U}$.

Now consider a diagram $\mathcal{I}' = (\mathcal{C}', \mathcal{D}, \{V\}, \mathcal{G}', \mathcal{P}', \{U\})$, which contains a single value variable V instead of the q value variables of $\mathcal{I}$ and an augmented set of chance variables $\mathcal{C}' = \mathcal{C} \cup \{W_1, \ldots, W_q, O_1, \ldots, O_q\}$, where $W_1, \ldots, W_q, O_1, \ldots O_q$ are binary variables. Furthermore, the subgraph of $\mathcal{G}'$ obtained by considering only nodes in $\mathcal{C}$ and $\mathcal{D}$ is identical to $\mathcal{G}$ with the chance variables $W_1, \ldots, W_q$ replacing the value variables $V_1, \ldots, V_q$, respectively. Also, the variables $O_1, \ldots, O_q$ are arranged in a chain such that W_1 is the parent of O_1, W_2 and O_1 are the parents of O_2 and so forth, as in Figure 2(b). Each variable W_i, for $i = 1, \ldots, q$, is associated to a probability distribution $P(W_i|\mathtt{Pa}(V_i))$ such that $P(w_i^{(1)}|\mathtt{Pa}(V_i)) = (U(\mathtt{Pa}(V_i)) - \underline{U})/(\overline{U} - \underline{U})$. Each variable O_i, $i = 1, \ldots, q$, is associated to a probability distribution $P(O_i|O_{i-1}, W_i)$ (we assume $O_0 = \emptyset$) such that $P(o_i^{(1)}|o_{i-1}^{(1)}, w_i^{(1)}) = 1$ and $P(o_i^{(1)}|o_{i-1}^{(1)}, w_i^{(2)}) = (i-1)/i$ and $P(o_i^{(1)}|o_{i-1}^{(2)}, w_i^{(1)}) = 1/i$ and $P(o_i^{(1)}|o_{i-1}^{(2)}, w_i^{(2)}) = 0$ ($P(o_1^{(1)}|w_1^{(1)}) = 1$ and $P(o_1^{(1)}|w_1^{(2)}) = 0$). Finally, the value node V, with O_q as sole parent, is associated to a utility function $U(O_q)$

[1] Any binary tree decomposition can be transformed to meet this requirement by repeatedly selecting a node i associated to a superset of the parents of a value variable V_i not meeting the requirement, and then adding two nodes j and k such that the children of i become children of j, and k is a child of i; the node j is associated to the set of variables associated to i, while k is associated to $\mathtt{Pa}(V_i)$. Note that the treewidth is unaltered by these operations.

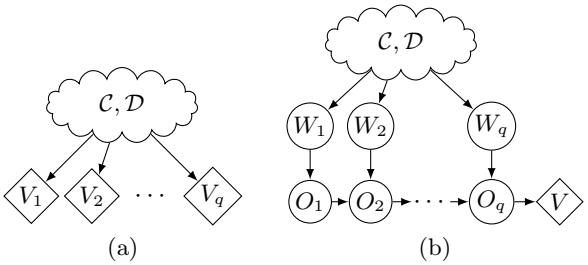

Figure 2: (a) Influence diagram with multiple value variables. (b) Its equivalent influence diagram containing a single variable as used in the proof of Theorem 1.

such that $U(o_q^{(1)}) = q\overline{U}$ and $U(o_q^{(2)}) = q\underline{U}$.

To show that the treewidth of $\mathcal{I}'$ is not greater than the treewidth of $\mathcal{I}$ by more than three, we build a tree decomposition $\mathcal{T}'$ for $\mathcal{I}'$, based on the tree decomposition $\mathcal{T}$, as follows. First, we take each node ℓ_i of $\mathcal{T}$ and include W_i, O_i and O_{i-1} in $\mathcal{X}_i$ (O_{i-1} is included for $i > 1$), which is enough to cover their families and to satisfy the family preserving property. Note that at this stage $\mathcal{T}'$ does not satisfy the running intersection property, because O_{i-1} appears in both ℓ_{i-1} and ℓ_i but not necessarily in every (set associated to a) node in between. Finally, we walk around the tree $\mathcal{T}'$ in a Euler tour tree traversal where each edge is visited exactly twice, and we include O_{i-1} in each node of $\mathcal{T}'$ that appears between ℓ_{i-1} and ℓ_i during the walk.[2] By doing so we guarantee that the running intersection property is also satisfied. Since the Euler tour tree traversal visits each leaf once and each internal node at most three times, the procedure inserts three new variables in the sets associated to $\ell_1, \ldots, \ell_q$ and at most three variables O_i in the sets associated to non-leaf nodes, and therefore does not increase the treewidth of the decomposition by more than three.

It remains to show that the diagrams are equivalent with respect to the expected utility of strategies. Let $\mathcal{S}$ be a strategy for $\mathcal{I}$. Then $\mathcal{S}$ is also a strategy for $\mathcal{I}'$ (because the two diagrams share the same decision variables and graph over $\mathcal{C},\mathcal{D}$). First, we need to show that for $i = 1, \ldots, q$ it follows that

$$P(o_i^{(1)}|\mathcal{C},\mathcal{D}) = \frac{1}{i}\left(\sum_{j=1}^{i} P(w_j^{(1)}|\mathcal{C},\mathcal{D})\right),$$

which we do by induction in i. The basis ($i = 1$) follows trivially, because $P(o_1^{(1)}|w_1^{(1)}) = 1$ by definition, so according to the graph structure we have that $P(o_1^{(1)}|\mathcal{C},\mathcal{D}) = P(w_1^{(1)}|\mathcal{C},\mathcal{D})$. Now assume by hypothesis of the induction that the above result is valid for every $1 \le i \le k < q$. Then $P(o_{k+1}^{(1)}|\mathcal{C},\mathcal{D})$

$$\begin{aligned}
&= P(o_{k+1}^{(1)}|o_k^{(1)}, w_{k+1}^{(1)})P(o_k^{(1)}|\mathcal{C},\mathcal{D})P(w_{k+1}^{(1)}|\mathcal{C},\mathcal{D}) \\
&\quad + P(o_{k+1}^{(1)}|o_k^{(1)}, w_{k+1}^{(2)})P(o_k^{(1)}|\mathcal{C},\mathcal{D})P(w_{k+1}^{(2)}|\mathcal{C},\mathcal{D}) \\
&\quad + P(o_{k+1}^{(1)}|o_k^{(2)}, w_{k+1}^{(1)})P(o_k^{(2)}|\mathcal{C},\mathcal{D})P(w_{k+1}^{(1)}|\mathcal{C},\mathcal{D}) \\
&\quad + P(o_{k+1}^{(1)}|o_k^{(2)}, w_{k+1}^{(2)})P(o_k^{(2)}|\mathcal{C},\mathcal{D})P(w_{k+1}^{(2)}|\mathcal{C},\mathcal{D}) \\
&= \left(\frac{1}{k+1} + \frac{k}{k+1}\right) P(o_k^{(1)}|\mathcal{C},\mathcal{D})P(w_{k+1}^{(1)}|\mathcal{C},\mathcal{D}) + \\
&\quad \left(\frac{k}{k+1}\right) P(o_k^{(1)}|\mathcal{C},\mathcal{D})P(w_{k+1}^{(2)}|\mathcal{C},\mathcal{D}) + \\
&\quad \left(\frac{1}{k+1}\right) P(o_k^{(2)}|\mathcal{C},\mathcal{D})P(w_{k+1}^{(1)}|\mathcal{C},\mathcal{D}) \\
&= \left(\frac{k}{k+1}\right) P(o_k^{(1)}|\mathcal{C},\mathcal{D}) + \frac{1}{k+1} P(w_{k+1}^{(1)}|\mathcal{C},\mathcal{D}) \\
&= \frac{k}{(k+1)}\left(\frac{1}{k}\sum_{j=1}^{k} P(w_j^{(1)}|\mathcal{C},\mathcal{D})\right) + \frac{1}{k+1} P(w_{k+1}^{(1)}|\mathcal{C},\mathcal{D}) \\
&= \frac{1}{k+1}\left(\sum_{j=1}^{k+1} P(w_j^{(1)}|\mathcal{C},\mathcal{D})\right),
\end{aligned}$$

which shows that the result holds also for $i = k + 1$.

We can now show that for any strategy $\mathcal{S}$ the associated expected utility $\mathrm{E}'_{\mathcal{S}}$ in $\mathcal{I}'$ equals the associated expected utility $\mathrm{E}_{\mathcal{S}}$ in $\mathcal{I}$. Let $\mathcal{C}'' = \mathcal{C}' \setminus \{O_q\}$. By definition, $\mathrm{E}'_{\mathcal{S}} = \sum_{\mathcal{C}',\mathcal{D}} P_{\mathcal{S}}(\mathcal{C}',\mathcal{D})U(\mathcal{C}',\mathcal{D}) = \sum_{\mathcal{C}',\mathcal{D}} P_{\mathcal{S}}(\mathcal{C}',\mathcal{D})U(O_q)$, which is equal to

$$\begin{aligned}
&\sum_{\mathcal{C}'',\mathcal{D}} P_{\mathcal{S}}(\mathcal{C}'',\mathcal{D})\left(q\overline{U}P(o_q^{(1)}|\mathcal{C}'',\mathcal{D}) + q\underline{U}P(o_q^{(2)}|\mathcal{C}'',\mathcal{D})\right) \\
&= q\underline{U} + \sum_{\mathcal{C}'',\mathcal{D}} P_{\mathcal{S}}(\mathcal{C}'',\mathcal{D})q(\overline{U} - \underline{U})P(o_q^{(1)}|\mathcal{C}'',\mathcal{D}) \\
&= q\underline{U} + q(\overline{U} - \underline{U})\sum_{\mathcal{C},\mathcal{D}} P_{\mathcal{S}}(\mathcal{C},\mathcal{D})P(o_q^{(1)}|\mathcal{C},\mathcal{D}) \\
&= q\underline{U} + q(\overline{U} - \underline{U})\sum_{\mathcal{C},\mathcal{D}} P_{\mathcal{S}}(\mathcal{C},\mathcal{D})\frac{1}{q}\sum_{i=1}^{q} P(w_i^{(1)}|\mathcal{C},\mathcal{D}) \\
&= q\underline{U} + q\frac{\overline{U} - \underline{U}}{q}\sum_{\mathcal{C},\mathcal{D}} P_{\mathcal{S}}(\mathcal{C},\mathcal{D})\sum_{i=1}^{q} P(w_i^{(1)}|\mathtt{Pa}(V_i)) \\
&= q\underline{U} + (\overline{U} - \underline{U})\sum_{\mathcal{C},\mathcal{D}} P_{\mathcal{S}}(\mathcal{C},\mathcal{D})\sum_{j=1}^{q}\frac{U(\mathtt{Pa}(V_i)) - \underline{U}}{\overline{U} - \underline{U}} \\
&= q\underline{U} + \frac{\overline{U} - \underline{U}}{\overline{U} - \underline{U}}\sum_{\mathcal{C},\mathcal{D}} P_{\mathcal{S}}(\mathcal{C},\mathcal{D})\sum_{i=1}^{q}[U(\mathtt{Pa}(V_i)) - \underline{U}] \\
&= q\underline{U} - q\underline{U} + \sum_{\mathcal{C},\mathcal{D}} P_{\mathcal{S}}(\mathcal{C},\mathcal{D})\sum_{i=1}^{q} U(\mathtt{Pa}(V_i)),
\end{aligned}$$

[2] An Euler tour tree traversal of $\mathcal{T}$ rooted at r is a list of $2m-1$ symbols produced by calling $ET(r)$, where $ET(i)$ is a recursive function that takes a node i with left children j and right children k (if they exist) and prints out i, calls $ET(j)$ (if j exists), prints out i again, calls $ET(k)$ (if k exists), and then prints out i once more.

which is equal to $\sum_{\mathcal{C},\mathcal{D}} P_{\mathcal{S}}(\mathcal{C},\mathcal{D})U(\mathcal{C},\mathcal{D}) = \mathrm{E}_{\mathcal{S}}$. □

Cooper [3] showed that in any influence diagram containing a single value variable the (single) utility function can be re-normalized to take values on the interval $[0, 1]$ without affecting the optimality of the strategies. Together with the above result, this allows us, without loss of generality, to focus exclusively on influence diagrams containing a single value variable taking values on the interval $[0, 1]$.

Under the usual assumptions of complexity theory, when a problem is NP-hard to solve the best available options are (i) trying to devise an algorithm that runs efficiently on many instances but has exponential worst-case complexity, or (ii) trying to develop an approximation algorithm that for all instances provides in polynomial time a solution that is provably within a certain range of the optimal solution. We have investigated option (i) in a recent work [11, 12], and showed empirically that a sophisticate variable elimination algorithm can, in spite of its exponential worst-case complexity, solve a large number of problems in feasible time. In the remainder, we study the theoretical feasibility of option (ii). Given $0 < \epsilon < 1$, we say that a procedure is an *ϵ-approximation* algorithm for the strategy selection problem if for any influence diagram it finds a strategy $\mathcal{S}$ such that $\mathrm{MEU} \leq (1+\epsilon)\,\mathrm{E}_{\mathcal{S}}$. The algorithm is said to be a *fully polynomial-time approximation scheme* if it runs in time polynomial in the input and in $1/\epsilon$ for any given ϵ. The following result implies that without assuming a bounded number of states per variable approximating the strategy selection problem in polynomial time by virtually any reasonable factor is NP-hard, and option (ii) is most likely unfeasible.

Theorem 2 ([12]). *Given a singly connected influence diagram of bounded treewidth, for any $1 < 1 + \epsilon < 2^{\theta}$, there is no polynomial-time ϵ-approximation algorithm unless P=NP, where θ is the number of numerical parameters (i.e., probabilities and rewards) needed to specify the problem.*

The result is obtained by a reduction from the SAT problem, similarly to the proof of inapproximability of MAP in Bayesian networks given by Park and Darwiche [16]. According to the above result, algorithms like SPU [10] or mini-bucket elimination [5], which find a strategy in polynomial time, cannot guarantee that the worst-case ratio between the expected utility of that strategy and the maximum expected utility is greater than $2^{-\theta}$, even if the input is constrained to influence diagrams of bounded treewidth. Since the factor $2^{-\theta}$ quickly approaches zero as the size of the problem increases, efficient algorithms eventually produce very poor solutions. As we show in the rest of the paper, this is no longer true if we assume that both the treewidth of the diagram and the cardinality of the variables are bounded. In this case, we show constructively the existence of a fully polynomial-time approximation scheme.

3 FINDING PROVABLY GOOD STRATEGIES

Our first step in showing the existence of a fully polynomial-time approximation scheme for the strategy selection problem is to devise an algorithm that obtains provably good strategies, that is, an ϵ-approximation scheme which returns, for any $\epsilon > 0$, a strategy $\mathcal{S}$ satisfying $\mathrm{MEU} \leq (1+\epsilon)\,\mathrm{E}_{\mathcal{S}}$. The algorithm (scheme) we devise is a generalization of the MPU algorithm [11, 12] to the case of (provably good) approximate inference in influence diagrams, and it consists in propagating sets of probability potentials over a tree decomposition. The idea behind the propagation of sets of potentials is that the expected utility of each strategy can be computed by propagating a (single) potential over the same tree decomposition, and so the propagated sets account for the simultaneous evaluation of many different strategies. To be efficient, some of these computations are halted early on, so that not every strategy has its expected value computed. The difficulty is in guaranteeing that within the evaluated strategies (i.e., those whose expected values were actually computed) there is at least one which achieves the desired approximation factor $1 + \epsilon$.

Let α be a real value greater than one, and $\mathcal{K}$ be a set of nonnegative functions (called potentials) over a set of variables $\mathcal{X}$. We say that $\mathcal{K}' \subseteq \mathcal{K}$ is a *α-covering* of $\mathcal{K}$ if for every potential $P(\mathcal{X})$ in $\mathcal{K}$ there is $Q(\mathcal{X})$ in $\mathcal{K}'$ such that $P(\mathcal{X}) \leq \alpha Q(\mathcal{X})$. We also define the potential $1(\mathcal{X})$ which returns one for every assignment to the variables in $\mathcal{X}$.

For any decision variable D, let $\mathcal{P}_D$ denote the set of all pure policies for D. Hence, $\mathcal{P}_D$ is a set containing $|D|^{\gamma}$ distributions $P(D|\mathtt{Pa}(D))$, where $|D|$ is the number of values D can assume and $\gamma = \prod_{X \in \mathtt{Pa}(D)} |X|$ is the number of assignments to its parents (i.e., the number of different combinations of values the parent variables can jointly assume).

The procedure in Algorithm 1 takes an influence diagram (which we assume contains a single value variable taking values on $[0, 1]$), a tree decomposition of the diagram, and a nonnegative value ϵ, and computes an expected utility $E_{\mathcal{S}}$ induced by some strategy $\mathcal{S}$ such that $\mathrm{MEU} \leq (1 + \epsilon)E_{\mathcal{S}}$, that is, it is an ϵ-approximation for computing the maximum expected utility. To keep things simple for now, let us assume

Algorithm 1 Finding Provably Good Strategies

Require: A positive number ϵ, an influence diagram $\mathcal{I}$ and a tree decomposition $\mathcal{T}$ with m nodes
Ensure: The value E satisfies MEU $\leq (1+\epsilon)\,\mathrm{E}$
1: // INITIALIZATION
2: let $\alpha = 1 + \epsilon/(2m)$
3: let $\mathcal{K}_1, \ldots, \mathcal{K}_m$ be singletons containing the potentials $1(\mathcal{X}_1), \ldots, 1(\mathcal{X}_m)$, respectively
4: **for each** chance variable C **do**
5: find a node i in $\mathcal{T}$ such that $\mathtt{Fa}(C) \subseteq \mathcal{X}_i$
6: set $\mathcal{K}_i \leftarrow \textsc{Combine}(\mathcal{K}_i, \{P(C|\mathtt{Pa}(C))\})$
7: **end for**
8: **for each** decision variable D **do**
9: find a node i in $\mathcal{T}$ such that $\mathtt{Fa}(D) \subseteq \mathcal{X}_i$
10: set $\mathcal{K}_i \leftarrow \textsc{Combine}(\mathcal{K}_i, \mathcal{P}_D)$
11: **end for**
12: find a node i in $\mathcal{T}$ such that $\mathtt{Pa}(V) \subseteq \mathcal{X}_i$
13: set $\mathcal{K}_i \leftarrow \textsc{Combine}(\mathcal{K}_i, \{U(\mathtt{Pa}(V))\})$
14: // PROPAGATION
15: select a node r as the root of $\mathcal{T}$
16: label all nodes as inactive
17: **while** there is an inactive node i **do**
18: select an inactive node i whose children are all active
19: set $\mathcal{A}_i \leftarrow \textsc{Combine}(\mathcal{K}_i, \mathcal{C}_j : j \in \mathtt{Ch}(i))$
20: set $\mathcal{B}_i \leftarrow \textsc{SumOut}(\mathcal{A}_i, \mathcal{X}_i \setminus \mathcal{X}_{\mathtt{Pa}(i)})$
21: set $\mathcal{C}_i \leftarrow \textsc{Covering}(\mathcal{B}_i, \alpha)$
22: label i as active
23: **end while**
24: let $\mathrm{E} = \max\{\mu : \mu \in \mathcal{C}_r\}$

this is our goal. We will see later on how to modify the algorithm to also provide the strategy $\mathcal{S}$, not only its expected value, and thus devise an ϵ-approximation algorithm for the strategy selection problem.

The algorithm is similar in spirit to the computation of marginal queries in Bayesian networks by junction trees [8], but differs radically in that it stores and propagates sets of probability potentials, instead of storing and propagating single probability potentials. Like junction-tree algorithms for Bayesian networks, the algorithm contains an initialization step, where the sets of probability potentials are assigned to nodes of the tree decomposition, and a propagation step, where messages are sent from the leaves towards the root node. The propagation finishes when the root receives a message from every child, and obtains a set of values $\mathcal{C}_r$ (since $\mathtt{Pa}(r) = \emptyset$, the set $\mathcal{B}_r$ marginalizes out all variables from each potential $P(\mathcal{X}_r)$ in $\mathcal{B}_r$, hence producing real numbers).

The operations Combine and SumOut are analogous to the multiplication and marginalization of probability potentials but operate over sets, that is, the former returns the set of all potentials obtained by pairwise multiplication of the potentials in the sets given as arguments, whereas the latter returns the set obtained by summing out the variables in the second argument from every potential in the first argument. More formally, given a list of sets $\mathcal{K}_1, \ldots, \mathcal{K}_n$ containing potentials over the sets of variables $\mathcal{Y}_1, \ldots, \mathcal{Y}_n$, respectively, we define the Combine operation as $\textsc{Combine}(\mathcal{K}_1, \ldots, \mathcal{K}_n) = \{P(\mathcal{Y}_1) \cdots P(\mathcal{Y}_n) : P(\mathcal{Y}_i) \in \mathcal{K}_i, i = 1, \ldots, n\}$; given a set $\mathcal{K}$ of potentials over the set of variables $\mathcal{Y}$ and a subset $\mathcal{Z} \subseteq \mathcal{Y}$, the SumOut operation is given by $\textsc{SumOut}(\mathcal{K}, \mathcal{Z}) = \{\sum_{\mathcal{Z}} P(\mathcal{Y}) : P(\mathcal{Y}) \in \mathcal{K}\}$. Finally, the Covering operation returns an α-covering for the argument, where $\alpha = 1 + \epsilon/(2m)$ is set according to the approximation factor ϵ and the number of nodes in the tree m. For the moment, let us ignore how α-coverings are actually obtained. We shall get back to this point later on.

The algorithm begins by assigning each probability distribution associated to a chance variable to a node of the tree decomposition. If two or more such functions are assigned to the same node i, the result is a singleton $\mathcal{K}_i$ containing their multiplication. The algorithm then assigns policies to nodes in much a similar way, except that the sets associated to nodes which have been chosen in the second loop are no longer singletons. Finally, the utility function is associated to a node of the tree. For example, if the tree decomposition contained only a single node with all decision and chance variables associated to it, the result of the initialization step would be a single set $\mathcal{K}_1$ containing all joint probability distributions $P_{\mathcal{S}}(\mathcal{C}, \mathcal{D})$ induced by strategies $\mathcal{S}$. On the other hand, if for each (decision, chance and value) variable X there were exactly one node i in the tree such that $\mathtt{Fa}(X) \subseteq \mathcal{X}_i$, then after the initialization step the set $\mathcal{K}_i$, for $i = 1, \ldots, m$, would be equal to the singleton $\{P(X|\mathtt{Pa}(X))\}$, if the node i were associated to the family of a chance variable X, to the singleton $\{U(\mathtt{Pa}(X))\}$, if i were the node associated to the parents of the value variable V, or to the set of policies $\mathcal{P}_X$, if i was associated to the family of a decision variable X.

The propagation step starts by rooting the tree decomposition $\mathcal{T}$ at an arbitrary node r. This allows us to organize the neighbors of a node in the tree as the parent (i.e., the one closer to the root) and the children (the ones farther from the root), and defines a direction for the propagation of messages, which consists in selecting a node i satisfying the condition (which initially only leaves do) and computing the corresponding sets of potentials $\mathcal{A}_i$, $\mathcal{B}_i$ and $\mathcal{C}_i$. The first two are set analogous to the potentials produced during a junction-tree propagation in a Bayesian network. The message set $\mathcal{C}_i$ is obtained by removing elements from

$\mathcal{B}_i$ in a way that satisfies the α-covering condition (we will get back to this). Once all nodes have been processed (including the root), the algorithm produces a solution E by seeking the highest value in the set $\mathcal{C}_r$. To show that this value is indeed the expected utility of a feasible strategy $\mathcal{S}$ such that MEU $\leq (1+\epsilon)\,\mathrm{E}_{\mathcal{S}}$, we need to introduce some additional notation.

For any node i of the tree decomposition, let $\mathcal{T}[i]$ be the subtree rooted at i, that is, the graph obtained by removing all nodes which are not descendants of i or i itself. Let also $\mathcal{X} = \mathcal{X}_1 \cup \cdots \cup \mathcal{X}_m = \mathcal{C} \cup \mathcal{D}$ denote all variables in the tree. We denote by $\mathcal{X}[i]$ the set of all variables associated to the nodes in $\mathcal{T}[i]$, that is, $\mathcal{X}[i] = \bigcup_{j \in \mathcal{T}[i]} \mathcal{X}_j$ (hence $\mathcal{X}_i \subseteq \mathcal{X}[i]$). We define a function $\sigma : \mathcal{X} \to \{1, \ldots, m\}$ that returns for each variable X the node i to which its associated (probability, policy or utility) potential was assigned in the initialization step. Given a node i, the function $U(\mathtt{Pa}(V); i)$ returns the utility function $U(\mathtt{Pa}(V))$ if $\sigma(V) = i$ and one otherwise. Finally, let $\mathcal{Y}_i = \mathcal{X}_i \cap \mathcal{X}_{\mathtt{Pa}(i)}$ be the separator set of i and $\mathtt{Pa}(i)$.

Lemma 3. *The value* E *computed by the procedure in Algorithm 1 is the expected utility* $\mathrm{E}_{\mathcal{S}}$ *associated to some valid strategy* $\mathcal{S}$*.*

Proof. First we show by induction in the nodes from the leaves toward the root that for any node i any potential $P(\mathcal{Y}_i)$ in $\mathcal{B}_i$ or $\mathcal{C}_i$ satisfies

$$P(\mathcal{Y}_i) = \sum_{\mathcal{X}[i] \setminus \mathcal{X}_{\mathtt{Pa}(i)}} \prod_{C : \sigma(C) \in \mathcal{T}[i]} P(C|\mathtt{Pa}(C)) \prod_{D : \sigma(D) \in \mathcal{T}[i]} P(D|\mathtt{Pa}(D)) \prod_{j \in \mathcal{T}[i]} U(\mathtt{Pa}(V); j)$$

for some partial strategy $\{P(D|\mathtt{Pa}(D)) : D \in \mathcal{D}, \sigma(D) \in \mathcal{T}[i]\}$. Consider a leaf node i. Then the induction hypothesis is trivially satisfied by applying the definitions of the Combine and SumOut operations, and noting that $\mathcal{T}[i]$ contains only the node i. Now consider an internal node i and assume that for every child j of i the induction hypothesis holds. Then for any $P(\mathcal{Y}_i)$ in $\mathcal{B}_i$ or in $\mathcal{C}_i$ it follows that $P(\mathcal{Y}_i)$

$$= \sum_{\mathcal{X}_i \setminus \mathcal{X}_{\mathtt{Pa}(i)}} \prod_{C : \sigma(C) = i} P(C|\mathtt{Pa}(C)) \prod_{D : \sigma(D) = i} P(D|\mathtt{Pa}(D)) \; U(\mathtt{Pa}(V); i) \prod_{j \in \mathtt{Ch}(i)} P(\mathcal{Y}_j)$$

$$= \sum_{\mathcal{X}[i] \setminus \mathcal{X}_{\mathtt{Pa}(i)}} \prod_{C : \sigma(C) \in \mathcal{T}[i]} P(C|\mathtt{Pa}(C)) \prod_{D : \sigma(D) \in \mathcal{T}[i]} P(D|\mathtt{Pa}(D)) \prod_{j \in \mathcal{T}[i]} U(\mathtt{Pa}(V); j)\,,$$

which satisfies the induction hypothesis. The result of the lemma is thus obtained by applying the induction result to the root node r. For any $\mu \in \mathcal{C}_r$ we have that

$$\mu = \sum_{\mathcal{X}} \prod_{C} P(C|\mathtt{Pa}(C)) \prod_{D} P(D|\mathtt{Pa}(D)) U(\mathtt{Pa}(V))$$

for some strategy $S = \{P(D|\mathtt{Pa}(D))\}$. □

Theorem 4. *The value* E *satisfies* MEU $\leq (1+\epsilon)\,\mathrm{E}$.

Proof. Let $S^* = \{P^*(D|\mathtt{Pa}(D)) : D \in \mathcal{D}\}$ denote an optimal strategy. We first show by induction from the leaves toward the root that for any node i there is a $P(\mathcal{Y}_i) \in \mathcal{C}_i$ such that $P^*(\mathcal{Y}_i) \leq \alpha^{s_i} P(\mathcal{Y}_i)$, where

$$P^*(\mathcal{Y}_i) = \sum_{\mathcal{X}[i] \setminus \mathcal{X}_{\mathtt{Pa}(i)}} \prod_{C : \sigma(C) \in \mathcal{T}[i]} P(C|\mathtt{Pa}(C)) \prod_{D : \sigma(D) \in \mathcal{T}[i]} P^*(D|\mathtt{Pa}(D)) \prod_{j \in \mathcal{T}[i]} U(\mathtt{Pa}(V); j)\,,$$

and s_i is the number of nodes in $\mathcal{T}[i]$. Consider a leaf node i. Then the induction hypothesis holds since $P^*(\mathcal{Y}_i) \in \mathcal{B}_i$ by design and by definition of α-covering there is $P(\mathcal{Y}_i) \in \mathcal{C}_i$ such that $P^*(\mathcal{Y}_i) \leq \alpha P(\mathcal{Y}_i)$. Assume the induction holds for all children j of a node i. By design, there is $P(\mathcal{Y}_i) \in \mathcal{B}_i$ such that

$$P(\mathcal{Y}_i) = \sum_{\mathcal{X}_i \setminus \mathcal{X}_{\mathtt{Pa}(i)}} \prod_{C : \sigma(C) = i} P(C|\mathtt{Pa}(C)) \prod_{D : \sigma(D) = i} P^*(D|\mathtt{Pa}(D)) U(\mathtt{Pa}(V); i) \prod_{j \in \mathtt{Ch}(i)} P(\mathcal{Y}_j)\,,$$

and by using the inductive hypothesis it follows that $P^*(\mathcal{Y}_i) \leq \alpha^{\sum_{j \in \mathtt{Ch}(i)} s_j} P(\mathcal{Y}_i)$. And since $\mathcal{C}_i$ is an α-covering of $\mathcal{B}_i$, there is $Q(\mathcal{Y}_i) \in \mathcal{C}_i$ such that $P(\mathcal{Y}_i) \leq \alpha Q(\mathcal{Y}_i)$, and thus $P^*(\mathcal{Y}_i) \leq \alpha^{1+\sum_{j \in \mathtt{Ch}(i)} s_j} Q(\mathcal{Y}_i) = \alpha^{s_i} Q(\mathcal{Y}_i)$. Since by Lemma 3, every $\mu \in \mathcal{C}_r$ corresponds to the expected utility of some strategy $\mathcal{S}$, it follows from the induction result on r that there is $\mathrm{E}_{\mathcal{S}} \in \mathcal{C}_r$ such that MEU $\leq \alpha^m\,\mathrm{E}_{\mathcal{S}}$, and since E maximizes over $\mu \in \mathcal{C}_r$, we have that MEU $\leq \alpha^m\,\mathrm{E} = (1 + \epsilon/(2m))^m\,\mathrm{E}$. Finally, it follows from the inequality $(1+2x) \geq (1+x/k)^k$, valid for every positive real $x \leq 1$ and positive integer k, that MEU $\leq (1+\epsilon)\,\mathrm{E}$. □

Recall from Section 2 that for any influence diagram of bounded treewidth we can obtain a binary tree decomposition of minimum treewidth in linear time. Assume, without loss of generality, that such a minimum treewidth binary tree decomposition is given as input to the approximation algorithm, and let ω be the treewidth of the influence diagram given as input and κ be the maximum number of values a decision or chance variable can assume. The complexity of the algorithm is bounded by the complexity of computing a potential $P(\mathcal{Y}_i)$ in a set $\mathcal{B}_i$ times the cardinality of the

largest set $\mathcal{B}_i$ plus the complexity of the initialization step and the complexity of the COVERING operation. Computing a $P(\mathcal{Y}_i)$ requires $2\prod_{X\in\mathcal{X}_i}|X|$ multiplications and $\prod_{X\in\mathcal{X}_i\setminus X_{\mathtt{Pa}(i)}}|X|$ additions, and hence takes $O(\kappa^\omega)$ time, which is polynomial in the cardinality of the (chance and decision) variables (since ω is assumed to be bounded by a constant). The complexity of the initialization step is bounded by the complexity of combining the sets of policies $\mathcal{P}_D$ with the sets $\mathcal{K}_i$ for each decision variable. Each decision variable has at most κ^{κ^ω} policies, which makes this step exponential in κ. Although it is possible to transform the diagram so that the complexity of the initialization step becomes polynomially bounded in κ [12, Prop. 7], we refrain from doing so here because it would make the algorithm more complicated, and it would not change the worst-case running time, which we know from Theorem 2 that cannot be polynomial in κ.

Regarding the cardinality of the sets $\mathcal{C}_i$ and the complexity of the COVERING operations, in principle, we would like to be able to implement COVERING in way that it takes polynomial time in its argument and provides an α-covering that is as small as possible. The former requirement is easily met by sequentially inspecting an element $P(\mathcal{Y}_i)$ in $\mathcal{B}_i$ and inserting it into $\mathcal{C}_i$ only if there is no other $Q(\mathcal{Y}_i)$ in $\mathcal{B}_i$ such that $P(\mathcal{Y}_i)\leq\alpha Q(\mathcal{Y}_i)$. This procedure takes time polynomial in the cardinality of $\mathcal{B}_i$ and in $|\mathcal{Y}_i|$, but does not guarantee that the size of the obtained set is bounded, and in the worst case we might simply output $\mathcal{C}_i=\mathcal{B}_i$ at every node i, which would cause $\mathcal{C}_r$ to contain as many as $\prod_{i=1}^m|\mathcal{K}|_i$ or $O(\kappa^{\kappa^{m\omega}})$ elements. As we show in the next section, there is a better way of finding α-coverings (in polynomial time) that guarantees that the cardinality of the sets $\mathcal{C}_i$ remains bounded in the (size of the influence diagram given as) input (measured in bits and using a reasonable encoding) if the cardinality of any variable is bounded.

Before introducing the fully polynomial-time approximation scheme, there is a minor detail we have postponed in the discussion, which is how to modify the algorithm to provide not only the expected value but also a strategy that obtains that value. This can be easily implemented by associating to any potential generated during the algorithm the policies that were used either directly or indirectly to produce it. More specifically, let δ be a dictionary, which is initialized with $\delta[1(\mathcal{X}_i)]\leftarrow\{\}$ for $i=1,\ldots,m$, $\delta[P(C|\mathtt{Pa}(C))]\leftarrow\{\}$ for every C in $\mathcal{C}$, $\delta[U(\mathtt{Pa}(V))]\leftarrow\{\}$, and $\delta[P(D|\mathtt{Pa}(D))]\leftarrow\{P(D|\mathtt{Pa}(D))\}$ for every D in $\mathcal{D}$ and $P(D|\mathtt{Pa}(D))$ in $\mathcal{P}_D$. We redefine the operations COMBINE and SUMOUT to update δ as the computations are done as follows. Let $\mathcal{K}$ be the output of COMBINE$(\mathcal{K}_1,\ldots,\mathcal{K}_n)$. Then for every $P(\mathcal{Y}_1)\cdots P(\mathcal{Y}_n)\in\mathcal{K}$, where $P(\mathcal{Y}_1)\in\mathcal{K}_1,\ldots,P(\mathcal{Y}_n)\in\mathcal{K}_n$, we assign $\delta[P(\mathcal{Y}_1)\cdots P(\mathcal{Y}_n)]\leftarrow\delta[P(\mathcal{Y}_1)]\cup\cdots\cup\delta[P(\mathcal{Y}_n)]$. Likewise, let $\mathcal{K}$ be the output of SUMOUT$(\mathcal{K}',\mathcal{Z})$. Then $\delta[\sum_{\mathcal{Z}}P(\mathcal{Y})]\leftarrow\delta[P(\mathcal{Y})]$ for every $\sum_{\mathcal{Z}}P(\mathcal{Y})$ in $\mathcal{K}$, where $P(\mathcal{Y})\in\mathcal{K}'$. The COVERING operation does not need modification since it returns a subset of its argument. Finally, we obtain a strategy $\mathcal{S}$ such that $\mathrm{E}_{\mathcal{S}}=\mathrm{E}$ from $\delta[\mathrm{E}]$. Note that these additional operations do not change the asymptotical running time complexity, and can be efficiently implemented using pointers to the original functions, incurring a very small increase in the space complexity.

4 A FULLY POLYNOMIAL-TIME APPROXIMATION SCHEME

When the maximum cardinality of a variable κ is assumed bounded, the complexity of computing each potential $P(\mathcal{Y}_i)$ in the procedure in Algorithm 1 as well as the cardinalities of the sets $\mathcal{K}_i$ are bounded by a constant. Hence, the only difficulty one needs to overcome in order to devise a fully polynomial-time approximation scheme out of that procedure is to guarantee that the operation COVERING returns sets $\mathcal{C}_i$ whose cardinality is polynomially bounded by the input size, where the latter is defined as the number of bits needed to encode all numerical parameters (i.e., probabilities and utilities) as well as the variables and the underlying graph of the diagram. For definiteness, we assume the numerical parameters are specified as rational numbers in a reasonable way. The procedure in Algorithm 2 partitions the space $\mathcal{Y}$ over which the potentials in the input set $\mathcal{K}$ are specified in hyperrectangles such that the ratio of any two potentials falling in the same rectangle is at most α. Thus, we can provide an α-covering of $\mathcal{K}$ by letting $\mathcal{K}'$ be a set obtained by selecting exactly one element from each non-empty rectangle.[3] Remarkably, we show that the number of elements in $\mathcal{K}'$ is a polynomial function of the size of the influence diagram (in bits).

The next result, which is inspired by a similar result by Papadimitriou and Yannakakis [15], relates the cardinality of the output of the COVERING procedure in Algorithm 2 with the size in bits of the input set $\mathcal{K}$.

Lemma 5. *Let $\mathcal{K}$ be a set of potentials $P(\mathcal{Y})$ whose range is contained in $[0,1]$. Then the set $\mathcal{K}'$ obtained by the procedure in Algorithm 2 is an α-covering of $\mathcal{K}$ with at most $(1-\lfloor\log_\alpha t\rfloor)^\eta$ elements, where t is the smallest (strictly) positive number in the range of a potential in $\mathcal{K}$ and $\eta=\prod_{X\in\mathcal{Y}}|X|$ is the number of assignments to $\mathcal{Y}$.*

[3]The notation $\lfloor\log_\alpha P(\mathcal{Y})\rfloor$ denotes a function $F(\mathcal{Y})$ such that $F(\boldsymbol{y})=\lfloor\log_\alpha P(\boldsymbol{y})\rfloor$ if $P(\boldsymbol{y})\neq 0$ and $F(\boldsymbol{y})=0$ otherwise, where $\boldsymbol{y}$ is an assignment to $\mathcal{Y}$.

Algorithm 2 Finding A Small α-Covering

Require: A set $\mathcal{K}$ of potentials over a set of variables $\mathcal{Y}$, a value $\alpha > 1$
Ensure: $\mathcal{K}'$ is an α-covering of $\mathcal{K}$
1: let $\mathcal{K}'$ and $\mathcal{L}$ initially be empty sets
2: **for each** $P(\mathcal{Y})$ in $\mathcal{K}$ **do**
3: **if** $\lfloor \log_\alpha P(\mathcal{Y}) \rfloor$ is not in $\mathcal{L}$ **then**
4: insert $\lfloor \log_\alpha P(\mathcal{Y}) \rfloor$ into $\mathcal{L}$
5: insert $P(\mathcal{Y})$ into $\mathcal{K}'$
6: **end if**
7: **end for**

Proof. To see that $\mathcal{K}'$ is an α-covering of $\mathcal{K}$, note that by design if a potential $P(\mathcal{Y}) \in \mathcal{K}$ is not in $\mathcal{K}'$ then the latter contains a potential $Q(\mathcal{Y}) \in \mathcal{K}$ such that $\lfloor \log_\alpha P(\mathcal{Y}) \rfloor = \lfloor \log_\alpha Q(\mathcal{Y}) \rfloor$, which implies $P(\mathcal{Y}) \leq \alpha Q(\mathcal{Y})$.

Regarding the cardinality of $\mathcal{K}'$, first note that there are $-\lfloor \log_\alpha t \rfloor$ (distinct) integers between t and one (the minus sign is because $t \leq 1$). Now consider a potential $P(\mathcal{Y}) \in \mathcal{K}$. By assumption, the range of $P(\mathcal{Y})$ is contained in $[0, 1]$, and for each assignment $\boldsymbol{y}$ to $\mathcal{Y}$ we have that either $P(\boldsymbol{y}) \geq t$ or $P(\boldsymbol{y}) = 0$. Hence, for each $\boldsymbol{y}$ there are only $(1 - \lfloor \log_\alpha t \rfloor)$ distinct values the number $\lfloor \log_\alpha P(\boldsymbol{y}) \rfloor$ can assume, and therefore only $(1 - \lfloor \log_\alpha t \rfloor)^\eta$ possibilities for $\lfloor \log_\alpha P(\mathcal{Y}) \rfloor$. □

The following result is an immediate consequence of the above result which shows that the cardinality of any set $\mathcal{C}_i$ is polylogarithmic in the smallest positive number being specified by a potential in $\mathcal{B}_i$.

Corollary 6. *For $i = 1, \ldots, m$, the set $\mathcal{C}_i$ contains $O([1 - \lfloor \log_\alpha t_i \rfloor]^{\kappa^\omega})$ elements, where t_i is the smallest (strictly) positive number in a potential in $\mathcal{B}_i$.*

We can now state the main result of this paper.

Theorem 7. *There is a fully polynomial-time approximation scheme for influence diagrams of bounded treewidth and bounded variable cardinality.*

Proof. Assume, without loss of generality, that the influence diagram given as input contains only one value variable taking values in $[0, 1]$. Let t denote the smallest (strictly) positive numerical parameter in the specification (i.e., the smallest nonzero probability or utility specified by the diagram), and let b denote the size of the diagram (in bits). Since the input probabilities and utilities are (by assumption) rational numbers, each positive input number is not smaller than 2^{-b} (otherwise we would need more than b bits to encode it). Any potential $P(\mathcal{Y})$ in a set $\mathcal{B}_i$ is obtained by multiplying and marginalizing the functions specified by the diagram, and hence any value $P(\boldsymbol{y})$ in $P(\mathcal{Y})$ is a polynomial in the numerical parameters in the input. Moreover, since each variable in the network is associated to a function over at most κ^{κ^ω} numbers, the polynomial has degree at most $O(n\kappa^{\kappa^\omega}) \leq O(n)$, where n is the number of variables. In particular, the smallest positive value t_i in a potential in $\mathcal{B}_i$, for $i = 1, \ldots, m$, is also a polynomial in the numerical parameters of the input of degree $O(n)$, and since these are either zero or some number greater than or equal to 2^{-b}, it follows that $t_i \geq 2^{-bO(n)}$. Thus, we have from Corollary 6 that the cardinality of any set $\mathcal{C}_i$ is $O([1 - \lfloor \log_\alpha 2^{-bO(n)} \rfloor]^{\kappa^\omega}) \leq O([bn/\ln(\alpha)]^{\kappa^\omega})$. But since $\alpha = 1 + \epsilon/2m$, we have from the inequality $\ln(1 + x) \geq x/(1 + x)$ valid for all $x > 0$ that

$$O\left(\left[\frac{bn}{\ln(\alpha)}\right]^{\kappa^\omega}\right) \leq O\left(\left[bn\frac{1+\frac{\epsilon}{2n}}{\frac{\epsilon}{2n}}\right]^{\kappa^\omega}\right) \leq O\left(\left[\frac{bn^2}{\epsilon}\right]^{\kappa^\omega}\right).$$

Hence, for $i = 1, \ldots, m$ the number of elements in any $\mathcal{C}_i$ is polynomial in b, n and $1/\epsilon$. □

4.1 CONCLUSION

Influence diagrams provide a very expressive language to describe decision problems under uncertainty, especially if no-forgetting and regularity are not required. Finding an optimal strategy for such problems is NP-hard even in diagrams of bounded treewidth and very simple structure (e.g., a tree), which makes approximation algorithms an interesting alternative. Here again the problem shows itself to be hard. Without assuming that variables have bounded cardinality, there is no polynomial-time approximation algorithm unless P=NP. As we show here, neither restricting the diagrams to a single value variable makes the problem easier to solve or approximate.

In this paper, we give some hope in light of so many negative results by showing that when the diagram has bounded treewidth and the variables take on a bounded number of values, there is a fully polynomial-time approximation algorithm for the (optimal) strategy selection problem. Although our proof is constructive, the algorithm we provide is not expected to be practical for any reasonably large problem due to the huge constants hidden in the asymptotic analysis. Nevertheless, the existence of such an scheme shall motivate researchers to investigate more efficient approximation algorithms to solve influence diagrams of low treewidth and low variable cardinality.

Abstract

Agents learning to act autonomously in real-world domains must acquire a model of the dynamics of the domain in which they operate. Learning domain dynamics can be challenging, especially where an agent only has partial access to the world state, and/or noisy external sensors. Even in standard STRIPS domains, existing approaches cannot learn from noisy, incomplete observations typical of real-world domains. We propose a method which learns STRIPS action models in such domains, by decomposing the problem into first learning a transition function between states in the form of a set of classifiers, and then deriving explicit STRIPS rules from the classifiers' parameters. We evaluate our approach on simulated standard planning domains from the International Planning Competition, and show that it learns useful domain descriptions from noisy, incomplete observations.

1 INTRODUCTION

Developing agents with the ability to act autonomously in the world is a major goal of artificial intelligence. One important aspect of this development is the acquisition of domain models to support planning and decision-making: to operate effectively in the world, an agent must be able to accurately predict when its actions will succeed, and what effects its actions will have. Only when a reliable action model is acquired can the agent usefully combine sequences of actions into plans, in order to achieve wider goals. However, learning domain dynamics can be a challenging problem: agents' observations may be noisy, or incomplete; actions may be non-deterministic; the world may be noisy or contain many irrelevant objects and relations.

In this paper we consider the problem of acquiring explicit domain models from the raw experiences of an agent exploring the world, where the agent's observations are incomplete, and observations and actions are subject to noise. The domains we consider are relational STRIPS (Fikes and Nilsson, 1971) domains, although our approach has the potential to be extended to more expressive domains. Given the autonomous learning setting, we assume only a weak domain model where the agent knows how to identify objects, has acquired predicates to describe object attributes and relations, and knows what types of actions it may perform, but not the appropriate contexts for the actions, or their effects. Experience in the world is then developed through observing changes to object attributes and relations when motor-babbling with primitive actions.

Other approaches to learning STRIPS operators do not handle both noisy and incomplete observations (see Section 3). We develop a two-stage approach to the problem which decouples the requirement to tolerate noisy, incomplete observations from the requirement to learn compact STRIPS operators. In the first stage we learn action models by constructing a set of kernel classifiers which tolerate noise and partial observability, but whose action models are implicit in the learnt parameters of the classifiers, similar to the work of Mourão *et al.* (2009, 2010). However, we additionally use the method to learn preconditions as well as effects, as suggested but not explored in earlier work. Also, we evaluate additional kernels for the learning problem and select a better performing alternative. The initial action model learnt in this first stage acts as a noise-free, fully observable source of observations from which to extract explicit action rules. In the second stage we devise a novel method to derive explicit STRIPS operators from the model implicit in the kernel classifiers. In experiments the resulting rules perform as well as the original classifiers, while providing a compact representation of the action models suitable for use in automated planning systems.

2 THE LEARNING PROBLEM

A *domain* is a tuple $\mathcal{D} = \langle \mathcal{O}, \mathcal{P}, \mathcal{A} \rangle$, where $\mathcal{O}$ is a finite set of world objects, $\mathcal{P}$ is a finite set of predicate (relation) symbols, and $\mathcal{A}$ is a finite set of actions. Each predicate and action also has an associated arity. A *fluent expression* is a statement of the form $p(c_1, c_2, ..., c_n)$, where $p \in \mathcal{P}$,

n is the arity of p, and each $c_i \in \mathcal{O}$. A *state* is any set of fluent expressions, and $\mathcal{S}$ is the set of all possible states. Since state observations may be incomplete we assume an open world where unobserved fluents are considered to be unknown. For any state $s \in \mathcal{S}$, a fluent expression ϕ is true at s iff $\phi \in s$. The negation of a fluent expression, $\neg\phi$, is true at s (also, ϕ is false at s) iff $\neg\phi \in s$. If $\phi \in s$ then $\neg\phi \notin s$. Any (legal) fluent expression not in s is unobserved.

Each action $a \in \mathcal{A}$ is defined by a set of *preconditions*, Pre_a, and a set of *effects*, Eff_a. In STRIPS domains Pre_a can be any set of fluent expressions and Eff_a can be any set of fluent expressions and negated fluent expressions. Action preconditions and effects can also be parameterised. An action with all of its parameters replaced with objects from $\mathcal{O}$ is said to be an *action instance*. Objects mentioned in the preconditions or the effects must be listed in the action parameters (the *STRIPS scope assumption* (SSA)).

The task of the learning mechanism is to learn the preconditions and effects Pre_a and Eff_a for each $a \in \mathcal{A}$, from data generated by an agent performing a sequence of randomly selected actions in the world and observing the resulting states. The sequence of states and action instances is denoted by $s_0, a_1, s_1, ..., a_n, s_n$ where $s_i \in \mathcal{S}$ and a_i is an instance of some $a \in \mathcal{A}$. Our data consists of *observations* of the sequence of states and action instances $s'_0, a_1, s'_1, ..., a_n, s'_n$, where state observations may be noisy (some $\phi \in s_i$ may be observed as $\neg\phi \in s'_i$) or incomplete (some $\phi \in s_i$ are not in s'_i). Action failures are allowed: the agent may attempt to perform actions whose preconditions are unsatisfied. In these cases the world state does not change, but the observed state may still be noisy or incomplete. To make accurate predictions in domains where action failures are permitted, the learning mechanism must learn both preconditions and effects of actions.

E.g. in BlocksWorld, where an agent stacks and unstacks blocks, consider a state with blocks `B1` and `B2` on the table:

```
(AND armempty (ontable B1) (ontable B2) (clear B1)
 (clear B2) (NOT (on B1 B2)) (NOT (on B2 B1))
 (NOT (holding B1)) (NOT (holding B2))).
```

A corresponding noisy, incomplete observation is:

```
(AND armempty (ontable B2) (holding B1) (clear B1)
 (NOT (on B1 B2)) (NOT (holding B2))).
```

It is noisy as `(holding B1)` is incorrect, and incomplete as `(ontable B1)`, `(clear B2)` and `(NOT(on B2 B1))` are missing. A sequence of noisy, incomplete observations of states and actions could be as follows:

```
s'_0: (AND armempty (ontable B2) (holding B1)
       (clear B1) (NOT (on B1 B2)) (NOT (holding B2)))
a_1: (pickup B1)
s'_1: (AND (NOT (clear B1)) (holding B1) (NOT (on B1 B2))
       (NOT (ontable B2)) (NOT (on B2 B1)))
a_2: (stack B1 B2)                                    (1)
s'_2: (AND armempty (clear B1) (clear B2)
       (ontable B2) (NOT (holding B1)))
a_3: (stack B2 B1)
s'_3: (AND armempty (clear B1) (NOT (clear B2))
       (NOT (on B2 B1)) (NOT (on B2))).
```

Taking a sequence of such inputs, we learn action descriptions for each action in the domain. For example, the `stack` action, which moves a block from the gripper on to another block, would be represented as:

```
(:action stack
  :parameters (?ob ?underob)
  :precondition (and (clear ?underob) (holding ?ob))
  :effect (and (arm-empty) (clear ?ob) (on ?ob ?underob)
          (not (clear ?underob)) (not (holding ?ob)))).
```

3 RELATED WORK

Previous work fulfils some but not all of the requirements for learning models in the setting we consider. In autonomous robotics, various techniques exist to learn preconditions and effects of actions in noisy, partially observable worlds (Doğar *et al.*, 2007; Metta and Fitzpatrick, 2003; Modayil and Kuipers, 2008). However, none of these approaches learn relational models. Conversely, much previous work on learning relational action models relies on the provision of prior knowledge of the action model. Strategies include seeding initial models with approximate planning operators (Gil, 1994), using known successful plans (Wang, 1995), excluding action failures (Amir and Chang, 2008), or the presence of a teacher (Benson, 1996). Such knowledge is unlikely to be available to an autonomous agent learning the dynamics of its domain. Additionally, only a few approaches are capable of learning under either partial observability (Amir and Chang, 2008; Yang *et al.*, 2007; Zhuo *et al.*, 2010), noise in any form (Pasula *et al.*, 2007; Rodrigues *et al.*, 2010), or both (Halbritter and Geibel, 2007; Mourão *et al.*, 2010). Approaches which handle both do so by generating implicit action models which must be used as a black-box to make predictions of state changes, and do not generate symbolic action representations.

We extract rules from classifiers based on the intuition that more discriminative features will contribute more to the classifier's objective function. This is similar to the insight underlying feature selection methods of the type which rank each feature according to the sensitivity of the classifier's objective function to the removal of the feature (Kohavi and John, 1997; Guyon *et al.*, 2002). Our approach differs in that features are selected separately for individual examples, rather than once across the entire training set, and we define a stopping criterion which identifies when the set of selected features can no longer form a rule.

Our work also has links with earlier work in version spaces (Mitchell, 1982) and the associated greedy search, which underlie many other approaches to rule learning (e.g. Amir and Chang, 2008; Pasula *et al.*, 2007). Our rule search benefits from extra information to guide the search, in the form of the weights associated with each hypothesis by the previously trained statistical classifiers, which can be highly robust to noise and incomplete observations.

4 LEARNING IMPLICIT MODELS

The basis of our approach is the division of the learning problem into two parts: initially a classification method is used to learn to predict effects of actions, then STRIPS rules are derived from the resulting action representations. We define the *implicit action model* to be the model of the domain implicit in the learnt parameters of the classifiers, and the *explicit action model* to be the domain model described by STRIPS rules. In learning an implicit action model, our approach follows earlier work (Croonenborghs *et al.*, 2007; Halbritter and Geibel, 2007; Mourão *et al.*, 2009, 2010) which encodes the learning problem in terms of the inputs and outputs of a set of classifiers. However, none of these methods generate explicit action models.

Following the approach of Mourão *et al.* (2009, 2010), we encode the state descriptions with a fixed dimension vector representation by only considering objects which are mentioned in the action parameter list. By the SSA this is sufficient to learn STRIPS rules. For an action instance with arguments $o_1, o_2, ..., o_n$ we therefore restrict the state description to all possible fluents whose arguments are in $\{o_1, o_2, ..., o_n\}$. Also we schematise descriptions by replacing the i-th action parameter with the label arg_i whenever it appears in any fluent. Thus all state descriptions are now written in terms of the action parameters and not in terms of specific objects. The SSA fixes a small number of objects to consider for an action, as well as their roles, which allows relational state descriptions to be encoded in a vector, as each possible fluent in a state maps to exactly one possible fluent in any other state. We encode state descriptions as vectors where each bit in the vector corresponds to each possible fluent which could exist in the schematised state description. The value of a bit is 1 if the fluent is true, -1 if false, and a wildcard value * if unobserved.

In our previous BlocksWorld example (1), the state descriptions for s'_0 and s'_1 in the context of the `pickup(B1)` action a_1 would include only `B1`, and are schematised to form prior and successor states s_{prior} = `(AND armempty(holding arg1)(clear arg1))` and s_{succ} = `(AND (holding arg1) (NOT(clear arg1)))` respectively, to give $\langle s_{prior}, \texttt{pickup(arg1)}, s_{succ}\rangle$ as a training example. Conversely, the descriptions for s'_1 and s'_2 in the context of the `stack(B1 B2)` action a_2 contain both `B1` and `B2` as both are action parameters, giving s_{prior} = `(AND (holding arg1) (NOT(on arg1 arg2)) (NOT(on arg2 arg1)) (NOT(clear arg1)) (NOT(ontable arg2)))` and s_{succ} = `(AND armempty (clear arg1) (clear arg2) (ontable arg2) (NOT(holding arg1)))`.

Encoding the state descriptions as vectors, where the bits correspond to `armempty` followed by `clear`, `ontable`, `holding` and `on` with first argument `arg1`, and then the same predicates with first argument `arg2`, we obtain $v^{prior} = \langle 1, 1, *, 1, *, *, *, *, * \rangle$ and $v^{succ} = \langle *, -1, *, 1, *, *, *, *, * \rangle$ for a_1 and $v^{prior} = \langle *, -1, *, 1, -1, *, -1, *, -1 \rangle$ and $v^{succ} = \langle 1, 1, *, -1, *, 1, 1, *, * \rangle$ for a_2.

Given the vectorised state descriptions, a changes vector v^{diff} is derived for each training example, where the i-th bit v_i^{diff} is defined as follows:

$$v_i^{diff} = \begin{cases} 0, \text{ if } v_i^{prior} = v_i^{succ} \text{ and } v_i^{succ}, v_i^{prior} \in \{-1, 1\} \\ 1, \text{ if } v_i^{prior} \neq v_i^{succ} \text{ and } v_i^{succ}, v_i^{prior} \in \{-1, 1\} \\ *, \text{ otherwise.} \end{cases}$$

A set of classifiers now learns the implicit action model. Each classifier $C_{a,i}$ corresponds to a particular action a in the domain and predicts the i-th bit of the changes vector. Thus if $\langle s_{prior}, a, s_{succ}\rangle$ is a training example for $C_{a,i}$ then the input to the classifier is v^{prior} with target value v_i^{diff}.

Voted perceptron classifiers equipped with a kernel function have previously been applied to the problem of learning action models (Mourão *et al.*, 2009, 2010) as they are computationally efficient and known to tolerate noise (Khardon and Wachman, 2007). We take a similar approach. Mourão *et al.* used voted perceptrons combined with a DNF kernel, $K(x, y) = 2^{same(x,y)}$, where $same(x, y)$ is the number of bits with equal values in x and y (Sadohara, 2001; Khardon and Servedio, 2005). In the $same(x, y)$ calculation, bits with unobserved values are excluded. The features of the DNF kernel are all possible conjunctions of fluents, seemingly ideal for learning action preconditions which are arbitrary conjunctions of fluents. However, DNF is not PAC-learnable by a perceptron using the DNF kernel, as examples exist on which it can make exponentially many mistakes (Khardon *et al.*, 2005). We therefore consider as an alternative the k-DNF kernel, whose features are all possible conjunctions of fluents of length $\leq k$ for some fixed k: $K(x, y) = \sum_{l=0}^{k} \binom{same(x,y)}{l}$ (Khardon and Servedio, 2005). Preconditions with more than k fluents are still possible since the voted perceptron supports hypotheses which are conjunctions of features.

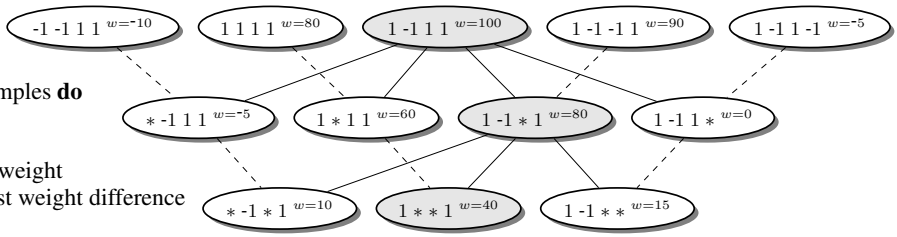
5 RULE EXTRACTION

Once the classifiers have been trained, the first step in deriving explicit action rules is to extract individual *per-effect* rules to predict each fluent in isolation. We will look at how to combine the rules to extract postconditions in Section 6.

The rule extraction process takes as input a classifier $C_{a,i}$ and returns a set of preconditions (as vectors) which predict that the fluent corresponding to bit i will change if action a is performed. For example, in the BlocksWorld domain a set of preconditions extracted from the classifiers for `stack` is shown in Figure 2.

for $v \in SV^+$ **do**
  $child := v$
  while $child$ only covers +ve training examples **do**
    $parent := child$
    for each valued bit in $parent$ **do**
      flip bit to its negation and calculate weight
    $child :=$ child whose parents have least weight difference
  $rule_v := parent$

(a) Rule Extraction Algorithm



(b) Example of Rule Extraction Process

Figure 1: Each node in (b) contains a vector corresponding to a possible precondition, and the weight w assigned to the vector by the voted perceptron model. Each level of the lattice contains vectors with one fewer feature than the level above. Lines join parent and children nodes: solid lines link the candidate parent rule at one level with its children in the level below, and dashed lines link children to their alternative parent. Shaded nodes are the preconditions selected at each iteration through the lattice. The positive support vector "seed" is the vector $\langle 1$ -1 1 $1\rangle$ with weight 100. Following the rule extraction algorithm in (a), the child whose parents have the least weight difference, the vector $\langle 1$ -1 * $1\rangle$, is chosen as the next candidate rule. The process ends with the rule $\langle 1$ * * $1\rangle$ as both children have a negative counterexample in the training data (not shown).

```
(armempty) changes when:
[8]  (AND (NOT(armempty)) (NOT(ontable arg1)))

(clear arg1) changes when:
[14] (AND (NOT(clear arg1)) (holding arg1)
      (NOT(on arg1 arg2)))
[12] (AND (NOT(clear arg1)) (NOT(ontable arg1))
      (NOT(on arg2 arg1)))
[8]  (AND (clear arg1) (ontable arg1) (clear arg2)
      (NOT(on arg1 arg2)) (NOT(on arg2 arg1)))

(ontable arg1) changes when:
[6]  (AND (NOT(ontable arg1)) (NOT(on arg1 arg2)))
[4]  (AND (NOT(armempty)) (ontable arg1)
      (NOT(clear arg2)))

(holding arg1) changes when:
[15] (AND (holding arg1))

(on arg1 arg2) changes when:
[3]  (AND (NOT(on arg1 arg2)))

(clear arg2) changes when:
[12] (AND (clear arg2) (ontable arg2)
      (NOT(holding arg2)))
[6]  (AND (NOT(armempty)) (NOT(clear arg1)) (clear arg2)
      (holding arg1) (NOT(on arg1 arg2)))
[2]  (AND (NOT(clear arg1)) (clear arg2)
      (NOT(ontable arg2)))
```

Figure 2: Per-effect rules generated for the BlocksWorld `stack` action from 1000 examples in a world with 5% noise and 25% observability. Weights are shown in square brackets. Fluents in bold are neither in, nor implied by, the true action specification. Many of these fluents will later be excluded by the rule combination process (Section 6).

Rules are extracted from a voted perceptron with kernel K and support vectors $SV = SV^+ \cup SV^-$, where SV^+ (SV^-) is the set of support vectors whose *predicted* values are 1 (-1). The positive support vectors are each instances of some rule learnt by the perceptron, and so are used to "seed" the search for rules. The extraction process aims to identify and remove all irrelevant bits in each support vector, using the voted perceptron's prediction calculation to determine which bits to remove.

The *weight* of any possible state description vector $\mathbf{x}$ is defined to be the value calculated by the voted perceptron's prediction calculation before thresholding (Freund and Schapire, 1999):

$$weight_e(\mathbf{x}) = \sum_{i=1}^{n} c_i \; sign \sum_{j=1}^{i} y_j \alpha_j K(\mathbf{x}_j, \mathbf{x})$$

where each x_i is one of the n support vectors, y_i is the corresponding target value, c_i and α_i are the parameters learnt by the classifier, and e is the effect predicted by the classifier. The predicted value for $\mathbf{x}$ is 1 if $weight_e(\mathbf{x}) > 0$ and -1 otherwise. A *child* of vector $\mathbf{x}$ is any distinct vector obtained by replacing a single bit of $\mathbf{x}$ with the value *. Similarly, a *parent* of $\mathbf{x}$ is any vector obtained by replacing a *-valued bit with the value 1 or -1.

The basic intuition behind the rule extraction process is that more discriminative features will contribute more to the weight of an example. Thus the rule extraction process operates by taking each positive support vector and repeatedly deleting the feature which contributes least to the weight until some stopping criterion is satisfied. This leaves the most discriminative features underlying the example, which can be used to form a precondition. An example of the process of extracting rules is shown in Figure 1(b), and an outline of the algorithm in Figure 1(a), as follows. Take each positive support vector v in turn, and aim to find a conjunction $rule_v$ which covers v and does not cover any negative training examples, but where every child of $rule_v$ covers at least one negative example. Construct $rule_v$ by a greedy algorithm which first takes v as a candidate rule and then repeatedly creates a new candidate rule by choosing one bit to set to the $*$ value. The bit is chosen by considering the difference in weights between the current candidate $\mathbf{x} = \langle x_1, ..., x_i, ..., x_n \rangle$ and

each $\mathbf{x}_{\neg i} = \langle x_1, ..., \neg x_i, ..., x_n \rangle$, finding

$$\underset{x_i \in \{x_1,...,x_i,...,x_n\}}{\operatorname{argmin}} (weight_e(\mathbf{x}) - weight_e(\mathbf{x}_{\neg i})).$$

Removing the resulting x_i removes the least discriminative bit in the current candidate rule. At each step the new candidate rule is tested against the training examples. If it classifies a negative training example as positive, then the rule is too general and $rule_v$ is set to the previous candidate rule, otherwise the process repeats. The result is a set of rules for each action, predicting when a particular output bit changes. There may be many rules, up to one per positive support vector, each consisting of a set of preconditions which, if satisfied, predict the output bit will change.

6 RULE COMBINATION

The rule extraction process described above produces a set of rules for an action, such as for the BlocksWorld `stack` action shown in Figure 2. However, in STRIPS we expect a single rule for each action, consisting of a set of preconditions and a set of effects such as in the definition of the BlocksWorld `stack` action given in Section 2.

The rule combination process therefore builds a single STRIPS-like rule for each action, taking as input the set of rules produced by the rule extraction process: $\{(v_1, e_1), (v_2, e_2), \ldots, (v_r, e_r)\}$ where v_i is the vector representing the i-th set of preconditions, and e_i is the bit which changes when v_i holds. Rule combination generates a rule (v_{rule}, e_{rule}) where the j-th element of v_{rule}, $v_{rule,j} \subseteq \bigcup_i v_{i,j}$ and $e_{rule} \subseteq \bigcup_i e_i$. Given the definitions in Section 4, we can directly convert the single state vector v_{rule} and the set of effects e_{rule} into a precondition and effect in STRIPS format.[1]

Without noise or partial observability, the combination process is a straightforward conjunction of all preconditions and all effects in the set of rules for an action, i.e., $\forall j \; v_{rule,j} = \bigcup_i v_{i,j}$ and $e_{rule} = \bigcup_i e_i$. However, when learning from noisy examples, unwanted additional fluents can be introduced to the per-effect rules via noisy support vectors. Similarly, incomplete training examples can mean some necessary fluents are missing from individual per-effect rules. In this section we describe an approach to identify and eliminate fluents introduced by noise while adding in fluents omitted due to partial observability.

To support the process of choosing between different potential rules which may contain noisy fluents, or omit necessary fluents, we introduce two filtering functions. *AcceptPrecons* takes an existing precondition and effects (v_{rule}, e_{rule}) for an action a, and assesses whether a new precondition v_{new} predicts the effects of a at least as well as the current precondition. *AcceptEffects* takes an existing precondition and effects for an action a, and assesses whether the precondition predicts a new effect e_{new} of a at least as well as it predicts the current effects. We describe *AcceptPrecons* and *AcceptEffects* in detail in Section 6.2.

[1] Since the effects in e_{rule} are changes it may be necessary to identify from what value the change is made, by referring to the rule from which the effect bit originated.

$R := \{(v_1, e_1), \ldots, (v_r, e_r)\}$
$rule := (v_1, \varnothing)$
$locks = \varnothing$
while $R \neq \varnothing$ **do**
  $next :=$ highest weighted rule in R
  $R := R \setminus \{next\}$
  $v_{candidate} = CombinePrecons(rule, next, locks)$
  if $v_{candidate} \neq v_{rule}$ **then**
    $v_{candidate} = SimplifyPrecons(rule, next, v_{candidate})$
    if $AcceptPrecons(rule, v_{candidate})$ **then**
      $v_{rule} := v_{candidate}$
    if $AcceptEffect(rule, e_{next})$ **then**
      $e_{rule} := e_{rule} \cup e_{next}$
    $e_{rule} = SimplifyEffects(rule)$

Figure 3: Outline Rule Combination Algorithm

6.1 RULE COMBINATION OVERVIEW

With the filtering functions in place, we now describe how the rule combination process generates STRIPS rules by combining and refining the per-effect rules. Figure 3 gives an outline of the algorithm, described below.

For each action the process derives a rule (v_{rule}, e_{rule}) from the set of rules $R = \{(v_1, e_1), \ldots, (v_r, e_r)\}$ produced by rule extraction, ordered so that $weight_{e_i}(v_i) \geq weight_{e_j}(v_j)$ if $i < j$. The process first initialises v_{rule} to the highest weighted precondition in R and sets $e_{rule} = \varnothing$. The rule is then refined by combining it with each of the remaining per-effect rules in turn, in order of highest weight.

Each time (in *CombinePrecons*) the process combines the current precondition v_{rule} with the precondition from the next per-effect rule v_i, which we will name v_{next}, into a candidate precondition $v_{candidate}$. This includes resolving any conflicts between v_{rule} and v_{next}. We now have a candidate precondition $v_{candidate}$ which is a merge of v_{rule} and v_{next}. The process refines $v_{candidate}$ further by testing it against a set of alternatives in *SimplifyPrecons* and setting $v_{candidate}$ to the best result. Now $v_{candidate}$ is tested against the original v_{rule}, using *AcceptPrecons*. If $v_{candidate}$ is accepted, v_{rule} is updated to $v_{candidate}$. Similarly, e_{next} is tested against the original set of effects e_{rule}, using *AcceptEffects*. If e_{next} is accepted, e_{rule} is updated to $e_{rule} \cup e_{next}$. Finally, the process refines e_{rule} by testing it against a set of alternatives in *SimplifyEffects* and setting e_{rule} to the best result. In the next section we describe each of the subprocedures in detail.

6.2 ALGORITHM DETAILS

CombinePrecons: In attempting to combine (v_{rule}, e_{rule}) with (v_{next}, e_{next}), the first check is whether e_{next} contradicts any effect in e_{rule}. Effects conflict if both rules predict change to a fluent, but the rules have different values for the fluent in their preconditions. (For example, the two per-effect rules for `(ontable arg1)` in Figure 2 conflict.) If there is a conflict, the new rule is rejected, as we assume only one rule per action, and the higher weighted baseline rule is more likely to be correct.

Second, *CombinePrecons* combines the preconditions on every bit which is not locked (listed in $locks$) and does not conflict, i.e., $\forall i$ $v_{rule,i} = v_{next,i}$ or $v_{rule,i} = *$:

$$v_{candidate,i} = \begin{cases} v_{rule,i}, & \text{if } v_{rule,i} = v_{next,i} \text{ or } i \in locks \\ v_{rule,i}, & \text{if } v_{next,i} = * \\ v_{next,i}, & \text{if } v_{rule,i} = * \text{ and } i \notin locks. \end{cases}$$

For conflicts, where $v_{rule,i} \neq v_{next,i}$ and $v_{rule,i}, v_{next,i} \in \{1, -1\}$, *CombinePrecons* decides which value each conflict bit should take in $v_{candidate}$, as follows.

For each conflicting fluent, there are three possible values the fluent could take in the preconditions of the true rule: $*$ (unobserved), 1 (true) or -1 (false). The weight $weight_e$ (for each effect e in e_{rule}) of each variant is calculated (with the values of other conflicting fluents set to $*$). The preferred variant is where the value is $*$, indicating a non-discriminative feature, and giving the simplest precondition. However, a variant is only acceptable if the weight of the resulting precondition is positive for all effects in e_{rule}, since then the new precondition still predicts the same effects as the current precondition v_{rule}. If accepted, the fluent is locked at the $*$ value, to prevent later, possibly noisy rules, from resetting it. Locked fluents are recorded in the $locks$ variable (see Figure 3). If the $*$-variant is unacceptable, then the (1)-valued or (-1)-valued cases are considered, provided they have positive weights on all the effects. If both variants are acceptable, whichever has the highest average weight over all the effects is selected. If neither variant is acceptable then the conflict is unresolved for this fluent. As long as the conflicts on every fluent are resolved, the rule combination process can continue with the new candidate precondition. If not, the current rule is rejected (and *CombinePrecons* returns v_{rule}).

SimplifyPrecons: Once *CombinePrecons* has generated a candidate precondition $v_{candidate}$, *SimplifyPrecons* considers alternative, less specific preconditions. It creates a set of alternatives $v_{candidate\backslash i}$ for each bit i in $v_{candidate}$ which differs from v_{rule}. $v_{candidate\backslash i} = v_{candidate}$ except at bit i where $v_{candidate\backslash i} = *$. Whenever the filtering function *AcceptPrecons* rates $v_{candidate}$ as worse than any $v_{candidate\backslash i}$, the associated fluent $v_{candidate,i}$ is set to $*$.

SimplifyEffects: In light of the new preconditions, *SimplifyEffects* tests if any of the effects should be removed from the new v_{rule} . For instance, more specific preconditions may lower the incidence of some effects (as seen in the training data) to the extent that *AcceptEffects* rejects them. Each effect is tested against all the other effects by *AcceptEffects* and, if rejected, removed from e_{rule}.

AcceptPrecons: In the precondition filtering function, before even making a comparison between preconditions, the new precondition v_{new} must be checked to ensure that it is consistent with the classifiers and supported by the training data. For this we require a notion of coverage of the training set. Coverage is defined to account for partial observability, so that precondition v_{new} covers example x at effect e (denoted $covers_e(v_{new}, x)$) if none of the fluents in the example state contradict the fluents in the rule preconditions, and e is in both the example state changes and the rule effects. Now v_{new} can form a rule precondition if:

1. v_{new} is consistent with the classifiers: for each $e \in e_{rule}$, v_{new} should be classified by the classifier $C_{a,e}$ as predicting change, that is,
   $\forall e \in e_{rule}\ weight_e(v_{new}) > 0$; and
2. v_{new} is supported by the training data: for each $e \in e_{rule}$, v_{new} should cover at least one training example where e changed, that is,
   $\forall e \in e_{rule}\ |\{x : covers_e(v_{new}, x)\}| > 0$.

Both should be considered, as weight alone may permit rules which do not cover any training examples, while coverage alone may allow negatively weighted rules.

Additionally, *AcceptPrecons* uses differences in precision and recall to identify and reject any new precondition which performs significantly worse than the existing precondition. It rejects preconditions where either the precision or recall on the training set drops substantially for any $e \in e_{rule}$. Since precision and recall is a trade-off, the comparison is made using the F-score[2] for precondition pre at effect e: $F_{pre,e}$. Ideally we want the new precondition to improve on (or at least not worsen) the F-score, but we must introduce some tolerance to account for the effects of noise.

For instance, suppose $v_{new} = \langle 1, 1, *, * \rangle$ is more general than $v_{rule} = \langle 1, 1, 0, * \rangle$, and that v_{new} is in fact the true rule. The F-score for v_{rule} is calculated on the subset of training examples which v_{rule} covers, while the F-score for v_{new} also includes training examples which $\langle 1, 1, 1, * \rangle$ covers. If the training set happens to have a higher proportion of training examples with a noisy outcome covered by $\langle 1, 1, 1, * \rangle$ than $\langle 1, 1, 0, * \rangle$ then the F-score for v_{new} can be lower than for v_{rule}. To account for such effects of noise, we allow the new F-score $F_{v_{new},e}$ to drop to some fraction ϵ_p of the F-score for the existing precondition $F_{v_{rule},e}$, for any effect $e \in e_{rule}$. For new F-scores below this value, the new precondition is rejected.

[2]F-score is the harmonic mean of precision and recall (true positives/predicted changes and true positives/actual changes, respectively) (Van Rijsbergen, 1979).

AcceptEffect: The effects filtering function similarly compares F-scores. Given (v_{rule}, e_{rule}) it compares how well v_{rule} predicts a new effect e_{new} relative to how well it predicts each $e \in e_{rule}$: specifically it compares $F_{v_{rule},e_{new}}$ to $F_{v_{rule},e}$ for each $e \in e_{rule}$. This identifies effects which are inconsistent with the other effects in terms of precision and recall. In particular, effects which occur in far fewer examples than other effects are identified in this way: these are likely to be caused by noise, or could be conditional effects. An effect is rejected by the function if its F-score is less than some fraction ϵ_e times the F-score on any other effect of the same rule.

In our evaluation, ϵ_p and ϵ_e were set to 0.95 and 0.5 respectively, and not varied across the domains. The values were selected empirically via experiments on a holdout dataset from one experimental domain (ZenoTravel).

6.3 RULE COMBINATION EXAMPLE

We now consider an example of one iteration of the rule combination process. Working with the BlocksWorld domain `stack` action, suppose the current rule is $(\langle *, -1, -1, 1, -1, 1, 1, *, * \rangle, \{1, 3, 5\})$ corresponding to the precondition `(AND (NOT(clear arg1)) (NOT(ontable arg1)) (holding arg1) (NOT(on arg1 arg2)) (clear arg2) (ontable arg2))` and effects {`(clear arg1) (holding arg1) (clear arg2)`}. We try to combine this with the new rule $(\langle *, *, -1, *, -1, *, -1, *, 1 \rangle, \{2\})$ corresponding to the precondition `(AND (NOT(ontable arg1)) (NOT(on arg1 arg2)) (NOT(ontable arg2)) (on arg2 arg1))` and effects {`(ontable arg1)`}.

CombinePrecons finds no conflicts in the effects, and generates the candidate precondition $\langle *, -1, -1, 1, -1, 1, ?, *, 1 \rangle$ where $?$ denotes a conflicting fluent. To resolve the conflict the weights of the vectors $\langle *, -1, -1, 1, -1, 1, *, *, 1 \rangle$, $\langle *, -1, -1, 1, -1, 1, 1, *, 1 \rangle$ and $\langle *, -1, -1, 1, -1, 1, -1, *, 1 \rangle$ are calculated for each of the $C_{stack,(clear\ arg_1)}$, $C_{stack,(holding\ arg_1)}$ and $C_{stack,(clear\ arg_2)}$ classifiers. If $\langle *, -1, -1, 1, -1, 1, *, *, 1 \rangle$ is accepted as $v_{candidate}$, *SimplifyPrecons* would consider the alternative precondition $\langle *, -1, -1, 1, -1, 1, *, *, * \rangle$ as the last bit in $v_{candidate}$ was different in v_{rule}.

Assuming $\langle *, -1, -1, 1, -1, 1, *, *, * \rangle$ is accepted as $v_{candidate}$ by *SimplifyPrecons*, it is compared to the original v_{rule} (the only difference now is that the bit corresponding to `(ontable arg2)` is unset in $v_{candidate}$). $v_{candidate}$ has higher weight and so *AcceptPrecons* accepts $v_{candidate}$ and $v_{rule} := v_{candidate}$. Conversely the new effect is rejected by *AcceptEffects* so $e_{rule} = \{1, 3, 5\}$ as before. Finally, *SimplifyEffects* uses *AcceptEffects* to test the relative prediction performance of the new v_{rule} on each effect, with no changes. The new rule is $(\langle *, -1, -1, 1, -1, 1, *, *, * \rangle, \{1, 3, 5\})$.

7 EXPERIMENTS

We tested our approach on several simulated domains taken from the International Planning Competition (IPC) at `http://ipc.icaps-conference.org/`. The domains differ in terms of the number and arity of actions and predicates, and the number and hierarchy of types. The main domain characteristics are detailed in Table 1.

Sequences of random actions and resulting states were generated from the PDDL domain descriptions and used as training and testing data. All data was generated using the Random Action Generator 0.5 available at `http://magma.cs.uiuc.edu/filter/`, modified to also generate action failures. Table 2 shows the numbers of objects used in training and testing data for each domain.

Ten different randomly generated training and testing sets were used. Training and testing sets were sequences of 20,000 and 2,000 actions respectively. Both sequences contained an equal mixture of successful and unsuccessful actions (where some precondition of the action was not satisfied, and so no change occurred in the world). In some domains (e.g. Rovers), portions of the state space can only be traversed once, and in these cases multiple shorter sequences of 400 actions were generated from randomly generated starting states. In line with previous work (Amir and Chang, 2008), incomplete observations were simulated by randomly selecting a fraction (10%, 25% or 50%) of fluents (including negations) from the world to observe after each action. The remaining fluents were discarded and the reduced state vector was generated from the observed fluents. Sensor noise was simulated similarly by flipping the value of each bit in the state vector with probability 1% and 5%.

7.1 RESULTS

We first tested the performance of different kernels on learning the implicit action model, comparing results for a standard (non-kernelised) perceptron, a voted (non-kernelised) perceptron, and a voted kernel perceptron. Both the DNF kernel and k-DNF kernel with $k = 2, 3$ and 5 were tested. Performance was measured in terms of the F-score of the predictions on the test sets.

The fully observable, noiseless cases are easily learnt by any of the perceptrons tested. After 5,000 training examples, the F-score on the test set is 1, in almost all cases. Per-

Table 1: Domain Characteristics

formance of the voted perceptron, with or without the various kernels, is almost identical (results not shown). With the introduction of unobserved fluents or noise, the voted perceptron performs better than the standard perceptron. However, the DNF kernel does not improve performance, with the unkernelised voted perceptron learning significantly more accurate action models. In contrast, the k-DNF kernels all produce significantly more accurate models than the DNF kernel or no kernel ($p < 0.05$, repeated measures ANOVA with post-hoc Bonferroni t-test). Figure 4 gives a comparison of the relative performance of each model. The use of k-DNF kernels therefore represents a significant improvement on previous work which used only the DNF kernel. In light of these results, the 3-DNF kernel was selected for the remainder of the experiments.

Next, we extracted explicit rules from the implicit action models. There was no statistically significant difference between the F-scores of predictions made by the perceptron models and those made by the extracted rules (repeated measures ANOVA, $p > 0.05$). We also compared the resulting models to the original domain descriptions using a measure of error rate (Zhuo *et al.*, 2010). The error rate for a single action is defined as the number of extra or missing fluents in the preconditions and effects (E_{pre} and E_{eff} respectively) divided by the number of possible fluents in the preconditions and effects (T): $Error(a) = \frac{1}{2T}(E_{pre} + E_{eff})$. The error rate of a domain model with a set of actions A is: $Error(A) = \frac{1}{|A|}\sum_{a \in A} Error(a)$.

The error rates indicate that the learnt models are close to the actual STRIPS domain definitions, falling below 0.1 after around 5,000 examples in all cases (Figure 5). In particular, for fully observable, noiseless domains the correct STRIPS model is given by the extracted rules in fewer than

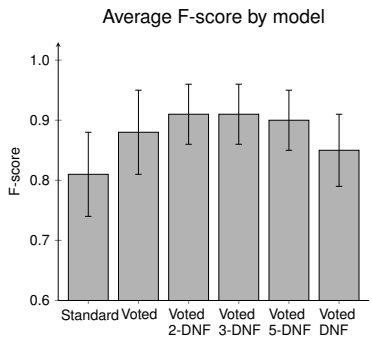

Figure 4: Comparison of the performance of different perceptrons learning action models from 20,000 random actions in STRIPS domains, averaged across all domains, levels of noise and partial observability. Error bars are standard error. Performance is significantly different between models which use a k-DNF kernel and those which do not.

2,000 training examples, except for the most complex domain, Rovers. Comparisons with other approaches in the literature are difficult due to differences in the learning settings. Nevertheless it is notable that the error rates of the learnt action models are low in comparison to action models learnt by (Yang *et al.*, 2007) for the same domains: their error rates at 90% observability (the highest reported) range from around 0.04 (ZenoTravel) to 0.1 or above (DriverLog and Depots) to more than 0.6 (Rovers). An example action model is shown in Figure 6, demonstrating that the method derives compact STRIPS-like rules even with high levels of incompleteness and noise in the observations.

We also calculated the F-scores for predictions made by the learnt rules on our (noiseless, fully observable) test sets (Figure 5). The F-scores are above 0.9 for all noise levels at 25% observability and above, for all domains except Rovers, indicating that in practice the rules correctly predict most fluents. The Rovers F-scores are somewhat lower, because there are fewer training examples per action than for the other domains, and more possible fluents.

Furthermore, our learning is fast. The longest-running example in the experiments (Rovers with 20,000 training examples, 5% noise, fully observable) takes under 1.5 hours on a single Intel Xeon 5160 processor to train the classifiers, and run rule extraction and combination. The ZenoTravel example (Figure 6) runs in under 2 minutes.

8 CONCLUSIONS AND FUTURE WORK

The results demonstrate that our approach successfully learns STRIPS operators from noisy, incomplete observations, in contrast to previous work which either generates explicit operators but cannot tolerate noise and incomplete examples, or tolerates noise and incomplete examples but does not generate explicit operators. We also show empirically that the 3-DNF kernel is a more appropriate choice

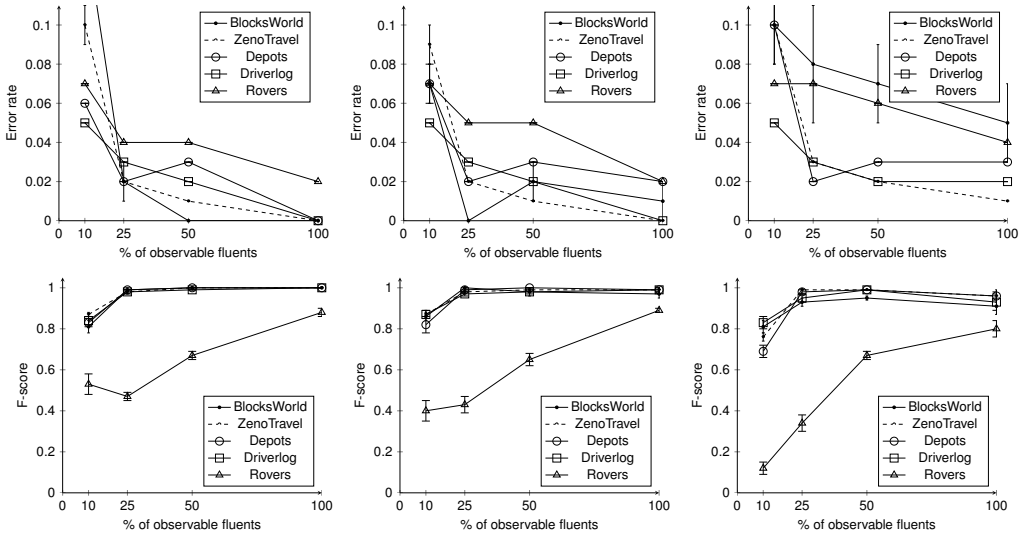

Figure 5: Results from learning explicit action rules from 5,000 training examples at varying levels of observability and noise in simulated planning domains. The error rate measures errors in the learnt domain model relative to the actual domain model (above). The F-score measures performance of the rules on fully observable, noiseless test domains (below).

than the DNF kernel for learning in this setting.

Our approach depends on decomposing the learning problem into two stages: learning implicit action models and then deriving explicit rules from the implicit models. Crucially, the implicit models produce noise-free, complete observations *for the domain model which has been learnt*. An alternative approach to our rule derivation process would be to apply existing action model learning techniques to the observations produced by the implicit models. However such an approach effectively restarts the learning process, ignoring information already learnt and available in the perceptron models, and so is likely to be less efficient.

Our approach also depends on the STRIPS scope assumption (SSA) which essentially identifies the objects which are relevant to the action and fixes their roles. In real-world scenarios the SSA may not apply. Without the SSA, during learning we must also consider state relating to objects which are not listed in the action parameters. Implicit action models in this setting may be learnt using a graphical representation of states combined with a suitable graph kernel (Mourão, 2012). In future work we therefore plan to extend our rule extraction method to derive rules from classifiers trained with graphical state representations. Additional steps will be required to efficiently handle the complexity introduced by the requirement to perform comparisons between graphical state descriptions. There are positive results in PAC-learning existential conjunctive and k-DNF concepts in noise-free structural domains with Boolean relations (Haussler, 1989; Valiant, 1985), which apply to learning from the implicit models, suggesting that our approach will scale to graphical state representations.

Markov Chains on Orbits of Permutation Groups

Mathias Niepert
Universität Mannheim
mniepert@gmail.com

Abstract

We present a novel approach to detecting and utilizing symmetries in probabilistic graphical models with two main contributions. First, we present a scalable approach to computing generating sets of permutation groups representing the symmetries of graphical models. Second, we introduce orbital Markov chains, a novel family of Markov chains leveraging model symmetries to reduce mixing times. We establish an insightful connection between model symmetries and rapid mixing of orbital Markov chains. Thus, we present the first lifted MCMC algorithm for probabilistic graphical models. Both analytical and empirical results demonstrate the effectiveness and efficiency of the approach.

1 Introduction

Numerous algorithms exploit model symmetries with the goal of reducing the complexity of the computational problems at hand. Examples are procedures for detecting symmetries of first-order theories [7] and propositional formulas [2] in order to avoid the exhaustive exploration of a partially symmetric search space. More recently, symmetry detection approaches have been applied to answer set programming [11] and (integer) linear programming [26, 27, 34, 30]. A considerable amount of attention to approaches utilizing model symmetries has been given by work on "lifted probabilistic inference [36, 9]." Lifted inference is mainly motivated by the large graphical models resulting from statistical relational formalism such as Markov logic networks [38]. The unifying theme of lifted probabilistic inference is that inference on the level of instantiated formulas is avoided and instead lifted to the first-order level. Notable approaches are lifted belief propagation [41, 22], bisimulation-based approximate inference algorithms [40], first-order knowledge compilation techniques [44, 16], and lifted importance sampling approaches [17]. With the exception of some results for restricted model classes [41, 44, 21], there is a somewhat superficial understanding of the underlying principles of graphical model symmetries and the probabilistic inference algorithms utilizing such symmetries. Moreover, since most of the existing approaches are designed for relational models, the applicability to other types of probabilistic graphical models is limited.

The presented work contributes to a deeper understanding of the interaction between model symmetries and the complexity of inference by establishing a link between the degree of symmetry in graphical models and polynomial approximability. We describe the construction of colored graphs whose automorphism groups are equivalent to those of the graphical models under consideration. We then introduce the main contribution, *orbital Markov chains*, the first general class of Markov chains for lifted inference. Orbital Markov chains combine the compact representation of symmetries with generating sets of permutation groups with highly efficient product replacement algorithms. The link between model symmetries and polynomial mixing times of orbital Markov chains is established via a path coupling argument that is constructed so as to make the coupled chains coalesce whenever their respective states are located in the same equivalence class of the state space. The coupling argument applied to orbital Markov chains opens up novel possibilities of analytically investigating classes of symmetries that lead to polynomial mixing times.

Complementing the analytical insights, we demonstrate empirically that orbital Markov chains converge faster to the true distribution than state of the art Markov chains on well-motivated and established sampling problems such as the problem of sampling independent sets from graphs. We also show that existing graph automorphism algorithms are applicable to compute symmetries of very large graphical models.

2 Background and Related Work

We begin by recalling some basic concepts of group theory and finite Markov chains both of which are crucial for understanding the presented work. In addition, we give a brief overview of related work utilizing symmetries for the design of algorithms for logical and probabilistic inference.

2.1 Group Theory

A symmetry of a discrete object is a structure-preserving bijection on its components. For instance, a symmetry of a graph is a graph automorphism. Symmetries are often represented with permutation groups. A group is an abstract algebraic structure $(\mathfrak{G}, \circ)$, where $\mathfrak{G}$ is a set closed under a binary associative operation $\circ$ such that there is a identity element and every element has a unique inverse. Often, we refer to the group $\mathfrak{G}$ rather than to the structure $(\mathfrak{G}, \circ)$. We denote the size of a group $\mathfrak{G}$ as $|\mathfrak{G}|$. A permutation group *acting on* a finite set Ω is a finite set of bijections $\mathfrak{g} : \Omega \to \Omega$ that form a group.

Let Ω be a finite set and let $\mathfrak{G}$ be a permutation group acting on Ω. If $\alpha \in \Omega$ and $\mathfrak{g} \in \mathfrak{G}$ we write $\alpha^{\mathfrak{g}}$ to denote the image of α under $\mathfrak{g}$. A cycle $(\alpha_1\ \alpha_2\ ...\ \alpha_n)$ represents the permutation that maps α_1 to α_2, α_2 to α_3,..., and α_n to α_1. Every permutation can be written as a product of disjoint cycles where each element that does not occur in a cycle is understood as being mapped to itself. We define a relation $\sim$ on Ω with $\alpha \sim \beta$ if and only if there is a permutation $\mathfrak{g} \in \mathfrak{G}$ such that $\alpha^{\mathfrak{g}} = \beta$. The relation partitions Ω into equivalence classes which we call *orbits*. We use the notation $\alpha^{\mathfrak{G}}$ to denote the orbit $\{\alpha^{\mathfrak{g}} \mid \mathfrak{g} \in \mathfrak{G}\}$ containing α. Let $f : \Omega \to \mathbb{R}$ be a function from Ω into the real numbers and let $\mathfrak{G}$ be a permutation group acting on Ω. We say that $\mathfrak{G}$ is an *automorphism group for* (Ω, f) if and only if for all $\omega \in \Omega$ and all $\mathfrak{g} \in \mathfrak{G}$, $f(\omega) = f(\omega^{\mathfrak{g}})$.

2.2 Finite Markov chains

Given a finite set Ω a *finite Markov chain* defines a random walk $(X_0, X_1, ...)$ on elements of Ω with the property that the conditional distribution of X_{n+1} given $(X_0, X_1, ..., X_n)$ depends only on X_n. For all $x, y \in \Omega$ $P(x, y)$ is the chain's probability to transition from x to y, and $P^t(x, y) = P^t_x(y)$ the probability of being in state y after t steps if the chain starts at x. A Markov chain is *irreducible* if for all $x, y \in \Omega$ there exists a t such that $P^t(x, y) > 0$ and *aperiodic* if for all $x \in \Omega$, $\mathsf{gcd}\{t \geq 1 \mid P^t(x, x) > 0\} = 1$. A chain that is both irreducible and aperiodic converges to its unique stationary distribution.

The total variation distance d_{tv} of the Markov chain from its stationary distribution π at time t with initial state x is defined by

$$d_{\mathsf{tv}}(P^t_x, \pi) = \frac{1}{2} \sum_{y \in \Omega} |P^t(x, y) - \pi(y)|.$$

For $\varepsilon > 0$, let $\tau_x(\varepsilon)$ denote the least value T such that $d_{\mathsf{tv}}(P^t_x, \pi) \leq \varepsilon$ for all $t \geq T$. The *mixing time* $\tau(\varepsilon)$ is defined by $\tau(\varepsilon) = \max\{\tau_x(\varepsilon) \mid x \in \Omega\}$. We say that a Markov chain is *rapidly mixing* if the mixing time is bounded by a polynomial in n and $\log(\varepsilon^{-1})$, where n is the size of each configuration in Ω.

2.3 Symmetries in Logic and Probability

Algorithms that leverage model symmetries to solve computationally challenging problems more efficiently exist in several fields. Most of the work is related to the computation of symmetry breaking predicates to improve SAT solver performance [7, 2]. The construction of our symmetry detection approach is largely derived from that of symmetry detection in propositional theories [7, 2]. More recently, similar symmetry detection approaches have been put to work for answer set programming [11] and integer linear programming [34]. Poole introduced the notion of lifted probabilistic inference as a variation of variable elimination taking advantage of the symmetries in graphical models resulting from probabilistic relational formalisms [36]. Following Poole's work, several algorithms for lifted probabilistic inference were developed such as lifted and counting belief propagation [41, 22], bi-simulation-based approximate inference [40], general purpose MCMC algorithm for relational models [29] and, more recently, first-order knowledge compilation techniques [44, 16]. In contrast to existing methods, we present an approach that is applicable to a much larger class of graphical models.

3 Symmetries in Graphical Models

Similar to the method of symmetry detection in propositional formulas [7, 2, 8] we can, for a large class of probabilistic graphical models, construct a colored undirected graph whose automorphism group is equivalent to the permutation group representing the model's symmetries. We describe the approach for sets of partially weighted propositional formulas since Markov logic networks, factor graphs, and the weighted model counting framework can be represented using sets of (partially) weighted formulas [38, 44, 16]. For the sake of readability, we describe the colored graph construction for partially weighted *clauses*. Using a more involved transformation, however, we can extend it to sets of partially weighted formulas. Let $\mathcal{S} = \{(f_i, w_i)\}, 1 \leq i \leq n$, be a set of

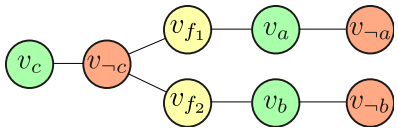

Figure 1: The colored graph resulting from the set of weighted clauses of Example 3.1.

partially weighted clauses with $w_i \in \mathbb{R}$ if f_i is weighted and $w_i = \infty$ otherwise. We define an *automorphism of* $\mathcal{S}$ as a permutation mapping (a) unnegated variables to unnegated variables, (b) negated variables to negated variables, and (c) clauses to clauses, respectively, such that this permutation maps $\mathcal{S}$ to an identical set of partially weighted clauses. The set of these permutations forms the automorphism group of $\mathcal{S}$.

The construction of the colored undirected graph $G(\mathcal{S}) = (V, E)$ proceeds as follows. For each variable a occurring in $\mathcal{S}$ we add two nodes v_a and $v_{\neg a}$ modeling the unnegated and negated variable, respectively, to V and the edge $\{v_a, v_{\neg a}\}$ to E. We assign color 0 (1) to nodes corresponding to negated (unnegated) variables. This coloring precludes permutations that map a negated variable to an unnegated one or vice versa. We introduce a distinct color c_∞ for unweighted clauses and a color c_w for each distinct weight w occurring in $\mathcal{S}$. For each clause f_i with weight $w_i = w$ we add a node v_{f_i} with color c_w to V. For each unweighted clause f_i we add a node v_{f_i} with color c_∞ to V. Finally, we add edges between each clause node v_{f_i} and the nodes of the negated and unnegated variables occurring in f_i. Please note that we can incorporate evidence by introducing two novel and distinct colors representing *true* and *false* variable nodes.

Example 3.1. Let $\{f_1 := (a \vee \neg c, 0.5), f_2 := (b \vee \neg c, 0.5)\}$ be a set of weighted clauses. We introduce 6 variable nodes $v_a, v_b, v_c, v_{\neg a}, v_{\neg b}, v_{\neg c}$ where the former three have color 1 (green) and the latter three color 0 (red). We connect the nodes v_a and $v_{\neg a}$; v_b and $v_{\neg b}$; and v_c and $v_{\neg c}$. We then introduce two new clause nodes v_{f_1}, v_{f_2} both with color 2 (yellow) since they have the same weight. We finally connect the variable nodes with the clause nodes they occur in. Figure 1 depicts the resulting colored graph. A generating set of $\mathsf{Aut}(G(\mathcal{S}))$, the automorphism group of this particular colored graph, is $\{(v_a\ v_b)(v_{\neg a}\ v_{\neg b})(v_{f_1}\ v_{f_2})\}$.

The following theorem states the relationship between the automorphisms of $\mathcal{S}$ and the colored graph $G(\mathcal{S})$.

Theorem 3.2. *Let* $\mathcal{S} = \{(f_i, w_i)\}, 1 \leq i \leq n$, *be a set of partially weighted clauses and let* $\mathsf{Aut}(G(\mathcal{S}))$ *be the automorphism group of the colored graph constructed for* $\mathcal{S}$. *There is a one-to-one correspondence between* $\mathsf{Aut}(G(\mathcal{S}))$ *and the automorphism group of* $\mathcal{S}$.

Given a set of partially weighted clauses $\mathcal{S}$ with variables $\mathbf{X}$ we have, by Theorem 3.2, that if we define a distribution Pr over random variables $\mathbf{X}$ with features f_i and weights w_i, $1 \leq i \leq n$, then $\mathsf{Aut}(G(\mathcal{S}))$ is an automorphism group for $(\{0,1\}^{\mathbf{X}}, \Pr)$. Hence, we can use the method to find symmetries in a large class of graphical models. The complexity of computing generating sets of $\mathsf{Aut}(G(\mathcal{S}))$ is in NP and not known to be in P or NP-complete. For graphs with bounded degree the problem is in P [25]. There are specialized algorithms for finding generating sets of automorphism groups of colored graphs such as Saucy[8] and Nauty[28] with remarkable performance. We will show that Saucy computes *irredundant* sets of generators of automorphism groups for graphical models with millions of variables. The size of these generating sets is bounded by the number of graph vertices.

We briefly position the symmetry detection approach in the context of existing algorithms and concepts.

3.1 Lifted Message Passing

There are two different lifted message passing algorithms. Lifted First-Order Belief Propagation [41] operates on Markov logic networks whereas Counting Belief Propagation [22] operates on factor graphs. Both approaches leverage symmetries in the model to partition variables and features into equivalence classes. Each variable class (supernode/clusternode) contains those variable nodes that would send and receive the same messages were (loopy) belief propagation (BP) run on the original model. Each feature class (superfeature/clusterfactor) contains factor nodes that would send and receive the same BP messages.

The colored graph construction provides an alternative approach to partitioning the variables and features of a graphical model. We simply compute the *orbit partition* induced by the permutation group $\mathsf{Aut}(G(\mathcal{S}))$ acting on the set of variables and features. For instance, the orbit partition of Example 3.1 is $\{\{a, b\}, \{c\}, \{f_1, f_2\}\}$. In general, orbit partitions have the following properties: For two variables v_1, v_2 in the same orbit we have that (a) v_1 and v_2 have identical marginal probabilities and (b) the variable nodes corresponding to v_1 and v_2 would send and receive the same messages were BP run on the original model; and for two features f_1 and f_2 in the same orbit we have that the factor nodes corresponding to f_1 and f_2 would send and receive the same BP messages.

3.2 Finite Partial Exchangeability

The notion of exchangeability was introduced by de Finetti [14]. Several theorems concerning finite (partial) exchangeability have been stated [10, 14]. Given

a finite sequence of n binary random variables $\mathbf{X}$, we say that $\mathbf{X}$ is *exchangeable* with respect to the distribution Pr if, for every $\mathbf{x} \in \{0,1\}^n$ and *every* permutation $\mathfrak{g}$ acting on $\{0,1\}^n$, we have that $\Pr(\mathbf{X} = \mathbf{x}) = \Pr(\mathbf{X} = \mathbf{x}^{\mathfrak{g}})$. This is equivalent to saying that the symmetric group $\mathsf{Sym}(n)$ is an automorphism group for $(\{0,1\}^n, \Pr)$. Whenever we have finite exchangeability, there are $n+1$ orbits each containing the variable assignments with Hamming weight $i, 0 \leq i \leq n$. Hence, every exchangeable probability distribution over n binary random variables is a unique mixture of draws from the $n+1$ orbits. In some cases of partial exchangeability, namely when the orbits can be specified using a *statistic*, one can use this for a more compact representation of the distribution as a product of mixtures [10]. The symmetries that have to be present for such a re-parameterization to be feasible, however, are rare and constitute one end of the symmetry spectrum.

Therefore, a central question is how *arbitrary symmetries*, compactly represented with irredundant generators of permutation groups, can be utilized for efficient probabilistic inference algorithms that go beyond (a) single variable marginal inference via lifted message passing and (b) the limited applicability of finite partial exchangeability. In order to answer this question, we turn to the major contribution of the present work.

4 Orbital Markov Chains

Inspired by the previous observations, we introduce *orbital Markov chains*, a novel family of Markov chains. An orbital Markov chain is always derived from an existing Markov chain so as to leverage the symmetries in the underlying model. In the presence of symmetries orbital Markov chains are able to perform wide-ranging transitions reducing the time until convergence. In the absence of symmetries they are equivalent to the original Markov chains. Orbital Markov chains only require a generating set of a permutation group $\mathfrak{G}$ acting on the chain's state space as additional input. As we have seen, these sets of generators are computable with graph automorphism algorithms.

Let Ω be a finite set, let $\mathcal{M}' = (X'_0, X'_1, ...)$ be a Markov chain with state space Ω, let π be a stationary distribution of $\mathcal{M}'$, and let $\mathfrak{G}$ be an automorphism group for (Ω, π). The *orbital Markov chain* $\mathcal{M} = (X_0, X_1, ...)$ *for* $\mathcal{M}'$ is a Markov chain which at each integer time $t+1$ performs the following steps:

1. Let X'_{t+1} be the state of the original Markov chain $\mathcal{M}'$ at time $t+1$;
2. Sample X_{t+1}, the state of the orbital Markov chain $\mathcal{M}$ at time $t+1$, uniformly at random from ${X'}_{t+1}^{\mathfrak{G}}$, the orbit of X'_{t+1}.

The orbital Markov chain $\mathcal{M}$, therefore, runs at every time step $t \geq 1$ the original chain $\mathcal{M}'$ first and samples the state of $\mathcal{M}$ at time t uniformly at random from the orbit of the state of the original chain $\mathcal{M}'$ at time t.

First, let us analyze the complexity of the second step which differs from the original Markov chain. Given a state X_t and a permutation group $\mathfrak{G}$ we need to sample an element from ${X_t}^{\mathfrak{G}}$, the orbit of X_t, uniformly at random. By the orbit-stabilizer theorem this is equivalent to sampling an element $\mathfrak{g} \in \mathfrak{G}$ uniformly at random and computing ${X_t}^{\mathfrak{g}}$. Sampling group elements nearly uniform at random is a well-researched problem [6] and computable in polynomial time in the size of the generating sets with product replacement algorithms [35]. These algorithms are implemented in several group algebra systems such as GAP[15] and exhibit remarkable performance. Once initialized, product replacement algorithms can generate pseudo-random elements by performing a small number of group multiplications. We could verify that the overhead of step 2 during the sampling process is indeed negligible.

Before we analyze the conditions under which orbital Markov chains are aperiodic, irreducible, and have the same stationary distribution as the original chain, we provide an example of an orbital Markov chain that is based on the standard Gibbs sampler which is commonly used to perform probabilistic inference.

Example 4.1. Let $\mathbf{V}$ be a finite set of random variables with probability distribution π, and let $\mathfrak{G}$ be an automorphism group for $(\times_{V \in \mathbf{V}} V, \pi)$. The orbital Markov chain for the *Gibbs sampler* is a Markov chain $\mathcal{M} = (X_0, X_1, ...)$ which, being in state X_t, performs the following steps at time $t+1$:

1. Select a variable $V \in \mathbf{V}$ uniformly at random;
2. Sample $X'_{t+1}(V)$, the value of V in the configuration X'_{t+1}, according to the conditional π-distribution of V given that all other variables take their values according to X_t;
3. Let $X'_{t+1}(W) = X_t(W)$ for all variables $W \in \mathbf{V} \setminus \{V\}$; and
4. Sample X_{t+1} from ${X'}_{t+1}^{\mathfrak{G}}$, the orbit of X'_{t+1}, uniformly at random.

We call this Markov chain the *orbital Gibbs sampler*. In the absence of symmetries, that is, if $\mathfrak{G}$'s only element is the identity permutation, the orbital Gibbs sampler is equivalent to the standard Gibbs sampler.

Let us now state a major result of this paper. It relates properties of the orbital Markov chain to those of the Markov chain it is derived from. A detailed proof can be found in the appendix.

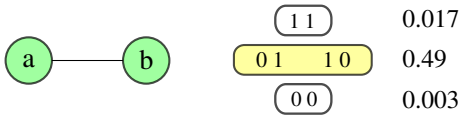

Figure 2: An undirected graphical model over two binary variables and one symmetric potential function with corresponding distribution shown on the right. There are three orbits each indicated by one of the rounded rectangles.

Theorem 4.2. *Let Ω be a finite set and let $\mathcal{M}'$ be a Markov chain with state space Ω and transition matrix P'. Moreover, let π be a probability distribution on Ω, let $\mathfrak{G}$ be an automorphism group for (Ω, π), and let $\mathcal{M}$ be the orbital Markov chain for $\mathcal{M}'$. Then,*

(a) if $\mathcal{M}'$ is aperiodic then $\mathcal{M}$ is also aperiodic;

(b) if $\mathcal{M}'$ is irreducible then $\mathcal{M}$ is also irreducible;

(c) if π is a reversible distribution for $\mathcal{M}'$ and, for all $\mathfrak{g} \in \mathfrak{G}$ and all $x, y \in \Omega$ we have that $P'(x, y) = P'(x^{\mathfrak{g}}, y^{\mathfrak{g}})$, then π is also a reversible and, hence, a stationary distribution for $\mathcal{M}$.

The condition in statement (c) requiring for all $\mathfrak{g} \in \mathfrak{G}$ and all $x, y \in \Omega$ that $P'(x, y) = P'(x^{\mathfrak{g}}, y^{\mathfrak{g}})$ conveys that the original Markov chain is compatible with the symmetries captured by the permutation group $\mathfrak{G}$. This rather weak assumption is met by all of the practical Markov chains we are aware of and, in particular, Metropolis chains and the standard Gibbs sampler.

Corollary 4.3. *Let $\mathcal{M}'$ be the Markov chain of the Gibbs sampler with reversible distribution π. The orbital Gibbs sampler for $\mathcal{M}'$ is aperiodic and has π as a reversible and, hence, a stationary distribution. Moreover, if $\mathcal{M}'$ is irreducible then the orbital Gibbs sampler is also irreducible and it has π as its unique stationary distribution.*

We will show both analytically and empirically that, in the presence of symmetries, the orbital Gibbs sampler converges at least as fast or faster to the true distribution than state of the art sampling algorithms. First, however, we want to take a look at an example that illustrates the advantages of the orbital Gibbs sampler.

Example 4.4. Consider the undirected graphical model in Figure 2 with two binary random variables and a symmetric potential function. The probabilities of the states 01 and 10 are both 0.49. Due to the symmetry in the model, the states 10 and 01 are part of the same orbit. Now, let us assume a standard Gibbs sampler is in state 10. The probability for it to transition to one of the states 11 and 00 is only 0.02 and, by definition of the standard Gibbs sampler, it cannot transition directly to the state 01. The chain is "stuck" in the state 10 until it is able to move to 11 or 00. Now, consider the orbital Gibbs sampler. Intuitively, while it is "waiting" to move to one of the low probability states, it samples the two high probability states horizontally uniformly at random from the orbit $\{01, 10\}$. In this particular case the orbital Gibbs sampler converges faster than the standard Gibbs sampler, a fact that we will also show analytically.

4.1 Mixing Time of Orbital Markov Chains

We will make our intuition about the faster convergence of the orbital Gibbs sampler more concrete. We accomplish this by showing that the more symmetry there is in the model the faster a coupling of the orbital Markov chain will coalesce and, therefore, the faster the chain will converge to its stationary distribution.

There are several methods available to prove rapid mixing of a finite Markov chain. The method we will use here is that of a *coupling*. A coupling for a Markov chain $\mathcal{M}$ is a stochastic process (X_t, Y_t) on $\Omega \times \Omega$ such that (X_t) and (Y_t) considered marginally are *faithful copies* of $\mathcal{M}$. The *coupling lemma* expresses that the total variation distance of $\mathcal{M}$ at time t is limited from above by the probability that the two chains have not *coalesced*, that is, have not met at time t (see for instance Aldous [1]). Coupling proofs on the joint space $\Omega \times \Omega$ are often rather involved and require complex combinatorial arguments. A possible simplification is provided by the *path coupling* method where a coupling is only required to hold on a subset of $\Omega \times \Omega$ (Bubley and Dyer [4]). The following theorem formalizes this idea.

Theorem 4.5 (Dyer and Greenhill [12])**.** *Let δ be an integer valued metric defined on $\Omega \times \Omega$ taking values in $\{0, ..., D\}$. Let $S \subseteq \Omega \times \Omega$ such that for all $(X_t, Y_t) \in \Omega \times \Omega$ there exists a path $X_t = Z_0, ..., Z_r = Y_t$ between X_t and Y_t with $(Z_l, Z_{l+1}) \in S$ for $0 \leq l \leq r$ and*

$$\sum_{l=0}^{r-1} \delta(Z_l, Z_{l+1}) = \delta(X_t, Y_t).$$

Define a coupling $(X, Y) \to (X', Y')$ of the Markov chain $\mathcal{M}$ on all pairs $(X, Y) \in S$. Suppose there exists $\beta \leq 1$ with $\mathbf{E}[\delta(X', Y')] \leq \beta\delta(X, Y)$ for all $(X, Y) \in S$. If $\beta < 1$ then the mixing time $\tau(\varepsilon)$ of $\mathcal{M}$ satisfies

$$\tau(\varepsilon) \leq \frac{\ln(D\varepsilon^{-1})}{1 - \beta}.$$

If $\beta = 1$ and there exists an $\alpha > 0$ such that $\Pr[\delta(X_{t+1}, Y_{t+1}) \neq \delta(X_t, Y_t)] \geq \alpha$ for all t, then

$$\tau(\varepsilon) \leq \left\lceil \frac{eD^2}{\alpha} \right\rceil \left\lceil \ln(\varepsilon^{-1}) \right\rceil.$$

We selected the *insert/delete* Markov chain for independent sets of graphs for our analysis. Sampling independent sets is a classical problem motivated by numerous applications and with a considerable amount of recent research devoted to it [24, 13, 45, 42, 37]. The coupling proof for the orbital version of this Markov chain provides interesting insights into the construction of such a coupling and the influence of the graph symmetries on the mixing time. The proof strategy is in essence applicable to other sampling algorithms.

Let $G = (V, E)$ be a graph. A subset X of V is an *independent set* if $\{v, w\} \notin E$ for all $v, w \in X$. Let $\mathcal{I}(G)$ be the set of all independent sets in a given graph G and let λ be a positive real number. The partition function $Z = Z(\lambda)$ and the corresponding probability measure π_λ on $\mathcal{I}(G)$ are defined by

$$Z = Z(\lambda) = \sum_{X \in \mathcal{I}(G)} \lambda^{|X|} \quad \text{and} \quad \pi_\lambda(X) = \frac{\lambda^{|X|}}{Z}.$$

Approximating the partition function and sampling from $\mathcal{I}(G)$ can be accomplished using a rapidly mixing Markov chain with state space $\mathcal{I}(G)$ and stationary distribution π_λ. The simplest Markov chain for independent sets is the so-called *insert/delete* chain [13]. If X_t is the state at time t then the state at time $t+1$ is determined by the following procedure:

1. Select a vertex $v \in V$ uniformly at random;
2. If $v \in X_t$ then let $X_{t+1} = X_t \backslash \{v\}$ with probability $1/(1+\lambda)$;
3. If $v \notin X_t$ and v has no neighbors in X_t then let $X_{t+1} = X_t \cup \{v\}$ with probability $\lambda/(1+\lambda)$;
4. Otherwise let $X_{t+1} = X_t$.

Using a path coupling argument one can show that the *insert/delete* chain is rapidly mixing for $\lambda \leq 1/(\Delta - 1)$ where Δ is the maximum degree of the graph [13]. We can turn the *insert/delete* Markov chain into the orbital *insert/delete* Markov chain $\mathcal{M}(\mathcal{I}(G))$ simply by adding the following fifth step:

5. Sample X_{t+1} uniformly at random from its orbit.

By Corollary 4.3 the orbital *insert/delete* chain for independent sets is aperiodic, irreducible, and has π_λ as its unique stationary distribution. We can now state the following theorem concerning the mixing time of this Markov chain. It relates the graph symmetries to the mixing time of the chain. The proof of the theorem is based on a path coupling that is constructed so as to make the two chains coalesce whenever their respective states are located in the same orbit. A detailed and instructive proof can be found in the appendix.

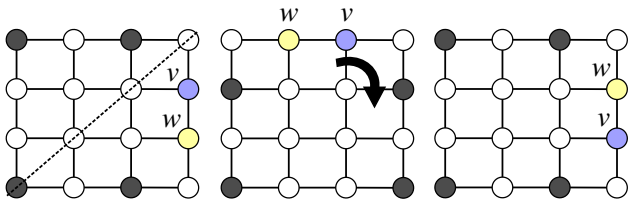

Figure 3: Two independent sets $X \cup \{v\}$ and $X \cup \{w\}$ of the 4x4 grid located in the same orbit. The first permutation is the reflection on the sketched diagonal the second a clockwise 90° rotation.

Theorem 4.6. *Let $G = (V, E)$ be a graph with maximum degree Δ, let λ be a positive real number, and let $\mathfrak{G}$ be an automorphism group for $(\{0,1\}^V, \pi_\lambda)$. Moreover, let $(X \cup \{v\}) \in \mathcal{I}(G)$, let $(X \cup \{w\}) \in \mathcal{I}(G)$, let $\{v, w\} \in E$, and let $\rho = \Pr[(X \cup \{v\}) \notin (X \cup \{w\})^{\mathfrak{G}}]$. The orbital* insert/delete *chain $\mathcal{M}(\mathcal{I}(G))$ is rapidly mixing if either $\rho \leq 0.5$ or $\lambda \leq 1/((2\rho - 1)\Delta - 1)$.*

The theorem establishes the important link between the graph automorphisms and the mixing time of the orbital *insert/delete* chain. The more symmetries the graph exhibits the larger the orbits and the sooner the chains coalesce. Figure 3 depicts the 4x4 grid with two independent sets $X \cup \{v\}$ and $X \cup \{w\}$ with $\{v, w\} \in E$ and $(X \cup \{v\}) \in (X \cup \{w\})^{\mathfrak{G}}$. Since $\rho < 1$ for nxn grids, $n \geq 4$, we can prove (a) rapid mixing of the orbital *insert/delete* chain for larger λ values and (b) more rapid mixing for identical λ values.

The next corollary follows from Theorem 4.6 and the simple fact that $X' \in X^{\mathfrak{G}}$ for all $X \subseteq V, X' \subseteq V$ with $|X| = |X'|$ whenever $\mathfrak{G}$ is the symmetric group on V.

Corollary 4.7. *Let $G = (V, E)$ be a graph, let λ be a positive real number, and let $\mathfrak{G}$ be an automorphism group for $(\{0,1\}^V, \pi_\lambda)$. If $\mathfrak{G}$ is the symmetric group $\mathsf{Sym}(V)$ then $\mathcal{M}(\mathcal{I}(G))$ is rapidly mixing with $\tau(\varepsilon) \leq |V| \ln(|V|\varepsilon^{-1})$.*

By analyzing the coupling proof of Theorem 4.6 and, in particular, the moves leading to states (X', Y') with $|X'| = |Y'|$ and the probability that X' and Y' are located in the same orbit in these cases, it is possible to provide more refined bounds. Moreover, to capture the full power of orbital Markov chains, a coupling argument should not merely consider pairs of states with Hamming distance 1. Indeed, the strength of the orbital chains is that, in the presence of symmetries in the graph topology, there is a non-zero probability that states with large Hamming distance (up to $|V|$) are located in the same orbit. The method presented here is also applicable to Markov chains known to mix rapidly for larger λ values than the *insert/delete* chain such as the *insert/delete/drag* chain [13].

5 Experiments

Two graphical models were used to evaluate the symmetry detection approach. The "Friends & Smokers" Markov logic network where for a random 10% of all people it is known (a) whether they smoke or not and (b) who 10 of their friends are [41]. Moreover, we used the kxk grid model, an established and well-motivated lattice model with numerous applications [37]. All experiments were conducted on a PC with an AMD Athlon dual core 5400B 1.0 GHz processor and 3 GB RAM. Table 1 lists the results for varying model sizes. SAUCY's runtime scales roughly quadratic with the number of vertices and it performs better for the kxk grid models. This might be due to the larger sets of generators for the permutation groups of the social network model. Table 1 also lists the number of features of the ground social network model (features), the number of feature orbits without (orbs w/o) and with (orbs w/) 10% evidence.

We proceeded to compare the performance of the orbital Markov chains with state-of-the-art algorithms for sampling independent sets. We used GAP[15], a system for computational discrete algebra, and the ORB package[31][1] to implement the sampling algorithms. The experiments can easily be replicated by installing GAP and the ORB package and by running the GAP files available at a dedicated code repository[2]. For the evaluation of the sampling algorithms we selected three different graph topologies exhibiting varying degrees of symmetry:

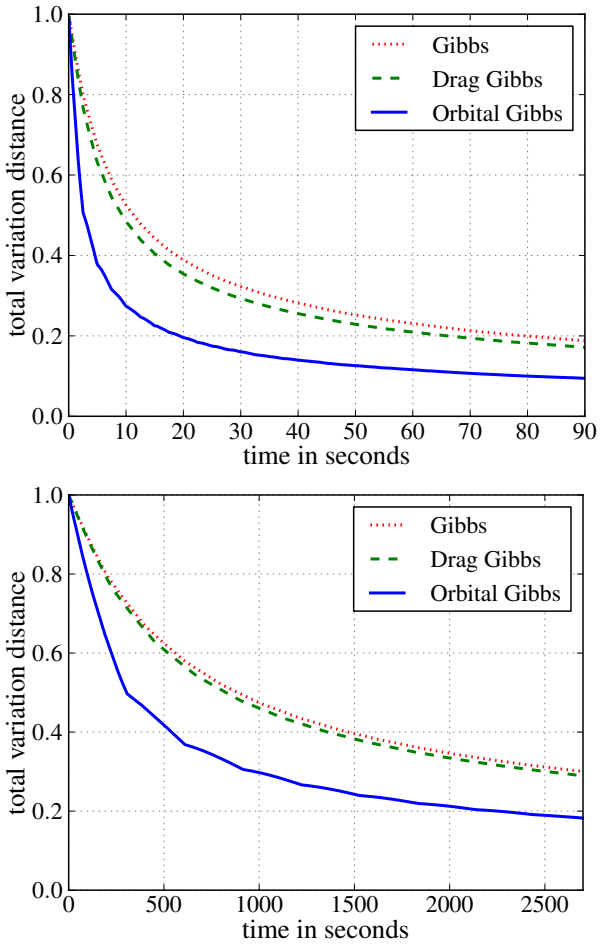

Figure 5: The results of the three Gibbs samplers for the 5-*grid model* (top) and the 6-*grid model* (bottom).

The k-*grid model* is the 2-dimensional kxk grid. An instance of the model for $k = 3$ is depicted in Figure 4 (left). Here, the generating set of the permutation group $\mathfrak{G}$ computed by SAUCY is $\{(a\ c)(d\ f)(g\ i), (a\ i)(b\ f)(d\ h)\}$ and $|\mathfrak{G}| = 8$. The permutation group $\mathfrak{G}$ partitions the set $\{0,1\}^9$ in 102 orbits with each orbit having a cardinality in $\{1, 2, 4, 8\}$.

The k-*connected cliques model* is a graph with $k+1$ distinct cliques each of size $k-1$ and each connected with one edge to the same vertex. Statistical relational formalisms such as Markov logic networks often lead to similar graph topologies. An in-

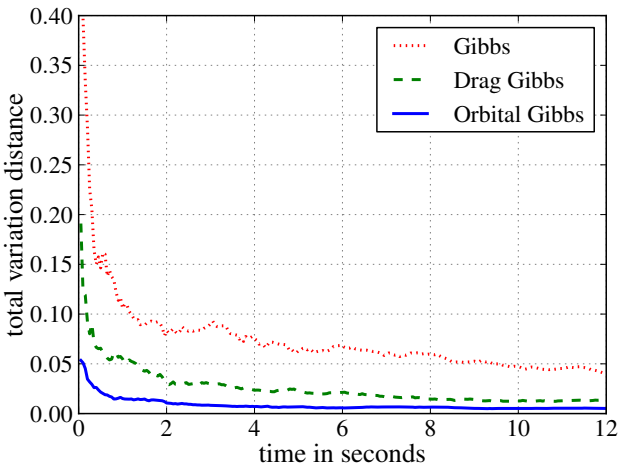

Figure 7: The results of the three Gibbs samplers for the 5-*complete graph* model.

stance for $k = 3$ is depicted in Figure 4 (center). Here, the generating set of $\mathfrak{G}$ computed by SAUCY is $\{(a\ g)(b\ f), (a\ c)(b\ d), (a\ i)(b\ h)\}$ and $|\mathfrak{G}| = 24$. The permutation group $\mathfrak{G}$ partitions the set $\{0,1\}^9$ in 70 orbits with cardinalities in $\{1, 4, 6, 12, 24\}$.

The *k-complete graph model* is a complete graph with k^2 vertices. Figure 4 (right) depicts an instance for $k = 3$. Here, the generating set of $\mathfrak{G}$ computed by SAUCY is $\{(b\ c), (b\ d), (b\ e), (b\ f), (b\ g), (b\ h), (b\ i), (a\ b)\}$ and $|\mathfrak{G}| = 9! = 362880$. The permutation group $\mathfrak{G}$ partitions the set $\{0,1\}^9$ in 10 orbits with each orbit having a cardinality in $\{1, 9, 36, 84, 126\}$.

SAUCY needed at most 5 ms to compute the sets of generators for the permutation groups of the three models for $k = 6$. We generated samples of the probability measure π_λ on $\mathcal{I}(G)$ for $\lambda = 1$ and the three different graph topologies by running (a) the *insert/delete* chain, (b) the *insert/delete/drag* chain [13], and (c) the orbital *insert/delete* chain. Each chain was started in the state corresponding to the empty set and no burn-in period was used. The orbital *insert/delete* chain did not require more RAM and needed 50 microseconds per sample which amounts to an overhead of about 25% relative to the 40 microseconds of the *insert/delete* chain. The 25% overhead remained constant and independent of the size of the graphs. Since the sampling algorithms create large files with all accumulated samples, I/O overhead is included in these times. For each of the three topologies and each of the three Gibbs samplers, we computed the total variation distance between the distribution approximated using *all* accumulated samples and the true distribution π_1. Figure 5 plots the total variation distance over elapsed time for the *k-grid model* for $k = 5$ and $k = 6$. The orbital *insert/delete* chain (Orbital Gibbs) converges the fastest. The *insert/delete/drag* chain (Drag Gibbs) converges faster than the *insert/delete* chain (Gibbs) but since there is a small computational overhead of the *insert/delete/drag* chain the difference is less pronounced for $k = 6$. The same results are observable for the other graph topologies (see Figures 6 and 7) where the orbital Markov chain outperforms the others. In summary, the larger the cardinalities of the orbits induced by the symmetries the faster converges the orbital Gibbs sampler relative to the other chains.

6 Discussion

The mindful reader might have recognized a similarity to *lumping* of Markov chains which amounts to partitioning the state space of the chain [5]. Computing the coarsest lumping quotient of a Markov chain with a bisimulation procedure is linear in the *number of nonzero probability transitions* of the chain and, hence, in most cases exponential in the number of random variables. Since merely counting equivalence classes in the Pólya theory setting is a #P-complete problem [18] there are clear computational limitations to this approach. Orbital Markov chains, on the other hand, combine the advantages of a compact representation of symmetries as generating sets of permutation groups with highly efficient product replacement algorithms and, therefore, provide the advantages of *lumping* while avoiding the intractable explicit computation of the partition of the state space.

One can apply orbital Markov chains to other graphical models that exhibit symmetries such as the Ising model. Since Markov chains in general and Gibbs samplers in particular are components in numerous algo-

rithms (cf. [43, 20, 38, 19, 23, 3]), we expect orbital Markov chains to improve the algorithms' performance when applied to problems that exhibit symmetries. For instance, sampling algorithms for statistical relational languages are obvious candidates for improvement. Future work will include the integration of orbital Markov chains with algorithms for marginal as well as maximum a-posteriori inference. We will also apply the symmetry detection approach to make existing inference algorithms more efficient by, for instance, using symmetry breaking constraints in combinatorial optimization approaches to maximum a-posteriori inference in Markov logic networks (cf. [39, 32, 33]).

While we have shown that permutation groups are computable with graph automorphism algorithms for a large class of models it is also possible to *assume* certain symmetries in the model in the same way (conditional) independencies are assumed in the design stage of a probabilistic graphical model. Orbital Markov chains could easily incorporate these symmetries in form of permutation groups.

Acknowledgments

Many thanks to Guy Van den Broeck, Kristian Kersting, Martin Mladenov, and Babak Ahmadi for insightful discussions concerning lifted inference, to Jürgen Müller for helpful remarks on the product replacement algorithm, and to all those who have contributed to the GAP system and the ORB package.

Abstract

Learning a Bayesian network structure from data is an NP-hard problem and thus exact algorithms are feasible only for small data sets. Therefore, network structures for larger networks are usually learned with various heuristics. Another approach to scaling up the structure learning is local learning. In local learning, the modeler has one or more target variables that are of special interest; he wants to learn the structure near the target variables and is not interested in the rest of the variables. In this paper, we present a score-based local learning algorithm called SLL. We conjecture that our algorithm is theoretically sound in the sense that it is optimal in the limit of large sample size. Empirical results suggest that SLL is competitive when compared to the constraint-based HITON algorithm. We also study the prospects of constructing the network structure for the whole node set based on local results by presenting two algorithms and comparing them to several heuristics.

1 INTRODUCTION

A Bayesian network is a representation of a joint probability distribution. It consists of two parts: the structure and the parameters. The structure of a Bayesian network is represented by a directed acyclic graph (DAG) that expresses the conditional independence relations among variables and the parameters determine the local conditional distributions for each variable.

Structure learning in Bayesian networks, that is, finding a DAG that fits to the data, has drawn lots of interest in recent years. There are two rather distinct approaches to structure learning. In score-based approach (Cooper and Herskovits, 1992; Heckerman et al., 1995) each DAG gets a score based on how well it fits to the data and the goal is to find the DAG that maximizes the score. On the other hand, the constraint-based approach (Pearl, 2000; Spirtes et al., 2000) is based on testing conditional independencies among variables and constructing a DAG that represents these relations. Both approaches are compatible in the sense that (under some general assumptions), no matter which approach one uses, exact algorithms converge to the same DAG when the number of samples tends to infinity.

Structure learning in Bayesian networks is NP-hard (Chickering, 1996; Chickering et al., 2004). Due to the NP-hardness of the problem, it is unlikely that there are exact algorithms that run in polynomial time. Indeed, the fastest exact algorithms (Silander and Myllymäki, 2006) run in exponential time. Although there have been several attempts to scale up the exact algorithms (de Campos et al., 2009; Parviainen and Koivisto, 2009; Jaakkola et al., 2010; Cussens, 2011; Malone et al., 2011), these methods quickly become infeasible with larger datasets.

As the exact algorithms do not work for large data sets, one often has to resort to heuristics. A common strategy is to use different variants of greedy search. An alternative approach to the problem is local learning. When one has a large data set, often it is a case that all variables are not equally interesting. One might have one or a handful of *target variables* and the goal is to learn the structure only in the vicinity of the targets. An example for a problem where local learning is feasible is prediction. If we know the Markov blanket of a target variable, that is, its parents, its children and the parents of its children, the remaining variables do not give any more information. Thus, if it is known that we are going to predict the values of only a handful of variables, we can just learn their Markov blankets and ignore the structure of the rest of the network.

Local learning is not a new approach. There have been several studies especially on constraint-based lo-

cal learning (Nägele et al., 2007; Aliferis et al., 2010a,b). These studies have shown that local learning can be a powerful tool in practice. In this paper we study the prospects of the score-based local learning of Bayesian network structures. We present a *score-based local learning algorithm (SLL)* that is a variant of the generalized local learning (GLL) framework (Aliferis et al., 2010a). Assuming a consistent scoring criterion is used, we conjecture that our algorithm is theoretically sound in the same sense as greedy equivalence search (GES) (Chickering, 2002) and HITON (Aliferis et al., 2010a), that is, it is guaranteed to find the true Markov blanket of the target node when the sample size tends to infinity.

Optimality guarantees in the limit or lack thereof do not tell anything about results with finite sample size. Thus, we conducted experiments and compared our algorithm to other heuristics. Based on the experiments, we found our algorithm promising.

2 PRELIMINARIES

2.1 BAYESIAN NETWORKS

The structure of a Bayesian network is represented by a *directed acyclic graph (DAG)*. Formally, a DAG is a pair (N, A) where N is the node set and A is the arc set. If there is an arc from u to v, that is, $uv \in A$, we say that u is a *parent* of v and v is a *child* of u. If v is either a parent or a child of u, they are said to be *neighbors*. Further, if there is a directed path from u to v in A then v is a *descendant* of u. Nodes v and u are are said to be *spouses* of each other if they have a common child and there is no arc between v and u. We denote the set of the parents of a node v in A by A_v. Further, we use $H^A(v)$ and $S^A(v)$ to denote the sets of the neighbors and spouses of v in A, respectively. When the node set is clear from the context, we identify a DAG by its arc set A. The cardinality of N is denoted by n.

Each node v corresponds to a random variable and the DAG expresses conditional independence assumptions between variables. Random variables u and v are said to be conditionally independent in distribution p given a set S of random variables if $p(u, v|S) = p(u|S)p(v|S)$. A DAG *contains* or *represents* a joint distribution of the random variables if the joint distribution satisfies the *local Markov condition*, that is, every variable is conditionally independent of its non-descendants given its parents. Such a distribution can be specified using local *conditional probability distributions (CPD)* which specify the distribution of a random variable given its parents A_v. CPDs are usually taken from a parameterized class of probability distributions, like discrete or Gaussian distributions. Thus, the CPD of variable v is determined by its parameters θ_v; the type and the number of parameters is specified by the particular class of probability distributions. The parameters of a Bayesian network are denoted by θ which consists of the parameters of each CPD. Finally, a Bayesian network is a pair (A, θ).

A distribution p is said to be *faithful* to a DAG A if all conditional independencies in p are implied by A. We say that a DAG A^p is a *perfect map* of a distribution p if A^p contains p and p is faithful to A^p. By $p[Z]$ we denote the marginal distribution of p on set Z.

The conditional independencies implied by a DAG can be extracted using a d-separation criterion; this is equivalent to local Markov condition. The *skeleton* of a DAG A is an undirected graph that is obtained by replacing all directed arcs $uv \in A$ with undirected edges between u and v. A *path* in a DAG is a cycle-free sequence of edges in the corresponding skeleton. A node v is a *head-to-head node* along a path if there are two consecutive arcs uv and wv on that path. Nodes v and u are *d-connected* by nodes Z along a path from v to u if every head-to-head node along the path is in Z or has a descendant in Z and none of the other nodes along the path is in Z. Nodes v and u are *d-separated* by nodes Z if they are not d-connected by Z along any path from v to u. If A^p is a perfect map of p then v and u are conditionally independent give Z in p if and only if v and u are d-separated by Z in A^p. If v and u are conditionally independent in p given Z we use notation $v \perp\!\!\!\perp_p u|Z$.

The *Markov blanket* of node v is the smallest node set S such that v is conditionally independent of all other nodes given S. The Markov blanket of node v consists of the parents of v, the children of v, and the spouses of v.

Nodes s, t, and u form a *v-structure* in a DAG if s and t are spouses and u is their common child. A v-structure is denoted by (s, u, t). Two DAGs are said to be *Markov equivalent* if they can contain the same set of distributions, or equivalently, imply the same set of conditional independence statements. It can be shown that two DAGs are Markov equivalent if and only if they have the same skeleton and same v-structures (Verma and Pearl, 1990).

2.2 CONSISTENT SCORING CRITERION

Score-based structure learning methods in Bayesian networks assign a score to each DAG based on how well the DAG fits to the data according to some statistical principle. A function $f(A, D)$ that assigns the score to a DAG A based on the data D is called a *scoring criterion*. A scoring criterion is *decomposable* if the score of a DAG is a sum of local scores that only depend

on a node and its parents. A local score function is denoted by $f(v, A_v, D_v, D_{A_v})$, where D_v and D_{A_v} are the data on a node v and a node set A_v, respectively. Now, a decomposable score for a DAG A can be written as

$$f(A, D) = \sum_{v \in N} f(v, A_v, D_v, D_{A_v}).$$

Let the data D consists of m independent and identically distributed (i.i.d.) samples from a distribution p on N. A scoring criterion f is said to be *consistent* if in the limit as m grows, the following two properties hold:

1. If A' contains p and A does not, then $f(A', D) > f(A, D)$.
2. If A' and A both contain p, and A' has fewer parameters, then $f(A', D) > f(A, D)$.

A related and in our case more useful property is local consistency. Let A be any DAG and A' be the DAG that results from adding the arc uv to A. A scoring criterion f is said to be *locally consistent* if in the limit as m grows, the following two properties hold for all u and v:

1. If $u \not\perp\!\!\!\perp_p v | A_v$, then $f(A', D) > f(A, D)$.
2. If $u \perp\!\!\!\perp_p v | A_v$, then $f(A', D) < f(A, D)$.

Intuitively, adding an arc that eliminates an independence constraint that does not hold in the data-generating distribution increases the score, and adding an arc that does not eliminate such a constraint decreases the score.

A scoring criterion is said to be *score equivalent* if two Markov equivalent DAGs always have the same score. With a score equivalent scoring criterion one can learn a structure of a Bayesian network up to an equivalence class but cannot distinguish the DAGs inside the class.

For example, commonly used BDeu score is locally consistent (Chickering, 2002) and score equivalent (Heckerman et al., 1995).

2.3 STRUCTURE DISCOVERY PROBLEM

The problem of structure discovery in Bayesian networks is to find, given data D, a DAG that in some sense is the best representation of the data. We call this global learning. In score-based approach the goodness of a DAG is measured by the score $f(A, D)$. In constraint-based approach one would like to find a DAG that is a perfect map of the data-generating distribution.

In the local learning problem the output is the neighbor and/or spouse sets for a target node, not a DAG. The goodness of the result can be measured by comparing learned neighbor and spouse sets to the corresponding sets in the A^p, the perfect map of the data-generating distribution. Note that this comparison can be made only if A^p is known.

3 LOCAL LEARNING ALGORITHM

In this section, we present a score-based local learning algorithm algorithm (SLL) that finds the Markov blanket of a given target node. SLL works in two phases: First, one learns the neighbors of the target and then the rest of the Markov blanket. SLL is a score-based variant of the constraint-based local learning algorithm by Aliferis et al. (2010a,b); the main difference between SLL and the algorithm by Aliferis et al. is that they use independence tests to identify the neighbors and spouses whereas we recognize them from optimal Bayesian networks. In this section, we also analyze the behavior of the algorithm in the limit. We also consider constructing a Bayesian network for the whole node set using the local structures that have been found.

3.1 FINDING PARENTS AND CHILDREN

We start by learning the potential neighbors of a target node. The idea of the algorithm is as follows. The input of the algorithm consists of the data D on the node set N and a target node $t \in N$. During the execution of the algorithm, we update two sets: Set O consists of the nodes that have not been analyzed yet and set H consists of nodes that are currently considered as potential neighbors of t. In the beginning, set H is empty and O contains all nodes but t. After the initialization, nodes in O are considered one by one: One learns an optimal DAG on the target, the current set of its potential neighbors and the new node under consideration. For the structure learning we use a subroutine OptimalNetwork which returns the highest scoring DAG on a given node set. The subroutine can use the dynamic programming algorithm of Silander and Myllymäki (2006) or any other exact algorithm. After an optimal DAG is found, the nodes that are the neighbors of t in that particular DAG form a new set of potential neighbors and the rest of the nodes are discarded. After all nodes are either discarded or in the set of potential neighbors, the set of the potential neighbors is returned.

The pseudocode of the above procedure is shown in Algorithm 1.

Next, we will show that if the data was generated from

Algorithm 1 FindPotentialNeighbors

Input: Data D on node set N, a target node $t \in N$.
Output: The potential neighbors of t.

Initialization: $O \leftarrow N \setminus \{t\}$, $H(t) \leftarrow \emptyset$
while O is nonempty **do**
  Choose $v \in O$
  $O \leftarrow O \setminus \{v\}$
  $Z \leftarrow \{t, v\} \cup H(t)$
  $A \leftarrow \text{OptimalNetwork}(Z, D_Z)$
  $H(t) \leftarrow H^A(t)$
end while
return $H(t)$

a distribution p, Algorithm 1 is guaranteed to find all correct neighbors, that is, all nodes that are neighbors of t in A^p will be included in $H(t)$ in the limit. The guarantee holds under the following assumptions.

Assumption 1. *The data D consists of i.i.d. samples from a distribution p that is faithful to a DAG A^p.*

Assumption 2. *The procedure* OptimalNetwork *uses a locally consistent and score equivalent scoring criterion.*

Lemma 3. *Let $H^{A^p}(t)$ be the neighbors of the target t in A^p. When Assumptions 1 and 2 hold, Algorithm 1 will return a set $H(t)$ such that $H^{A^p}(t) \subseteq H(t)$.*

Proof. If nodes t and v are not conditionally independent in p given any set $X \subseteq N \setminus \{t, v\}$, then any Bayesian network that contains p must have an arc between t and v. Thus, if we have two networks A and A' on $Y \cup \{t, v\}$ such that A' has an arc between t and v and A has not and otherwise they are the same, then by the local consistency, A' has higher score than A. Thus, the highest scoring network must have an arc between t and v. As the above reasoning applies to every set $Y \subseteq N \setminus \{t, v\}$, v will be in $H(t)$ when Algorithm 1 stops. □

Based on the previous lemma we know that if a node v is a neighbor of a node t in A^p, then it will be in $H(t)$. However, we have no guarantees that no nodes that are non-adjacent to t in A^p are included in $H(t)$. Indeed, Aliferis et al. (2010a) point out that if we have a perfect map A^p described in Figure 1 an extra node might be added to $H(t)$. To see this, assume that t is our target and its true neighbors u and s are in $H(t)$ and w has been discarded. Then $t \not\perp\!\!\!\perp_p v|X$ for all $X \subseteq \{u, s\}$ and thus, by local consistency, adding an arc between t and v always increases the score and therefore it is always included in the optimal DAG.

The neighbor relation is symmetric: if v is a child of t then t is a parent of v. This allows us to try to remove

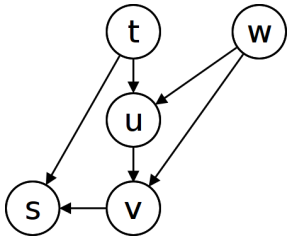

Figure 1: A DAG where non-adjacent nodes t and v are not conditionally independent given any subset of the neighbors of t.

extra nodes from $H(t)$ using a simple symmetry correction in similar fashion as Aliferis et al. (2010a): t and v are neighbors in A^p only if both v is a potential neighbor of t and t is a potential neighbor of v. Algorithm 2 uses symmetry correction to find the neighbors of a target node.

Algorithm 2 FindNeighbors

Input: Data D on node set N, a target node $t \in N$.
Output: The neighbors of t.

$H^*(t) \leftarrow \text{FindPotentialNeighbors}(D, t)$
for all $v \in H^*(t)$ **do**
  $H(v) \leftarrow \text{FindPotentialNeighbors}(D, v)$
  if $t \notin H(v)$ **then**
    $H^*(t) \leftarrow H^*(t) \setminus \{v\}$
  end if
end for
return $H^*(t)$

To analyze the optimality of the algorithm, we use the below lemma which shows that if t and v are not neighbors in A^p but they are dependent given every subset of the neighbors of t then they are conditionally independent given some subset of the neighbors of v. Formally, let $E^{A^p}(t)$ be the set consisting of the nodes $v \in N \setminus \{t\}$ such that $t \not\perp\!\!\!\perp_p v|X$ for all $X \subseteq H^{A^p}(t)$.

Lemma 4 (Aliferis et al. (2010a), Lemma 2)**.** *If $v \in E^{A^p}(t) \setminus H^{A^p}(t)$, then $t \notin E^{A^p}(v) \setminus H^{A^p}(v)$.*

However, it is not clear whether the output of Algorithm 1 is a subset of the the nodes that are conditionally dependent on t given any subset of the neighbors of t. As we are not aware of any counterexamples, we conjecture the follows.

Conjecture 5. *Let $H(t)$ be the output of Algorithm 1. Then $H(t) \subseteq E^{A^p}(t)$.*

The next lemma shows the optimality of Algorithm 2 in the limit assuming Conjecture 5 holds.

Lemma 6. *Let $H^{A^p}(t)$ be the neighbors of the target t in A^p. When Assumptions 1 and 2 and Conjecture 5*

hold, Algorithm 2 will return a set $H^*(t)$ such that $H^*(t) = H^{A^p}(t)$.

Proof. First, let us prove that $H^{A^p}(t) \subseteq H^*(t)$. By Lemma 3, $H^{A^p}(t) \subseteq H(t)$ and $H^{A^p}(v) \subseteq H(v)$ for all v. Thus, if $v \in H^{A^p}(t)$ then $v \in H(t)$ and $t \in H(v)$.

Let us prove that $H^*(t) \subseteq H^{A^p}(t)$. By Conjecture 5 we observe that $H(t) \subseteq E^{A^p}(t)$. Suppose that we have nodes $t, v \in N$ such that $v \in H(t)$ and $t \perp\!\!\!\perp_p v|X$ for some $X \subseteq N \setminus \{t, v\}$. Therefore, it must be that $v \in E^{A^p}(t)$ and $v \notin H^{A^p}(t)$. Thus, $v \in E^{A^p}(t) \setminus H^{A^p}(t)$. By Lemma 4, we have that $t \notin E^{A^p}(v) \setminus H^{A^p}(v)$. By symmetry, $t \notin H^{A^p}(v)$ and thus $t \notin E^{A^p}(v)$. Therefore, $t \notin H(v)$ and Algorithm 2 does not include t and v as neighbors of each other.

□

3.2 FINDING THE MARKOV BLANKET

Learning the spouses of the target t is quite similar to the learning the neighbors of t. In addition to the data D and target node t we take as input the set $H^*(t)$, learned by Algorithm 2, consisting of the neighbors of t. The set $S(t)$ will consist the potential spouses of t. As all potential spouses are neighbors of a neighbor of t, we need to go through only a subset of all nodes. The set of neighbors $H^*(t)$ is fixed and we keep updating the set $S(t)$. All nodes that have a common child with t and are not neighbors of t are kept in and the rest are discarded. Again, the nodes that remain in $S(t)$ once all nodes have been considered, are considered potential spouses of t.

The procedure is summarized in Algorithm 3.

Algorithm 3 FINDPOTENTIALSPOUSES

Input: Data D on node set N, a target node $t \in N$, neighbors of the target $H^*(t)$.
Output: Potential spouses of t.

Find set H': the neighbors of the nodes in $H^*(t)$.
Initialization: $O \leftarrow H' \setminus (H^*(t) \cup \{t\})$, $S(t) \leftarrow \emptyset$
while O is nonempty **do**
  Choose $v \in O$
  $O \leftarrow O \setminus \{v\}$
  $Z \leftarrow \{t, v\} \cup H^*(t) \cup S(t)$
  $A \leftarrow$ OPTIMALNETWORK(Z, D_Z)
  $S(t) \leftarrow S^A(t)$
end while
return $S(t)$

The following lemma shows that the set $S(t)$ will not contain any nodes that are not spouses of the target t in A^p.

Lemma 7. *Let $S^{A^p}(t)$ be the spouses of the target t in A^p. When Assumptions 1 and 2 and Conjecture 5 hold, Algorithm 3 will return a set $S(t)$ such that $S(t) \subseteq S^{A^p}(t)$.*

Proof. Let t be the target, u its neighbor and v a neighbor of u. A spouse v is added to $S(t)$ only when there is a v-structure (t, u, v) in A.

Suppose that there is no v-structure (t, u, v) in A^p. Then $t \not\perp\!\!\!\perp_p v|X$ for all $X \subseteq N \setminus \{t, u, v\}$. Now, if a DAG A has the v-structure (t, u, v) then A_t does not contain u and thus $t \not\perp\!\!\!\perp_p v|A_t$. This means that, by local consistency, adding an arc vt to A increases the score. Symmetrically, A_v does not contain u and by local consistency, adding an arc tv increase the score. Since it is always possible to add at least one of these arcs without introducing a cycle, A cannot be the optimal graph.

□

Lemma 7 does not guarantee that all spouses are found (in the limit) using Algorithm 3. Indeed, Figure 1 shows an example where Algorithm 3 leaves one spouse out. Let t be our target. Then, its neighbors are s and u. Consider learning an optimal DAG on $\{s, t, u, v\}$. We notice that t and v are not conditionally independent given any subset of $\{s, u\}$ and thus by local consistency the optimal network must contain an arc between t and v. Therefore, v cannot be part of a v-structure and is discarded. However, in the original graph v is involved in a v-structure (t, s, v). To find spouses, we use Algorithm 4.

Algorithm 4 FINDSPOUSES

Input: Data D on node set N, a target node $t \in N$, neighbors of the target $H^*(t)$, neighbors of the neighbors of the target $H^*(v)$ for all $v \in H^*(t)$.
Output: The spouses of t.

$S^*(t) \leftarrow$ FINDPOTENTIALSPOUSES$(D, t, H^*(t))$
for all $v \in N \setminus (\{t\} \cup H^*(t))$ **do**
  $S(v) \leftarrow$ FINDPOTENTIALSPOUSES$(D, v, H^*(v))$
  if $t \in S(v)$ **then**
    $S^*(t) \leftarrow S^*(t) \cup \{v\}$
  end if
end for
return $S^*(t)$

It is not known whether Algorithm 4 is guaranteed to find all spouses in the limit. Finding a counterexample seems difficult and thus we conjecture as follows.

Conjecture 8. *Let $S^{A^p}(t)$ be the spouses of the target t in A^p. When Assumptions 1 and 2 hold, Algorithm 4 will return a set $S^*(t)$ such that $S^*(t) = S^{A^p}(t)$.*

Once we have found the neighbors $H^*(t)$ and spouses $S^*(t)$ of a target node t, the Markov blanket is simply

$H^*(t) \cup S^*(t)$. The following conjecture that holds if Conjectures 5 and 8 hold summarizes the theoretical guarantees.

Conjecture 9. *When Assumptions 1 and 2 hold, the local learning algorithm is optimal in the limit, that is, when the sample size m approaches infinity the algorithm always finds the correct Markov blanket for every target.*

3.3 TIME AND SPACE REQUIREMENT

In both Algorithm 1 and 3, the while loop is executed at most $n-1$ times. The time and space requirement inside the loop is dominated by the procedure OptimalNetwork. On a node set Z it runs in $O(|Z|^2 2^{|Z|})$ time and $O(|Z|2^{|Z|})$ space, where in the worst case $|Z| = O(n)$. Thus, these algorithms have a worst case time requirement $O(n^3 2^n)$ and space requirement $O(n2^n)$. In practice, however, the networks are often relatively sparse and the running times are significantly lower than in the worst case; see the experiments. Algorithms 2 and 4 call Algorithms 1 and 3 at most n times, respectively. Thus, the total time requirement is at most $O(n^4 2^n)$.

The above algorithms were presented for computing the Markov blanket for a single target. If one computes Markov blankets for all nodes, one can store and reuse the the potential neighbor and spouse sets. Thus, in the worst case the Markov blanket for all nodes can be found in $O(n^4 2^n)$ time.

3.4 FROM LOCAL TO GLOBAL

Above we have learned Markov blankets of target nodes. Next, we introduce two methods to construct a DAG on the whole node set based on the local results.

The first method uses a constraint-based approach. As mentioned in the previous section, when computing the local neighbor sets we do not need to do the symmetry correction separately for each node. Instead, we can first find the potential neighbors for each node and then get the actual neighbors and build the skeleton using AND-rule; an edge between u and v is added to the skeleton only if both u and v are potential neighbors of each other. Similar way we can also skip the separate symmetry checks when finding the spouses of each node. As a result, we can use the procedure SLL+C described in Algorithm 5 to construct a DAG.

On lines 1–4 of the Algorithm 5 the skeleton E is built and on lines 5–19 the v-structures are directed; this specifies the Markov equivalence class of the DAG. To direct the rest of the arcs which is done on line 20 we can use the rules listed in Pearl (2000). Note that in practice there may be conflicts between v-structures.

Algorithm 5 SLL+C

Input: Data D on node set N.
Output: Directed acyclic graph A.

```
1: for all v ∈ N do
2:    H(v) ← FindPotentialNeighbors(D, v)
3: end for
4: E ← {{u, v} | v ∈ H(u) and u ∈ H(v)}
5: for all v ∈ N do
6:    H*(v) ← {u | {v, u} ∈ E}
7:    S(v) ← FindPotentialSpouses(D, v, H*(v))
8: end for
9: A ← ∅
10: for all v ∈ N do
11:    for all u ∈ S(v) do
12:       for all w is a common child of v and u do
13:          if possible without introducing cycles then
14:             remove {v, w} and {u, w} from E
15:             add vw and uw to A
16:          end if
17:       end for
18:    end for
19: end for
20: direct the rest of the edges without introducing
    cycles or (if possible) additional v-structures
21: return A
```

With a finite sample size, one v-structure could, for example, force an arc to be oriented from u to v and another v-structure from v to u.

Another way to construct a DAG from the local results is to use a heuristic such as greedy search with some constraints imposed by the local neighbors. As we will see later in the experiments section, this often leads to a structure with better score compared to the constraint-based approach. Another advantage is that there is no need to find the spouses of the nodes, which is often the more computationally intensive phase in SLL. Algorithm 6 describes SSL+G procedure which uses OR-rule to build a skeleton E of potential edges from the local neighbor sets. Then it calls a greedy search as a subroutine, which may only add an arc if the corresponding edge is present in the skeleton. This approach is similar to the MMHC algorithm by Tsamardinos et al. (2006a) and comes with no correctness guarantees in the limit.

4 EXPERIMENTS

We implemented the SLL algorithm as well as both SLL+C and SLL+G algorithms in C++. As OptimalNetwork subroutine we used the dynamic programming algorithm by Silander and Myllymäki (2006) with fallback to greedy equivalence search (GES) (Chickering, 2002) if the number of nodes in the input is larger

Algorithm 6 SLL+G

Input: Data D on node set N.
Output: Directed acyclic graph A.

```
for all v ∈ N do
    H(v) ← FindPotentialNeighbors(D, v)
end for
E ← {{u, v} | v ∈ H(u) or u ∈ H(v)}
A ← GreedySearch(D, E)
return A
```

than 20. In the dynamic programming we limited the maximum in-degree of a node to 5. The implementation is available at `http://www.cs.helsinki.fi/u/tzniinim/uai2012/`. These algorithms were compared against several state-of-the-art algorithms, namely the constraint-based HITON (Aliferis et al., 2010a) for local structure discovery and greedy search (GS), greedy equivalence search (GES) and the max-min hill-climbing (MMHC) (Tsamardinos et al., 2006a) for global structure discovery. The association test used by HITON and MMHC was the built in Assoc function of the implementation, that is, G^2 test according to Aliferis et al. (2010a) and Tsamardinos et al. (2006a). For HITON the maximum conditioning set size was set to 5. BDeu prior with equivalent sample size 1 was used in all algorithms when applicable.

In our experiments we used discrete data generated from real world Bayesian networks. We chose a subset of (smaller) data sets which were used by Tsamardinos et al. (2006a) and are freely available online[1]. These are listed in Table 1. Some of the networks have been generated by tiling 3, 5 or 10 copies of the original network using a method by Tsamardinos et al. (2006b). For each network we had 10 independently generated random datasets containing 500, 1000 and 5000 i.i.d. samples.

To accommodate to limited space we chose a representative sample of four of the networks for which we have figures: Alarm5, Child10, Insurance5, and Hailfinder. The figures for the rest of the networks are available as an online appendix.

4.1 LOCAL LEARNING

In the local learning experiments the goal was to learn both the neighbor sets and the Markov blankets for all nodes. We compared SLL to the constraint-based HITON from Causal Explorer toolkit[2] by Aliferis et al. (2011).

For both the neighbor sets and the Markov blankets we measured the local Hamming distance between the learned set of nodes and the true set of nodes. The Hamming distance of two sets A and B is the number of elements which are contained in only one of the sets, that is, $|A \setminus B| + |B \setminus A|$. For each data set we computed the Sum of Local Hamming Distances over all possible target nodes, call it SLHD.

Network	Num vars	max in/out -degree	domain size
Alarm	37	4 / 5	2–4
Alarm3	111	4 / 5	2–4
Alarm5	185	4 / 6	2–4
Barley	48	4 / 5	2–67
Child	20	2 / 7	2–6
Child3	60	3 / 7	2–6
Child5	100	2 / 7	2–6
Child10	200	2 / 7	2–6
Hailfinder	56	4 / 16	2–11
Insurance	27	3 / 7	2–5
Insurance3	81	4 / 7	2–5
Insurance5	135	5 / 8	2–5

Table 1: Bayesian networks used in the experiments. Information from Tsamardinos et al. (2006a).

Figure 2 shows the average SLHDs as a function of the size of the data set for learning the neighbor nodes. As expected, the accuracy of the learned neighbor set improves as the number of data samples increases. In most of the cases SLL beats HITON. The average SLHDs for learning the Markov blankets are shown in Figure 3. The results are similar to those for neighbor nodes.

4.2 GLOBAL LEARNING

In the global learning experiments the goal was to learn the entire structure (DAG) of the underlying Bayesian network. We considered both SLL+C and SLL+G heuristics. As the greedy search algorithm we used the steepest ascent hill-climbing with a TABU list of the last 100 structures and a stopping criterion of 15 steps without improvement in the maximum score. These parameters were chosen to be same as in the MMHC and greedy search implementation by Tsamardinos et al. (2006a). We compared our algorithms to greedy search (GS) and max-min hill-climbing (MMHC) from Causal Explorer toolkit as well as greedy equivalent search (GES) from TETRAD software[3].

Some of the algorithms return a DAG but the others return a PDAG, a partially directed acyclic graph which

[2] `http://www.dsl-lab.org/causal_explorer/`

[3] `http://www.phil.cmu.edu/projects/tetrad/`

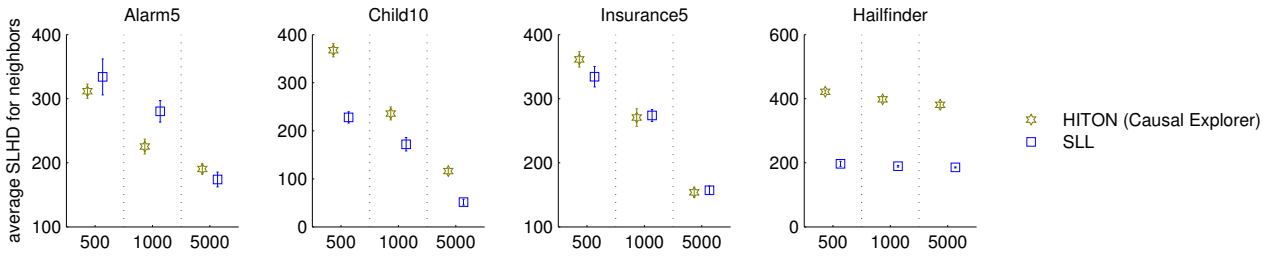

Figure 2: Average SLHD (Sum of Local Hamming Distances) between the returned neighbor sets (parents and children) and the true neighbor sets for different data sizes (500, 1000 and 5000 samples). Standard deviations are shown as vertical bars.

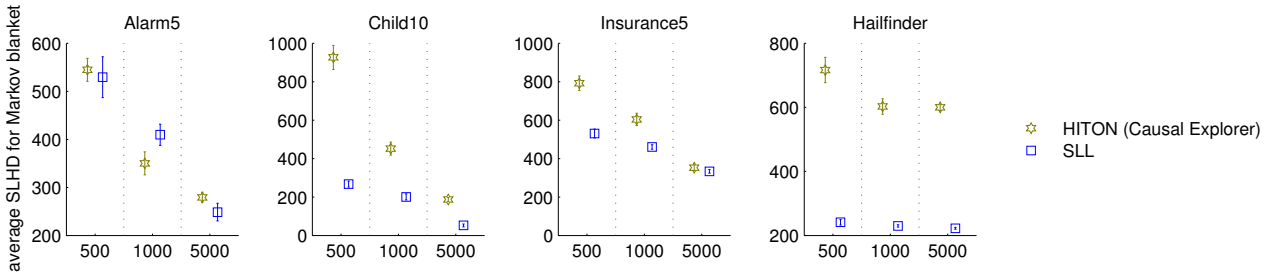

Figure 3: Average SLHD between the returned Markov blankets and the true Markov blankets.

corresponds to a Markov equivalence class. Compared to a DAG, in the corresponding PDAG the edges which are not oriented the same way in all members of the class are undirected. Since the DAGs belonging to a same equivalence class cannot be distinguished using score equivalent scores, we converted all returned DAGs to PDAGs and compared the PDAGs. If the algorithm failed (i.e. did not return a valid DAG) the run was ignored. This only affected GES, which failed to return an acyclic graph in several runs.

We used two measures the evaluate the goodness of the PDAGs returned by the algorithms: normalized BDeu score and Structural Hamming Distance from the true structure. The normalized BDeu score was obtained by computing the BDeu score with equivalent sample size 1 for a DAG extension of the PDAG and dividing the result by the score of the true structure; the lower the normalized score, the better the structure fits to the data. Average normalized scores are shown in Figure 4. The basic greedy search seems to do surprisingly well, even compared to the GES. For some networks SLL+G works better than MMHC, for other it is the other way around. SLL+C loses to the other methods in most of the cases.

The Structural Hamming Distance (SHD) between two PDAGs is defined as the number of edges which are missing/extra or of wrong type (reversed or directed in one PDAG and undirected in the other). We measured the distances between the resulting PDAGs and the true structures. Figure 5 shows the average SHDs. Compared to the observations for scores, here SLL+C performs clearly better and a basic greedy search much worse.

4.3 TIME CONSUMPTION

Figure 6 shows the average running times. For local learning the times include learning both the neighbors and the Markov blankets for all nodes. As in SLL+C the most of the time is spent in local learning part which is the same as running the SLL algorithm for all nodes, these times are combined. The times for HITON are not directly comparable to SLL since it does the symmetry correction for each node separately. In spite of this extra work, HITON is often not any slower than SLL. Also for global learning the rival algorithms are usually faster than SLL+G and SLL+C.

5 DISCUSSION

In this paper we have studied prospects of score-based local learning. We have conjectured that the score-based local learning provides same the theoretical guarantees as greedy equivalence search (GES) (Chickering, 2002) and constraint-based local learning (Aliferis et al., 2010a). A natural avenue for future research is to prove these guarantees or lack thereof.

Our experiments suggest that our method provides

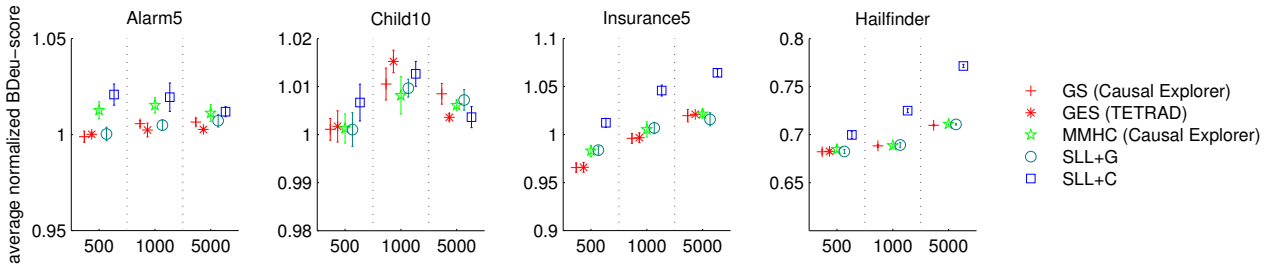

Figure 4: Average normalized score of the returned network structures. Smaller is better and 1.0 corresponds to the true network.

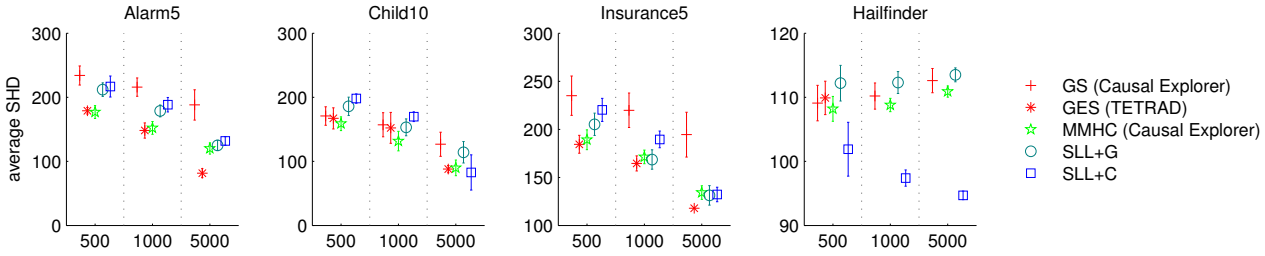

Figure 5: Average SHD (Structural Hamming Distance) between the returned structures and the true structure.

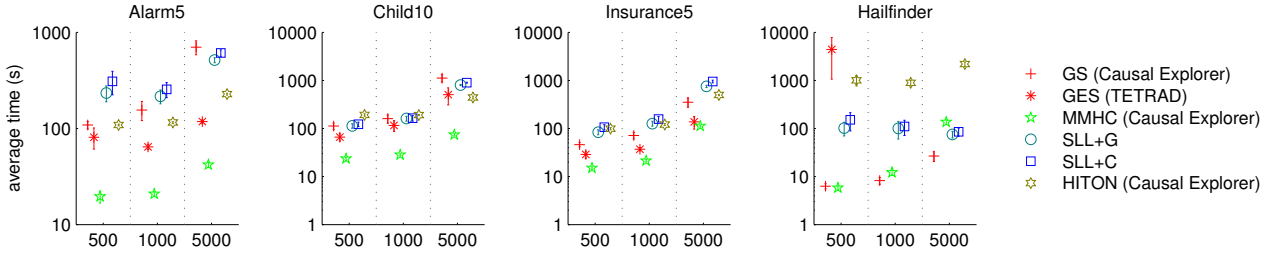

Figure 6: Average running times for the algorithms.

a competitive alternative for constraint-based local learning. Our algorithm seems to often find local neighborhoods more accurately than the competitor. However, as a downside our algorithm usually consumes significantly more time. We hope that our algorithm could bridge the gap between exact algorithms and constraint-based local learning by providing a way to trade off between accuracy and scalability. The local-to-global approach seem to perform less well compared to various other heuristics. However, in some data sets local-to-global algorithms outperformed all benchmarks in structural Hamming distance especially when there was lots of data. This suggests that with further development, score-based local-to-global heuristic could be competitive in certain types of networks.

Abstract

A nonparametric approach for policy learning for POMDPs is proposed. The approach represents distributions over the states, observations, and actions as embeddings in feature spaces, which are reproducing kernel Hilbert spaces. Distributions over states given the observations are obtained by applying the kernel Bayes' rule to these distribution embeddings. Policies and value functions are defined on the feature space over states, which leads to a feature space expression for the Bellman equation. Value iteration may then be used to estimate the optimal value function and associated policy. Experimental results confirm that the correct policy is learned using the feature space representation.

1 Introduction

Partially Observable Markov Decision Processes (POMDPs) are general models for sequential control problems in partially observable environments, in which an agent executes an action under uncertainty while reward delivery and state transitions vary depending on the state and action. The objective is to find an optimal policy that maximizes a value function defined on beliefs (distributions over states), and determined by the reward function. When the value is the expected sum of discounted rewards, the optimal policy and the optimal value function are computed by solving a Bellman equation. Solutions to the Bellman equation are generally very difficult to obtain, with a number of approaches being employed. These include tractable parametric models of the system (parametric POMDPs [Poupart et al., 2006, Even-dar, 2005]); Monte Carlo methods for more complex models (Monte Carlo POMDPs [Silver and Veness, 2010, Thrun, 2000]); and methods that take advantage of the piece-wise linear and convex (PWLC) property (PBVI [Pineau et al., 2003], Perseus [Spaan and Vlassis, 2005], HSVI [Smith and Simmons, 2004]), where these last approaches use the fact that value functions computed by finite-step value iteration algorithms are PWLC in the beliefs [Sondik, 1971, Porta. et al., 2006]. All these methods have drawbacks, however: parametric models can cause bias errors if they oversimplify, Monte Carlo sampling methods can be computationally costly, and PWLC-based methods require the observations and actions to be discrete.

Our nonparametric approach is based on a series of recent works in which probability distributions are represented as embeddings in reproducing kernel Hilbert spaces (RKHSs) [Fukumizu et al., 2008, Gretton et al., 2007, Gretton et al., 2012]. Probability distributions can be embedded as points in RKHSs, and expectations of RKHS functions may be obtained as inner products with these embeddings, using the kernel trick. For a sufficiently rich RKHS (i.e., a characteristic RKHS), every probability distribution has a unique embedding, and the distance between embeddings is a metric on distributions [Fukumizu et al., 2008, Sriperumbudur et al., 2010]. Recently, inference methods which make use of the embeddings have been proposed, including for Hidden Markov Models [Song et al., 2009, Song et al., 2010], and belief propagation [Song et al., 2010, Song et al., 2011]. More recently, the embeddings have been used in performing value iteration and optimal policy learning in Markov decision processes (MDPs) [Grunewalder et al., 2012]; and the Kernel Bayes' Rule (KBR) [Fukumizu et al., 2011] was proposed, which updates a prior distribution embedding via feature space operations to obtain a posterior embedding.

In this paper, we propose kernel POMDPs (kPOMDPs), a new approach to solving the Bellman

equations and determining policy, based on a nonparametric model defined in appropriate RKHSs. All probability distributions required for the algorithm are represented as embeddings in RKHSs, including the beliefs over the states, the transition models, the observation models, and the predictive distributions over subsequent states given actions, observations, and current beliefs. These embeddings are updated sequentially based on actions and observations. Likewise, value functions are defined over feature representations of states, and policies map RKHS representations of states to actions, which leads to an expression for the Bellman equation in feature space.

We use the feature representation of the Bellman equations to define a value iteration algorithm for POMDPs, which directly estimates both the expected immediate rewards and expected values of posterior beliefs in feature space. As in the earlier work cited above, expectations are represented by inner products in respective state and observation feature spaces, and can be efficiently computed using the kernel trick. While the original Bellman operator has contractive and isotonic properties, i.e., the original value iteration is guaranteed to converge monotonically [Porta. et al., 2006], the resulting kernel Bellman operator does not. That said, these properties can be enforced following a simple correction, as proposed by [Grunewalder et al., 2012]. Approaches from the classical POMDP literature for initializing and enhancing efficiency can be applied, including ways to set initial values over the state feature space, and pruning methods for action edges.

Since kPOMDPs are nonparametric, the embeddings of the distributions used in the algorithm are learned from training samples. Note that in training, we must have access to samples from the hidden state, although for the test phase no such observations are necessary. This setting is reasonable in cases where hidden states are relatively costly to obtain: while it might be possible to observe them initially when learning the system dynamics, we would not have access to them during the value iteration phase, when learning an optimal policy.

Advantages of kPOMDPs include

- kPOMDPs can handle complex distributions over states and observations, since kPOMDPs are nonparametric.
- kPOMDPs can handle a wide variety of data types, as RKHS kernels have been defined on many domains: these include discrete, continuous, and structured data.
- kPOMDPs can be applied to high-dimensional POMDPs, since the computation scales with training sample size, and not with state and observation dimensionality. The convergence of the distribution embedding is at a rate independent of the dimension of the underlying space [Fukumizu et al., 2011, Gretton et al., 2012].

Our experiments confirm that the proposed kernel value iteration algorithm learns the correct policy on POMDP benchmark tasks.

This paper is organized as follows. We introduce the notations for POMDPs in the next section, and review recent kernel methods for probability distributions in Section 3. We present kernel POMDPs in Section 4, where Bellman equations in feature spaces (Subsection 4.1), the empirical expression and value iteration algorithms (Subsection 4.2) are shown. Experiments follow for an online planning algorithm.

2 POMDPs

A POMDP is specified by a tuple $\langle \mathcal{S}, \mathcal{A}, T, R, \mathcal{O}, Z \rangle$ where $\mathcal{S}$ is the set of states, $\mathcal{A}$ is the set of actions, $T : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \to [0, \infty)$[1] is the transition function where $T(s, a, s') = \Pr(s'|s, a)$ represents the distribution of the next state s' given an action a in a state s, $R : \mathcal{S} \times \mathcal{A} \to \mathbb{R}$ is the reward function given an action a in a state s, $\mathcal{O}$ is the set of observations, $Z : \mathcal{S} \times \mathcal{O} \to [0, \infty)$[2] is the observation function where $Z(s, o) = \Pr(o|s)$ represents the distribution of observation o given a state s. We assume that R is bounded.

An agent executes an action a under the setting that the true state s is not known, but partial information o can be observed according to $Z(s, o)$. The agent then transitions to its next state s' according to $T(s, a, s')$, receiving a reward $R(s, a)$ and making a new observation o' according to $Z(s', o')$. The agent executes then its next action a', and the process is repeated.

The goal of reinforcement learning in a POMDP is, given an initial belief b_0 for the initial state and a history of actions and observations $h_{t+1} = \{a_0, o_1, ..., a_t, o_{t+1}\}$, to find an optimal policy $\pi^*_{t+1} : (b_0, h_{t+1}) \mapsto a_{t+1}$ that maximizes the value function of the expected sum of discounted rewards with infinite horizon $\mathbb{E}[\sum_{t=0}^{\infty} \gamma^t R_t]$, where $\gamma \in (0, 1)$ is a discount factor.

In POMDPs, all the information (b_0, h_{t+1}) is condensed in a sufficient statistic of a belief distribution b over the state set $\mathcal{S}$, and the optimal policy π^*_{t+1} is reduced to $\pi^* : b \mapsto a$. Belief $b_{t+1} (t \geq 0)$ is updated

[1] In discrete case, $T : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \to [0, 1]$.
[2] In discrete case, $Z : \mathcal{S} \times \mathcal{O} \to [0, 1]$.

according to Bayes' rule

$$b_{t+1}(s_{t+1}) = \frac{Z(s_{t+1}, o_{t+1})P(s_{t+1}|a_t; b_t)}{P(o_{t+1}|a_t; b_t)}, \quad (1)$$

where

$$P(s_{t+1}|a_t; b_t) = \mathbb{E}_{S_t \sim b_t}\left[T(S_t, a_t, s_{t+1})\right],$$
$$P(o_{t+1}|a_t; b_t) = \mathbb{E}_{S_{t+1} \sim P(\cdot|b_t, a_t)}\left[Z(o_{t+1}, S_{t+1})\right].$$

A variable with a prime indicates a value at the next timestep. $b^{a,o'}$ denotes the posterior belief for the next state S' when the next observation o' is observed after executing action a in belief b.

The value function of belief b following a fixed policy π is given by

$$V^\pi(b) = \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t \mathbb{E}_{S_t \sim b_t}\left[R(S_t, \pi(b_t))\right]\right], \quad (2)$$

and it is the fixed point of the Bellman equation

$$V^\pi(b) = Q^\pi(b, \pi(b)),$$
$$Q^\pi(b, a) = \mathbb{E}_{S \sim b}\left[R(S, a)\right] + \gamma \mathbb{E}_{O' \sim P(\cdot|b,a)}\left[V^\pi(b^{a,O'})\right] \quad (3)$$

where $Q^\pi(b, a)$ is the action value function, i.e., the value of executing action a in belief b while future actions $a', a'', \ldots$ are chosen according to policy π.

The optimal policy π^* and its optimal value function $V^*(b)$ are given by the fixed point of the Bellman optimality equation

$$V^*(b) = \max_{a \in \mathcal{A}} Q^*(b, a),$$
$$Q^*(b, a) = \mathbb{E}_{S \sim b}\left[R(S, a)\right] + \gamma \mathbb{E}_{O' \sim p(\cdot|b,a)}\left[V^*(b^{a,O'})\right],$$
$$\pi^* = \arg\max_{a \in \mathcal{A}} Q^*(b, a). \quad (4)$$

$V^*(b)$ can be estimated by the value iteration algorithm $V_d = HV_{d-1} (d \geq 1)$, where V_d is the d-step value function and H is the Bellman operator

$$(HV)(b) = \max_{a \in \mathcal{A}}\left[\mathbb{E}_{S \sim b}\left[R(S, a)\right] + \gamma \mathbb{E}_{O' \sim p(\cdot|b,a)}\left[V(b^{a,O'})\right]\right]. \quad (5)$$

H is known to be isotonic, contractive, and V_d is guaranteed to be more accurate than V_{d-1}; that is, if V_{d-1} satisfies $\varepsilon = \sup_b |V^*(b) - V_{d-1}(b)|$, then V_d has an error bound of $|V^*(b) - \hat{V}_d(b)| \leq \gamma\varepsilon$ where $\gamma \in (0, 1)$ [Ross et al., 2008].

The initial value $V_0(b)$ of belief b used for value iteration can be defined using the initial Q-value $Q_0(s, a)$ over states and actions,

$$V_0(b) = \max_{a \in \mathcal{A}} \mathbb{E}_{S \sim b(\cdot)}\left[Q_0(S, a)\right]. \quad (6)$$

A simple choice for $Q_0(s, a)$ is the reward $Q_0(s, a) = R(s, a)$. Alternatively, a QMDP approximation $Q_0(s, a) = Q^{MDP}(s, a)$ may be used [Littman, 1995], where $Q^{MDP}(s, a)$ is given by running MDP value iteration, and approximating the POMDP by an MDP.

In kernel POMDPs, all the expectations appearing above are computed nonparametrically, without explicitly estimating the distributions $b(S)$, $P(S'|a; b)$, $P(O'|a; b)$, $b^{a,o'}(S')$ and transition and observation models, T and Z. Instead, we obtain feature representations of the distributions (distribution embeddings) and the models (conditional embedding operators), as described in Section 3.

We end this section with a key to matching the probabilistic and reinforcement learning results presented in this section with their nonparametric, kernel-based counterparts in the following section. Bayes' rule (1) becomes the kernel Bayes' rule eq.(12), and its empirical counterpart leads to the updates (15)(16); the Bellman equations (3)(4) take the form of Claims 1-4, the Bellman operator (5) becomes the kernel Bellman operator (19), and the value initializations (6) lead to the initializations (20),(21).

3 Kernel Methods for Probabilities

In the present section, we provide an overview of distribution embeddings in reproducing kernel Hilbert spaces [Smola et al., 2007, Sriperumbudur et al., 2010, Gretton et al., 2012]. The embeddings are represented as mean (nonlinear) features of distributions, hence may also be referred to as *mean embeddings*. We also recall conditional embedding operators [Song et al., 2009, Song et al., 2010], and the Kernel Bayes' Rule (KBR) [Fukumizu et al., 2011]. Mean embeddings can be updated using conditional embedding operators; in particular, KBR allows us to obtain posterior embeddings given prior embeddings in feature spaces.

3.1 Embedding Distributions

Let $\mathcal{H}_\mathcal{X}$ be an RKHS associated with a bounded and measurable positive definite kernel $k_\mathcal{X} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ over domain $(\mathcal{X}, \mathcal{B}_\mathcal{X})$, with $\langle \cdot, \cdot \rangle_{\mathcal{H}_\mathcal{X}}$ the corresponding inner product. The embedding of a distribution P over $(\mathcal{X}, \mathcal{B}_\mathcal{X})$ in $\mathcal{H}_\mathcal{X}$ is given by the RKHS element $\mu_X = \mathbb{E}_{X \sim P}\left[k_\mathcal{X}(X, \cdot)\right] \in \mathcal{H}_\mathcal{X}$. μ_X coincides with the unique element satisfying $\langle \mu_X, f \rangle_{\mathcal{H}_\mathcal{X}} = \mathbb{E}_{X \sim P}\left[f(X)\right]$ for all $f \in \mathcal{H}_\mathcal{X}$, which means that the expectation of any function $f \in \mathcal{H}_\mathcal{X}$ can be computed as an inner product of the embedding μ_X and f in $\mathcal{H}_\mathcal{X}$, without explicitly estimating the distribution P.

The element μ_X can be estimated by a linear combination of feature vectors on samples $(X_1, \ldots, X_n)$ over $\mathcal{X}$, i.e., $\hat{\mu}_X = \Upsilon\boldsymbol{\alpha}$ where $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_n)^\top \in \mathbb{R}^n$ and $\Upsilon = (k_\mathcal{X}(\cdot, X_1), \ldots, k_\mathcal{X}(\cdot, X_n))$. Using the empirical embedding $\hat{\mu}_X$, the expectation can be nonparametrically estimated as

$$\mathbb{E}_{X\sim P}[f(X)] \sim \langle \hat{\mu}_X, f\rangle_{\mathcal{H}_\mathcal{X}} = \boldsymbol{\alpha}^\top \mathbf{f}, \tag{7}$$

where $\mathbf{f} = (f(X_1), \ldots, f(X_n))^\top$.

We use characteristic kernels, e.g., Gaussian kernels and Laplacian kernels, which guarantee that each distribution maps to a unique embedding in the RKHS [Sriperumbudur et al., 2010, Fukumizu et al., 2011].

3.2 Conditional Embedding Operators & Kernel Bayes' Rule (KBR)

Let $\mathcal{H}_\mathcal{X}$ and $\mathcal{H}_\mathcal{Y}$ be RKHSs associated with $k_\mathcal{X}$ and $k_\mathcal{Y}$ over $(\mathcal{X}, \mathcal{B}_\mathcal{X})$ and $(\mathcal{Y}, \mathcal{B}_\mathcal{Y})$, respectively. Let (X, Y) be a random variable taking values on $\mathcal{X}\times\mathcal{Y}$ with distribution P and the density $p(x, y)$. The conditional density functions $\{p(Y|X = x)|x \in \mathcal{X}\}$ define a family of embeddings $\{\mu_{Y|x}\}$ in $\mathcal{H}_\mathcal{Y}$. According to [Song et al., 2009], a mapping from $k_\mathcal{X}(x, \cdot) \in \mathcal{H}_\mathcal{X}$ to $\mu_{Y|x} \in \mathcal{H}_\mathcal{Y}$ for all $x \in \mathcal{X}$ can be characterized by conditional embedding operator $\mathcal{U}_{Y|X} : \mathcal{H}_\mathcal{X} \to \mathcal{H}_\mathcal{Y}$,

$$\mu_{Y|x} = \mathcal{U}_{Y|X} k_\mathcal{X}(x, \cdot) = C_{YX} C_{XX}^{-1} k_\mathcal{X}(x, \cdot), \tag{8}$$

where C_{YX} and C_{XX} are uncentred covariance operators with respect to P,

$$\begin{aligned} C_{YX} &= \mathbb{E}_{(X,Y)\sim P}\left[k_\mathcal{Y}(Y, \cdot) \otimes k_\mathcal{X}(X, \cdot)\right], \\ C_{XX} &= \mathbb{E}_{(X,Y)\sim P}\left[k_\mathcal{X}(X, \cdot) \otimes k_\mathcal{X}(X, \cdot)\right], \end{aligned} \tag{9}$$

and we use the tensor product definition $(a \otimes b)c = a\langle b, c\rangle$. Feature representations of conditional distributions $\mu_{Y|x}$ are obtained by applying the operator $\mathcal{U}_{Y|X}$ to the feature map $k_\mathcal{X}(x, \cdot)$.

Since a posterior distribution is also written as a conditional distribution, the embedding of a posterior can be expressed as a conditional embedding operator [Fukumizu et al., 2011]. Let Π be a prior distribution with density $\pi(x)$, and $(\bar{X}, \bar{Y})$ be a new random variable with distribution Q corresponding to the density $q(x, y) = p(y|x)\pi(x)$. The embedding of a posterior $q(\bar{X}|\bar{Y} = y)$ given y can be expressed by a corresponding conditional embedding operator $\mathcal{U}_{\bar{X}|\bar{Y}}$

$$\mu_{\bar{X}|y} = \mathcal{U}_{\bar{X}|\bar{Y}} k_\mathcal{Y}(y, \cdot) = C_{\bar{X}\bar{Y}} C_{\bar{Y}\bar{Y}}^{-1} k_\mathcal{Y}(y, \cdot), \tag{10}$$

where $C_{\bar{X}\bar{Y}}$ and $C_{\bar{Y}\bar{Y}}$ are covariance operators with respect to Q.

$$\begin{aligned} C_{\bar{X}\bar{Y}} &= \mathbb{E}_{(\bar{X},\bar{Y})\sim Q}\left[k_\mathcal{X}(\bar{X}, \cdot) \otimes k_\mathcal{Y}(\bar{Y}, \cdot)\right], \\ C_{\bar{Y}\bar{Y}} &= \mathbb{E}_{(\bar{X},\bar{Y})\sim Q}\left[k_\mathcal{Y}(\bar{Y}, \cdot) \otimes k_\mathcal{Y}(\bar{Y}, \cdot)\right]. \end{aligned} \tag{11}$$

See Appendix for further details and empirical estimates.

The inference underlying kPOMDPs is accomplished with the embedding operator $\mathcal{U}_{Y|X}$ and posterior embedding operator $\mathcal{U}_{\bar{X}|\bar{Y}}$.

4 Kernel POMDPs (kPOMDPs)

We now present our main results: we formulate POMDPs in feature spaces, and propose a kernelized value iteration algorithm. A key to the notation is given in Table 1.

4.1 Kernel Bellman Equations (KBEs)

To kernelize the Bellman equations, we introduce three RKHSs for state set $\mathcal{S}$, action set $\mathcal{A}$, and observation set $\mathcal{O}$. Let $\mathcal{H}_\mathcal{S}$, $\mathcal{H}_\mathcal{A}$, $\mathcal{H}_\mathcal{O}$ be RKHSs associated with bounded and measurable positive definite kernels $k_\mathcal{S}$, $k_\mathcal{A}$, $k_\mathcal{O}$ over $(\mathcal{S}, \mathcal{B}_\mathcal{S})$, $(\mathcal{A}, \mathcal{B}_\mathcal{A})$, $(\mathcal{O}, \mathcal{B}_\mathcal{O})$, respectively. $\langle\cdot,\cdot\rangle_{\mathcal{H}_\mathcal{S}}$, $\langle\cdot,\cdot\rangle_{\mathcal{H}_\mathcal{A}}$, $\langle\cdot,\cdot\rangle_{\mathcal{H}_\mathcal{O}}$ denote their respective inner products, and $\varphi(S)$, $\psi(A)$, $\phi(O)$ their feature vectors.

The relevant distributions $b(S)$, $P(S'|a; b)$, $P(O'|a; b)$, $b^{a,o'}(S')$ can be embedded in the corresponding RKHSs $\mathcal{H}_\mathcal{S}$, $\mathcal{H}_\mathcal{O}$ as follows:

$$\begin{aligned} \mu_S &= \mathbb{E}_{S\sim b(\cdot)}[\varphi(S)], \\ \mu_{S'|a;\mu_S} &= \mathbb{E}_{S'\sim p(\cdot|a;b)}[\varphi(S')], \\ \mu_{O'|a;\mu_S} &= \mathbb{E}_{O'\sim p(\cdot|a;b)}[\phi(O')], \\ \mu_{S'}^{a,o'} &= \mathbb{E}_{S'\sim b^{a,o'}(\cdot)}[\varphi(S')]. \end{aligned}$$

These embeddings are related via conditional embedding operators expressing transition models T, observation models Z, and posteriors.

Let $\mathcal{U}_{S'|S,A} : \mathcal{H}_\mathcal{S} \otimes \mathcal{H}_\mathcal{A} \to \mathcal{H}_\mathcal{S}$ be the conditional embedding operator for the transition model T, and $\mathcal{U}_{O|S} : \mathcal{H}_\mathcal{S} \to \mathcal{H}_\mathcal{O}$ be the operator for the observation model Z. Let $\mathcal{U}_{\bar{S}|\bar{O}}^{(a,\mu_S)} : \mathcal{H}_\mathcal{O} \to \mathcal{H}_\mathcal{S}$ be the posterior embedding operator corresponding to eq.(10), where we use the prior embedding $\mu_{S'|a;\mu_S}$ in the KBR.

The four embeddings above are related as

$$\begin{aligned} \mu_{S'|a;\mu_S} &= \mathcal{U}_{S'|S,A}\mu_S \otimes k_A(a, \cdot), \\ \mu_{O'|a;\mu_S} &= \mathcal{U}_{O|S}\mu_{S'|a;\mu_S}, \\ \mu_{S'}^{a,o'} &= \mathcal{U}_{\bar{S}|\bar{O}}^{(a,\mu_S)} k_O(o', \cdot). \end{aligned} \tag{12}$$

The sequence of mappings $\mu_S \mapsto \mu_{S'|a;\mu_S} \mapsto \mu_{O'|a;\mu_S} \mapsto \mu_{S'}^{a,o'}$ depends on the action a. A policy π is defined to be a mapping from embeddings μ_S to actions. In evaluating policies, value functions $V(\cdot)$ are defined to be functions of embeddings μ_S, and thus (indirectly) of the actions a and observations o.

Table 1: Notation

	State	Action	Observation	(State, Action)
domain	$\mathcal{S}$	$\mathcal{A}$	$\mathcal{O}$	$\mathcal{S}\times\mathcal{A}$
r.v.	S	A	O	(S,A)
Instance	s	a	o	(s,a)
kernel	$k_{\mathcal{S}}(\cdot,\cdot)$	$k_{\mathcal{A}}(\cdot,\cdot)$	$k_{\mathcal{O}}(\cdot,\cdot)$	$k_{\mathcal{S}\times\mathcal{A}}(\cdot,\cdot)=k_{\mathcal{S}}(\cdot,\cdot)\otimes k_{\mathcal{A}}(\cdot,\cdot)$
RKHS	$\mathcal{H}_{\mathcal{S}}$	$\mathcal{H}_{\mathcal{A}}$	$\mathcal{H}_{\mathcal{O}}$	$\mathcal{H}_{\mathcal{S}\times\mathcal{A}}=\mathcal{H}_{\mathcal{S}}\otimes\mathcal{H}_{\mathcal{A}}$
feature map	$\varphi(s)=k_{\mathcal{S}}(s,\cdot)$	$\psi(a)=k_{\mathcal{A}}(a,\cdot)$	$\phi(o)=k_{\mathcal{O}}(o,\cdot)$	$\vartheta(s,a)=k_{\mathcal{S}\times\mathcal{A}}((s,a),\cdot)$
finite Sample Set	$\mathcal{S}_0$	$\mathcal{A}_0$	$\mathcal{O}_0$	$(\mathcal{S}_0,\mathcal{A}_0)$
feature matrix	Υ	Ψ	Φ	Θ
Gram matrix	$G_S=\Upsilon^\top\Upsilon$	$G_A=\Psi^\top\Psi$	$G_O=\Phi^\top\Phi$	$G_{(S,A)}=G_S\odot G_A$
feature column	$\mathbf{k}_S(s)=\Upsilon^\top\varphi(s)$	$\mathbf{k}_A(a)=\Psi^\top\psi(a)$	$\mathbf{k}_O(o)=\Phi^\top\phi(o)$	$\mathbf{k}_{(S,A)}(s,a)=\Theta^\top\vartheta(a,o)$

Using value functions over embeddings, the expected immediate rewards and expected values of posterior beliefs in the Bellman equations (Section 2) can be computed as inner products in RKHSs,

$$\begin{aligned}\mathbb{E}_{S\sim b}\left[R(S,a)\right]&=\left\langle\mu_S,R\left(\cdot,a\right)\right\rangle_{\mathcal{H}_{\mathcal{S}}},\\ \mathbb{E}_{O'\sim P(\cdot|b,a)}\left[V^\pi(b^{a,O'})\right]&=\left\langle\mu_{O'|a;\mu_S},V^\pi\left(\mu_{S'}^{a,(\cdot)}\right)\right\rangle_{\mathcal{H}_{\mathcal{O}}},\\ \mathbb{E}_{O'\sim P(\cdot|b,a)}\left[V^*(b^{a,O'})\right]&=\left\langle\mu_{O'|a;\mu_S},V^*\left(\mu_{S'}^{a,(\cdot)}\right)\right\rangle_{\mathcal{H}_{\mathcal{O}}},\end{aligned}$$

assuming $R(\cdot,a)\in\mathcal{H}_{\mathcal{S}}$ and $V^\pi\left(\mu_{S'}^{a,(\cdot)}\right),V^*\left(\mu_{S'}^{a,(\cdot)}\right)\in\mathcal{H}_{\mathcal{O}}$.

We are now ready to introduce the kernel Bellman equation as an operation on the embeddings μ_S. Let $\mathcal{P}_{\mathcal{S}}$ be the set of beliefs and $\mathcal{I}_{\mathcal{S}}$ be the set of embeddings of $\mathcal{P}_{\mathcal{S}}$ in $\mathcal{H}_{\mathcal{S}}$.

Claim 1. *Let $R(\cdot,a)\in\mathcal{H}_{\mathcal{S}}$ and $V^\pi\left(\mu_{S'}^{a,(\cdot)}\right)\in\mathcal{H}_{\mathcal{O}}$ for all $a\in\mathcal{A}$ and $\mu_S\in\mathcal{I}_{\mathcal{S}}$. The kernel Bellman equations on $\mathcal{H}_{\mathcal{S}}$ are*

$$\begin{aligned}V^\pi(\mu_S)&=Q^\pi\left(\mu_S,\pi\left(\mu_S\right)\right),\\ Q^\pi(\mu_S,a)&=\left\langle\mu_S,R\left(\cdot,a\right)\right\rangle_{\mathcal{H}_{\mathcal{S}}}+\gamma\left\langle\mu_{O'|a;\mu_S},V^\pi\left(\mu_{S'}^{a,(\cdot)}\right)\right\rangle_{\mathcal{H}_{\mathcal{O}}}.\end{aligned}$$

The solution of these equations following a fixed policy π on $\mathcal{H}_{\mathcal{S}}$ yields a value function $V^\pi(\cdot)$. The kernel Bellman optimality equations take similar form.

Claim 2. *Let $R(\cdot,a)\in\mathcal{H}_{\mathcal{S}}$ and $V^*\left(\mu_{S'}^{a,(\cdot)}\right)\in\mathcal{H}_{\mathcal{O}}$ for all $a\in\mathcal{A}$ and $\mu_S\in\mathcal{I}_{\mathcal{S}}$. The kernel Bellman optimality equations on RKHS $\mathcal{H}_{\mathcal{S}}$ are*

$$\begin{aligned}V^*(\mu_S)&=\max_{a\in\mathcal{A}}Q^*(\mu_S,a),\\ Q^*(\mu_S,a)&=\left\langle\mu_S,R\left(\cdot,a\right)\right\rangle_{\mathcal{H}_{\mathcal{S}}}+\gamma\left\langle\mu_{O'|a;\mu_S},V^*\left(\mu_{S'}^{a,(\cdot)}\right)\right\rangle_{\mathcal{H}_{\mathcal{O}}},\\ \pi^*(\mu_S)&=\arg\max_{a\in\mathcal{A}}Q^*\left(\mu_S,a\right).\end{aligned}\tag{13}$$

The solution of these equations is the optimal value function $V^*(\cdot)$ with corresponding optimal policy $\pi^*(\cdot)$ on $\mathcal{H}_{\mathcal{S}}$. We use the following tuple for solving a POMDP in feature space:

$$\left\langle\mathcal{H}_{\mathcal{S}},\mathcal{H}_{\mathcal{A}},\mathcal{U}_{S|S,A},R,\mathcal{H}_{\mathcal{O}},\mathcal{U}_{O|S},\mathcal{U}_{\bar{S}|\bar{O}}^{(\mathcal{A},\mathcal{I}_{\mathcal{S}})}\right\rangle,$$

where $\mathcal{U}_{\bar{S}|\bar{O}}^{(\mathcal{A},\mathcal{I}_{\mathcal{S}})}=\{\mathcal{U}_{\bar{S}|\bar{O}}^{(a,\mu_S)}|a\in\mathcal{A},\mu_S\in\mathcal{I}_{\mathcal{S}}\}$.

4.2 Empirical Expression

We next provide a finite sample version of the kernel POMDP. Suppose that $D_n=\{(\tilde{s}_i,\tilde{o}_i),\tilde{a}_i,\tilde{R}_i,(\tilde{s}_i',\tilde{o}_i')\}_{i=1}^n$ are n training samples according to a POMDP $\langle\mathcal{S},\mathcal{A},T,R,\mathcal{O},Z\rangle$. Note that state samples $\{(\tilde{s}_i,\tilde{s}_i')\}$ are included, and will used for estimating belief embeddings μ_S, $\mu_{S'}^{a,o'}$. We assume that such samples from the true state are available for training, but not during the test phase.

Let $\mathcal{S}_0$, $\mathcal{O}_0$, $\mathcal{A}_0$, $\mathcal{S}_0'$, $\mathcal{O}_0'$ be finite sets of states, observations, and actions taken from the training samples D_n. The associated feature vectors are

$$\begin{aligned}&\Upsilon=\left(\varphi\left(\tilde{s}_1\right),\ldots,\varphi\left(\tilde{s}_n\right)\right),\Upsilon'=\left(\varphi\left(\tilde{s}_1'\right),\ldots,\varphi\left(\tilde{s}_n'\right)\right),\\ &\Phi=\left(\phi\left(\tilde{o}_1\right),\ldots,\phi\left(\tilde{o}_n\right)\right),\Phi'=\left(\phi\left(\tilde{o}_1'\right),\ldots,\phi\left(\tilde{o}_n'\right)\right),\\ &\Psi=\left(\psi\left(\tilde{a}_1\right),\ldots,\psi\left(\tilde{a}_n\right)\right),\Theta=\left(\vartheta\left(\tilde{s}_1,\tilde{a}_1\right),\ldots,\vartheta\left(\tilde{s}_n,\tilde{a}_n\right)\right).\end{aligned}$$

We build Gram matrices from the feature matrices Υ, Ψ, Φ as $G_S=\Upsilon^\top\Upsilon$, $G_A=\Psi^\top\Psi$, $G_O=\Phi^\top\Phi$, $G_{(S,A)}=G_S\odot G_A$, where $\odot$ denotes the Hadamard (element-wise) product. The embeddings μ_S, $\mu_{O'|a;\mu_S}$, $\mu_{S'}^{a,o'}$ take respective forms

$$\begin{aligned}\hat{\mu}_S&=\Upsilon\boldsymbol{\alpha},\\ \hat{\mu}_{O'|a;\mu_S}&=\Phi\boldsymbol{\beta'}_{a;\boldsymbol{\alpha}},\\ \hat{\mu}_{S'}^{a,o'}&=\Upsilon\boldsymbol{\alpha}'_{a,o'}.\end{aligned}\tag{14}$$

The update rules for the weight vectors $\boldsymbol{\alpha}\mapsto\boldsymbol{\beta'}_{a;\boldsymbol{\alpha}}\mapsto\boldsymbol{\alpha}'_{a,o'}$ corresponding to $\mu_S\mapsto\mu_{O'|a;\mu_S}\mapsto\mu_{S'}^{a,o'}$ in eq.(12) are given as follows:

- The update $\boldsymbol{\alpha}\mapsto\boldsymbol{\beta'}_{a;\boldsymbol{\alpha}}$ uses the empirical estimates of conditional embedding operators $\mathcal{U}_{S'|S,A}$,

$\mathcal{U}_{O|S}$, which results in a linear transformation $\boldsymbol{\beta}'_{a;\boldsymbol{\alpha}} = L_{O|S,a}\boldsymbol{\alpha}$ for all $a \in \mathcal{A}$ by the $n \times n$ matrix $L_{O|S,a}$:

$$(G_S + \varepsilon_S n I_n)^{-1} G_{SS'} \left(G_{(S,A)} + \varepsilon_{(S,A)} n I_n\right)^{-1} G_{(S,A)(S,a)} \tag{15}$$

with $G_{SS'} := \Upsilon^\top \Upsilon'$, $G_{(S,A)(S,a)} := D\left(\mathbf{k}_A(a)\right) G_S$, and $\mathbf{k}_A(a) = \Psi^\top \psi(a)$.

- The update $\boldsymbol{\beta}'_{a;\boldsymbol{\alpha}} \mapsto \boldsymbol{\alpha}'_{a,o'}$ is based on the kernel Bayes' rule. The Gram matrix expression, eq.(25), results in $\boldsymbol{\alpha}'_{a,o'} = R_{S|O}(\hat{\boldsymbol{\beta}}'_{a;\boldsymbol{\alpha}})\mathbf{k}_O(o')$ using a non-negative vector $\hat{\boldsymbol{\beta}}'_{a;\boldsymbol{\alpha}}$ and an $n \times n$ matrix $R_{S|O}(\hat{\boldsymbol{\beta}}'_{a;\boldsymbol{\alpha}})$:

$$\left(D(\hat{\boldsymbol{\beta}}'_{a;\boldsymbol{\alpha}})G_O + \epsilon n I_n\right)^{-1} D(\hat{\boldsymbol{\beta}}'_{a;\boldsymbol{\alpha}}). \tag{16}$$

Given samples D_n, the embeddings $\hat{\mu}_S, \hat{\mu}_{O'|a;\mu_S}, \hat{\mu}^{a,o'}_{S'}$ are identified with n-dimensional vectors $\boldsymbol{\alpha}, \boldsymbol{\beta}'_{a;\boldsymbol{\alpha}}, \boldsymbol{\alpha}'_{a;\boldsymbol{\alpha}} \in \mathbb{R}^n$, respectively, and the Bellman equations (Claims 1, 2) can be represented in terms of these weight vectors. Therefore, the belief and predictive distributions are represented by n-dimensional vectors for any sets $\mathcal{S}$ and $\mathcal{O}$.

Claim 3. *Given samples D_n, the kernel Bellman equation (Claim 1) has the empirical expression*

$$\begin{aligned}\hat{V}^\pi(\boldsymbol{\alpha}) &= \hat{Q}^\pi(\boldsymbol{\alpha}, \pi(\boldsymbol{\alpha})),\\ \hat{Q}^\pi(\boldsymbol{\alpha}, a) &= \boldsymbol{\alpha}^\top \boldsymbol{R}_a + \gamma \boldsymbol{\beta}'^\top_{a;\boldsymbol{\alpha}} \hat{\mathbf{V}}^\pi\left(\boldsymbol{\alpha}'_{a,\mathcal{O}_0}\right),\end{aligned} \tag{17}$$

where $\mathbf{R}_a = (R(\tilde{s}_1, a), \ldots, R(\tilde{s}_n, a))^\top \in \mathbb{R}^n$ is the reward vector on samples $\mathcal{S}_0$ for action a and $\hat{\mathbf{V}}^\pi\left(\boldsymbol{\alpha}'_{a,\mathcal{O}_0}\right) = \left(\hat{V}^\pi\left(\boldsymbol{\alpha}'_{a,\tilde{o}_1}\right), \ldots, \hat{V}^\pi\left(\boldsymbol{\alpha}'_{a,\tilde{o}_n}\right)\right)^\top \in \mathbb{R}^n$ is the posterior belief value vector on samples $\mathcal{O}_0$ given action a.

Claim 4. *Given samples D_n, the kernel Bellman optimality equation (Claim 2) has the expression*

$$\begin{aligned}\hat{V}^*(\boldsymbol{\alpha}) &= \max_{a \in \mathcal{A}} \hat{Q}^*(\boldsymbol{\alpha}, a),\\ \hat{Q}^*(\boldsymbol{\alpha}, a) &= \boldsymbol{\alpha}^\top \boldsymbol{R}_a + \gamma \boldsymbol{\beta}'^\top_{a;\boldsymbol{\alpha}} \mathbf{V}^*\left(\boldsymbol{\alpha}'_{a,\mathcal{O}_0}\right),\\ \hat{\pi}^*(\boldsymbol{\alpha}) &= \arg\max_{a \in \mathcal{A}} \hat{Q}^*(\boldsymbol{\alpha}, a),\end{aligned} \tag{18}$$

where $\mathbf{R}_a = (R(\tilde{s}_1, a), \ldots, R(\tilde{s}_n, a))^\top \in \mathbb{R}^n$ and $\hat{\mathbf{V}}^*\left(\boldsymbol{\alpha}'_{a,\mathcal{O}_0}\right) = \left(\hat{V}^*\left(\boldsymbol{\alpha}'_{a,\tilde{o}_1}\right), \ldots, \hat{V}^*\left(\boldsymbol{\alpha}'_{a,\tilde{o}_n}\right)\right)^\top \in \mathbb{R}^n$.

Figure 1 illustrates the planning forward search using the Bellman equations. Even when the assumptions in Claims 1, 2 do not hold, we use Claims 3, 4 as an approximation, and Claim 4 for value iteration. Let $\hat{H}_n$ be the kernel Bellman operator,

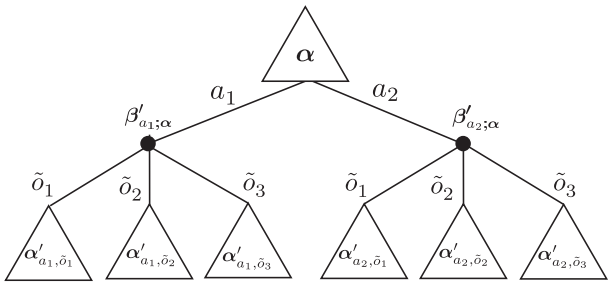

Figure 1: A search tree using kernel Bellman equations. Beliefs are represented by n-dimensional weight vectors $\boldsymbol{\alpha}$ on samples. The expected immediate reward (first term) is given by the linear combination $\boldsymbol{\alpha}^\top \boldsymbol{R}_a$ on samples $\mathcal{S}_0$ and associated with the action link a. The discounted expected value for next beliefs (second term) is given by the linear combination $\gamma \boldsymbol{\beta}'^\top_{a;\boldsymbol{\alpha}} \hat{\mathbf{V}}\left(\boldsymbol{\alpha}'_{a,\mathcal{O}_0}\right)$ on samples $\mathcal{O}_0$ and associated with the observation links $\mathcal{O}_0 = \{\tilde{o}_1, \ldots, \tilde{o}_n\}$. Observation links are expanded with respect to finite set $\mathcal{O}_0$ instead of $\mathcal{O}$. The kernel Bayes' rule is applied to each pair $(a, \tilde{o})$. Values are back-propagated bottom to top starting at initial values $V_0(\cdot)$ in the kernel value iteration algorithm.

$$\left(\hat{H}_n V\right)(\boldsymbol{\alpha}) = \max_{a \in \mathcal{A}} \left[\boldsymbol{\alpha}^\top \boldsymbol{R}_a + \gamma \boldsymbol{\beta}'^\top_{a;\boldsymbol{\alpha}} \mathbf{V}\left(\boldsymbol{\alpha}'_{a,\mathcal{O}_0}\right)\right]. \tag{19}$$

We run value iteration $\hat{V}_d = \hat{H}_n \hat{V}_{d-1} (d \geq 1)$ with an initial value function $V_0(\cdot)$ on weights. The detailed algorithm is shown in Algorithm 1. The computational complexity is given in Subsection 4.3. We use the same value initializations as in distributional POMDPs (Section 2). If $Q_0(\cdot, a) \in \mathcal{H}_\mathcal{S}$ for all $a \in \mathcal{A}$, the initial values $V_0(\cdot)$ over embeddings can be set as

$$V_0(\mu_S) = \max_{a \in \mathcal{A}} \langle \mu_S, Q_0(\cdot, a) \rangle_{\mathcal{H}_\mathcal{S}}, \tag{20}$$

which leads to the empirical expression

$$V_0(\boldsymbol{\alpha}) = \max_{a \in \mathcal{A}} \boldsymbol{\alpha}^\top \mathbf{Q}^0_a, \tag{21}$$

where $\mathbf{Q}^0_a = \left(Q_0(\tilde{s}_1, a), \ldots, Q_0(\tilde{s}_n, a)\right)^\top \in \mathbb{R}^n$ is an initial action value vector on samples $\mathcal{S}_0$. The reward function $Q_0(s, a) = R(s, a)$ or the QMDP value $Q_0(s, a) = Q^{MDP}(s, a)$ can be used for initialization.

Since $\boldsymbol{\alpha}, \boldsymbol{\beta}'_{a;\boldsymbol{\alpha}}, \boldsymbol{\alpha}'_{a;\boldsymbol{\alpha}}$ do not always give nonnegative vectors, the Bellman operator $\hat{H}_n$ is not guaranteed to be isotonic and contractive, although empirically, $\hat{H}_n$ can be used for the value iteration algorithm. $\hat{H}_n$ is corrected to have the isotonic and contractive properties by approximating the weight vectors as probability

Algorithm 1 Kernel Value Iteration ($\boldsymbol{\alpha}$, d)

Input: belief weights $\boldsymbol{\alpha}$, tree depth d
Output: Value $V_d(\boldsymbol{\alpha})$, Policy $\pi_d(\boldsymbol{\alpha})$
if $d = 0$ **then**
  Set: $V_d(\boldsymbol{\alpha}) = \max_{a \in \mathcal{A}} Q_0(\boldsymbol{\alpha}, a)$,

        Set:
          $V(\boldsymbol{\alpha}'_{a,\tilde{o}_i}) \leftarrow$ Kernel Val. Iter.$(\boldsymbol{\alpha}'_{a,\tilde{o}_i}, d-1)$
      end if
    end for
  end for
  Set: $V_d(\boldsymbol{\alpha}) = \max_{a \in \mathcal{A}} Q_d(\boldsymbol{\alpha}, a)$,
    $\pi_d(\boldsymbol{\alpha}) = \arg\max_{a \in \mathcal{A}} Q_d(\boldsymbol{\alpha}, a)$
end if

vectors [Grunewalder et al., 2012]. Let $\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}}'_{a;\boldsymbol{\alpha}}, \hat{\boldsymbol{\alpha}}'_{a;\boldsymbol{\alpha}}$ be probability vectors derived from $\boldsymbol{\alpha}, \boldsymbol{\beta}'_{a;\boldsymbol{\alpha}}, \boldsymbol{\alpha}'_{a;\boldsymbol{\alpha}}$ according to $\hat{w}_i = \frac{\max\{w_i,0\}}{\sum_{i=1}^n \max\{w_i,0\}}$ for weight vectors $\boldsymbol{w}$. The corresponding kernel Bellman operator $\hat{H}_n^+$ using the probability vectors $\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}}'_{a;\boldsymbol{\alpha}}$ is guaranteed to be isotonic and contractive. The proof is given in the Supplementary material.

Given samples D_n, we use the following tuple for the kernel value iteration:

$$\left\langle (\mathcal{H}_S, \mathbf{k}_S), (\mathcal{H}_A, \mathbf{k}_A), R, (\mathcal{H}_O, \mathbf{k}_O), L_{O|S,\mathcal{A}}, R_{S|O}(\cdot) \right\rangle,$$

where $L_{O|S,\mathcal{A}} = \{L_{O|S,a} | a \in \mathcal{A}\}$.

4.3 Computational Complexity

The update rule $\boldsymbol{\alpha} \mapsto \boldsymbol{\beta'}_{a;\boldsymbol{\alpha}}$ has complexity $O(n^2)$ with respect to the number of samples n for an action a, where the matrix $L_{S|O,a}$ is computed only once in the training phase. The update rule $\boldsymbol{\beta}'_{a;\boldsymbol{\alpha}} \mapsto \boldsymbol{\alpha}'_{a,o'}$ has complexity $O(n^3)$ for an observation o', due to the inversion of an $n \times n$ matrix (eq. 16). In total, the computation of the posterior weights $\boldsymbol{\alpha}'_{a,o'}$ for a pair (a, o') costs $O(n^3)$, compared with $O(|\mathcal{S}|^2)$ for Bayes' rule in eq.(1). Kernel value iteration to depth d costs $O(n^3(n|\mathcal{A}|)^d)$, whereas classical value iteration costs $O(|\mathcal{S}|^2(|\mathcal{O}||\mathcal{A}|)^d)$. The complexity $O(n^3)$ for computing $\boldsymbol{\alpha}'_{a,o'}$ can be reduced to $O(nr^2)$ via a low rank approximations of the $n \times n$ Gram matrices, where r is the rank.

Algorithm 2 Online Planning with Finite Horizon d

Set: T, $t = 0$
Get: Initial observation o
Compute: Initial belief $\boldsymbol{\alpha} = (G_O + n\epsilon_O I_n)^{-1}\mathbf{k}_O(o)$
repeat
  Planning: $a \leftarrow$ Kernel Value Iteration ($\boldsymbol{\alpha}$, d)
  Get: reward and new observation (R, o')
  Compute next belief: $\boldsymbol{\alpha} = R_{S|O}(\boldsymbol{\beta}'_{a;\boldsymbol{\alpha}})\mathbf{k}_O(o')$
  $t = t + 1$
until $t > T$

5 Experiments

We implemented an online planning algorithm in POMDPs using the kernel Bellman equations (Algorithm 2). An example of kPOMDP dynamics is shown in Figure 3. An agent computes the initial belief weights $\boldsymbol{\alpha} \in \mathbb{R}^n$ by $\boldsymbol{\alpha} = (G_O + n\epsilon_O I_n)^{-1}\mathbf{k}_O(o)$ with an initial observation o, which corresponds to a belief estimate without a prior. The agent makes a decision a by kernel value iteration to finite horizon d under the current belief weights $\boldsymbol{\alpha}$. The agent then updates the belief weights using a function $R_{S|O}(\cdot)$ and predictive weights $\boldsymbol{\beta}'_{a;\boldsymbol{\alpha}}$ when obtaining a reward R and a next observation o'. When the prediction fails (e.g., $D(\boldsymbol{\beta}'_{a;\boldsymbol{\alpha}})\mathbf{k}_O(o') = \mathbf{0}$, or in discrete cases $\boldsymbol{\beta}'_{a;\boldsymbol{\alpha}}(o') = 0$) in the case of small training samples, we reset current belief weights and estimated initial belief weights. To make the online planning algorithms more efficient, we computed the inverses of the $n \times n$ matrices in our algorithm by combining low rank approximations based on the incomplete Cholesky factorization and the Woodbury identity [Fine and Scheinberg, 2001]

Figure 2 shows some results on benchmarks [Littman, 1995], where the state, action, and observation sets are finite. Results are $d = 2$, $d = 1$, $d = 1$ for 10×10 Grid World, Network, Hallway, respectively. The exact policy is computed by an agent having complete knowledge about the POMDP environment. The histogram policy computed by running a classical value iteration algorithm, where transition and observation models are estimated by histograms using the same samples as our algorithm. Since the histogram policy requires samples over all the combinations of states and actions to estimate transition models, we introduced prior samples drawn from a uniform prior to test kPOMDP and Histograms under exactly the same conditions. Note that KBR does not need prior samples. We used QMDP initial values and pruned action links based on the QMDP values [Ross et al., 2008]. An action link was pruned if its QMDP value was lower than the current estimated value. The KBR-controller learned the exact policy as the number of training samples

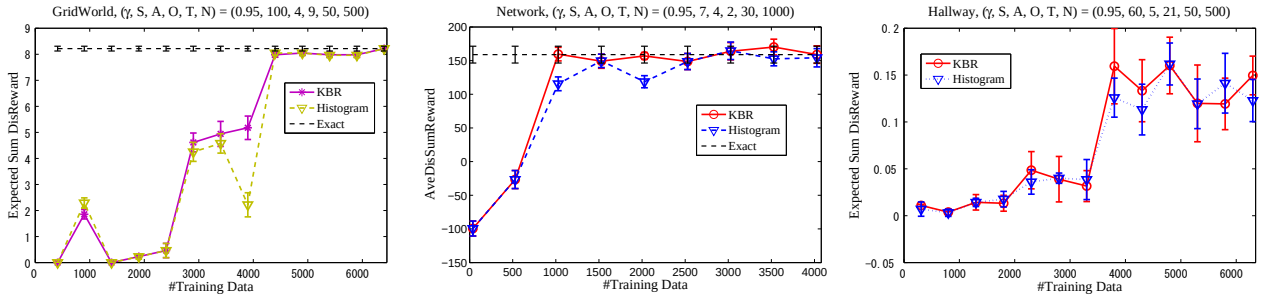

Figure 2: kPOMDPs+KBR controller. The left, middle, and right figures are 10×10 Gridworld, Network, and Hallway problems, respectively. Averaged discounted sum of rewards an agent got in test experiments are plotted against the number of training samples. We ran N experiments, where one experiment consists of T steps. The parameters are accompanied with the titles, (γ, S, A, O, T, N) = (γ, $|\mathcal{S}|$, $|\mathcal{A}|$, $|\mathcal{O}|$, T, N). Training samples are collected by uniform random actions. The leftmost plot for each figure is the result of uniform prior samples where no information about the environment. 10×10 grid world problem is similar to the 4×4 grid world, where state size is 100, reward is delivered by any action at a goal state with value 1, otherwise 0, and observations are 9 wall patterns about 4 nearest neighbors.

was increased in the 10×10 grid world and network problems. In our limited experiments, though KBR and histogram methods sometimes showed different results depending on training data, they gave similar results on average.

We also implemented a simulator of a swing-up cart-balancing system. The system consists of a cart with mass 8 kg running on a 2 m track and a freely swinging pendulum with mass 2 kg attached to the cart with a 50 cm rod. The state of the system is the angle and the angular velocity of the pendulum $(\theta, \dot{\theta})$, however the agent observes only the angle. The agent may apply a horizontal force or action to the cart, chosen from $a \in \{-250, -150, -50, 0, 50, 150, 250\}$N. The dynamics of the system are nonlinear. The states are continuous, but time is discretized in steps of 0.1 s. The objective is to balance the pendulum in the inverted position. Training samples are collected by applying uniform random actions from uniformly random states over $\theta = [-\pi/3, \pi/3]$, $\dot{\theta} = [3, 3]$. The reward function is given by $R(\theta, \dot{\theta}) = \exp(-\theta^2/2\sigma_1^2 - \dot{\theta}^2/10\sigma_2^2)$, where σ_1^2 and σ_2^2 are the variances of uniform distributions over $\theta = [-\pi/3, \pi/3]$, $\dot{\theta} = [3, 3]$, respectively.

Figure 3 shows a visualization of the kPOMDP dynamics and the inverted pendulum results (see caption details). The rightmost figure plots the averaged result of the earned rewards (height=cos(θ)) of the learned policies as a function of training samples. The episode length was 10 sec, i.e., the maximum of the total rewards is 100. The result was averaged over 20 experiments, the planning depth was $d = 1$, and the initial value function was the reward function $R(\theta, \dot{\theta})$. In kPOMDP, we used Gaussian kernels $G(\cdot, \cdot)$ for states and observations $k_{\mathcal{S}}((\theta_1, \dot{\theta}_1), (\theta_2, \dot{\theta}_2)) = G(\theta_1, \theta_2)G(\dot{\theta}_1, \dot{\theta}_2)$, $k_{\mathcal{O}}(\theta_1, \theta_2) = G(\theta_1, \theta_2)$, where the kernel parameters σ were $\sigma = \text{MedDist}/30$ for θ and $\sigma = \text{MedDist}/10$ for $\dot{\theta}$, where MedDist is the median inter-sample distance. The kernel for actions was the identity. We compared kPOMDP to histogram policies where the environment is discretized. Histogram(M) indicates $M \times M$ discretized states over $[-\pi/3, \pi/3] \times [3, 3]$. kPOMDP almost reached the maximum value 100 and showed better results than histogram policies.

6 Summary

We have introduced POMDPs in feature spaces, where beliefs over states are represented as distribution embeddings in feature spaces and updated via the kernel Bayes' rule. The Bellman equations, value functions, and policies are all expressed as functions of this feature representation. We further proposed a policy learning strategy by value iteration in the kernel framework, where the isotonic and contraction properties of the kernel Bellman operator are enforced by a simple correction. Value initialization and action edge pruning can be implemented for kernel POMDPs, following the approach of distributional POMDPs such as QMDP. Experiments confirm that the controller learned in feature space converges to the optimum policy. Our approach serves as a first step towards more powerful kernel-based algorithms for POMDPs.

A Appendix: Kernel Bayes' Rule

A variant of the kernel Bayes' rule algorithm we have used in this paper is described. [Fukumizu et al., 2011] propose a squared regularization form for the empirical

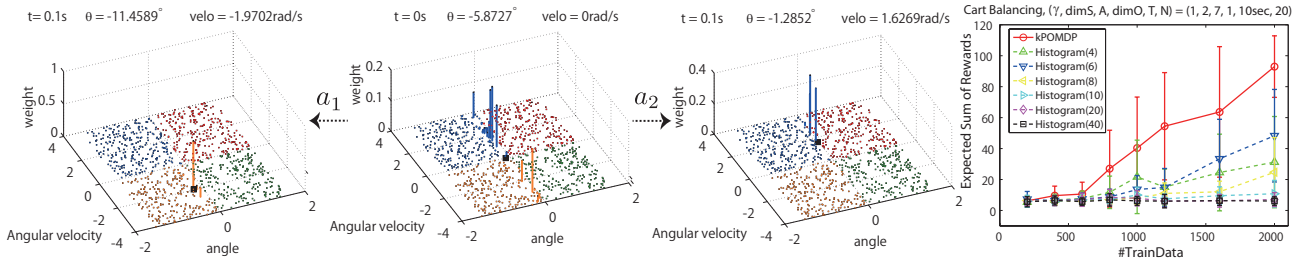

Figure 3: Inverted pendulum results with an example of kPOMDP dynamics. In the three 3D plots, all the points indicate training samples on state set $\mathcal{S} = (\theta, \dot{\theta})$ and z axis indicates the magnitude of weights on their samples (after normalization), i.e., belief embedding weights $\hat{\boldsymbol{\alpha}}$ identifying belief embedding $\hat{\mu}_S$. The true state of the system is also marked by the black point in each 3D plot. The four colors indicate different combinations of signs of states (for instance, blue denotes positive angular velocity and negative angle). The middle figure in the 3D plots shows the initial belief estimate given an initial observation $o = \theta$, estimated by $\boldsymbol{\alpha} = (G_O + n\epsilon_O I_n)^{-1}\mathbf{k}_O(o)$ in Algorithm 2. Since $\dot{\theta}$ is uncertain at the initial point, positive weights spread in the direction of $\dot{\theta}$ axis. The left and right figures in the 3D plots correspond to the updated weights $\boldsymbol{\alpha}'_{a,o'}$ of belief embeddings depending on the executed actions a_1 (positive) and a_2 (negative) after observing a new observation $o' = \theta'$. Angular velocity $\dot{\theta}$ is then well estimated by the kPOMDPs. The rightmost figure shows the averaged result of the total rewards obtained by learned policies as training samples increased. More description is in the text.

posterior embedding in (10),

$$\hat{\mu}_{\bar{X}|y} = \hat{C}_{\bar{X}\bar{Y}} \left(\hat{C}^2_{\bar{Y}\bar{Y}} + \delta n I_n\right)^{-1} \hat{C}_{\bar{Y}\bar{Y}} k_{\mathcal{Y}}(y, \cdot), \qquad (22)$$

where δ is a small regularization parameter to avoid the instability of $\hat{C}^{-1}_{\bar{Y}\bar{Y}}$, since the empirical estimate $\hat{C}_{\bar{Y}\bar{Y}}$ may include negative weights. The estimate (22) is consistent under smoothness assumptions, and converges to $\mu_{\bar{X}|y}$ in the infinite sample limit. Since we always normalize weight vectors to probability vectors as in subsection 4.2, however, we use the simpler and more computationally efficient estimate

$$\hat{\mu}_{\bar{X}|y} = \hat{C}_{\bar{X}\bar{Y}} (\hat{C}_{\bar{Y}\bar{Y}} + \epsilon n I_n)^{-1} k_{\mathcal{Y}}(y, \cdot), \qquad (23)$$

where ϵ is a small regularization parameter. Though the consistency of (23) with the combination of the normalization is not theoretically proven, experiments (Section 5) show good empirical results. In what follows we give the KBR algorithm when the estimate (23) is used with normalized weights.

Denote feature vectors $\varphi(X) = k_{\mathcal{X}}(X, \cdot)$ and $\phi(Y) = k_{\mathcal{Y}}(Y, \cdot)$. Let $U_1, \ldots, U_l$ be l samples drawn from the prior Π and $(X_1, Y_1), \ldots, (X_n, Y_n)$ be n samples drawn from P. Consider an empirical prior embedding $\hat{\mu}_\Pi = \bar{\Upsilon}\boldsymbol{\gamma}$ where $\bar{\Upsilon} = (\varphi(U_1), \ldots, \varphi(U_l))$ are feature mappings of the prior samples and $\boldsymbol{\gamma} \in \mathbb{R}^l$ is a weight vector. Define the $n \times l$ matrix $G_{XU} = \Upsilon^\top \bar{\Upsilon}$, and

$$\Upsilon \circ \Phi := (\varphi(X_1) \otimes \phi(Y_1), \ldots, \varphi(X_n) \otimes \phi(Y_n)),$$
$$\Phi \circ \Phi := (\phi(Y_1) \otimes \phi(Y_1), \ldots, \phi(Y_n) \otimes \phi(Y_n)). \qquad (24)$$

Empirical estimates of the covariance operators $C_{\bar{X}\bar{Y}}$, $C_{\bar{Y}\bar{Y}}$ are then given by $\hat{C}_{\bar{X}\bar{Y}} = (\Upsilon \circ \Phi)\boldsymbol{\beta}$, $\hat{C}_{\bar{Y}\bar{Y}} = (\Phi \circ \Phi)\boldsymbol{\beta}$ with the weight vector $\boldsymbol{\beta} = (G_X + \varepsilon n I_n)^{-1} G_{XU}\boldsymbol{\gamma}$ [Fukumizu et al., 2011]. We approximate $\boldsymbol{\beta}$ by a non-negative vector $\hat{\boldsymbol{\beta}}$, as in subsection 4.2, leading to the following proposition:

Proposition 1. *The empirical estimate eq.(23) has the following Gram matrix expression using a non-negative vector $\hat{\boldsymbol{\beta}}$ for all $y \in \mathcal{Y}$:*

$$\hat{\mu}_{\bar{X}|y} = \Upsilon R_{X|Y}(\hat{\boldsymbol{\beta}})\mathbf{k}_Y(y),$$
$$R_{X|Y}(\hat{\boldsymbol{\beta}}) := \left(D(\hat{\boldsymbol{\beta}})G_Y + \delta n I_n\right)^{-1} D(\hat{\boldsymbol{\beta}}), \qquad (25)$$

where $\mathbf{k}_Y(y) = \Phi^\top \phi(y)$ and $D(\hat{\boldsymbol{\beta}}) = \mathrm{diag}(\hat{\boldsymbol{\beta}})$.

Proof. The proof follows the same reasoning as Proposition 3.4 of [Fukumizu et al., 2011]. □

Let $\boldsymbol{\alpha}(y) = R_{X|Y}(\boldsymbol{\beta})\Phi^\top \phi(y) \in \mathbb{R}^n$. The posterior embedding $\mu_{\bar{X}|y}$ can be estimated by a linear combination of feature vectors on samples $\Upsilon = (\varphi(X_1), \ldots, \varphi(X_n))$ with weights $\boldsymbol{\alpha}(y) \in \mathbb{R}^n$ that depend on $y \in \mathcal{Y}$.

Abstract

Cooperative *Bayesian games* (BGs) can model decision-making problems for teams of agents under imperfect information, but require space and computation time that is exponential in the number of agents. While *agent independence* has been used to mitigate these problems in perfect information settings, we propose a novel approach for BGs based on the observation that BGs additionally possess a different types of structure, which we call *type independence*. We propose a factor graph representation that captures both forms of independence and present a theoretical analysis showing that *non-serial dynamic programming* cannot effectively exploit type independence, while Max-Sum can. Experimental results demonstrate that our approach can tackle cooperative Bayesian games of unprecedented size.

1 Introduction

Cooperative multiagent systems are an essential tool, not only for tackling inherently distributed problems, but also for decomposing problems too complex to be tackled by a single agent (Huhns, 1987; Sycara, 1998; Panait and Luke, 2005; Vlassis, 2007; Buşoniu et al., 2008). However, to make such systems effective, the constituent agents must be able to coordinate their action selection in order to achieve a common goal.

This problem is particularly vexing in the presence of *imperfect information* (Harsanyi, 1967–1968). Even a single-agent system may have incomplete knowledge of the state of its environment (Kaelbling et al., 1998), e.g., due to noisy sensors. However, the presence of multiple agents often greatly exacerbates this problem, as each agent typically has access to only a fraction of the whole system's sensors. In principle, agents could synchronize their beliefs and coordinate their actions by communicating. However, communication is often unreliable and limited by bandwidth constraints, leaving each agent uncertain how others will act.

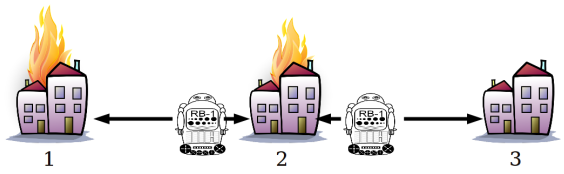

Figure 1: Illustration of multiagent decision making with imperfect information. Both agents know house 2 is on fire. However, each agent receives only a noisy observation of the single neighboring house it can observe in the distance.

Consider the example depicted in Fig. 1. Both fire-fighting agents know there is fire at house H_2 but each receives only a noisy observation about one of the other houses. Consequently, effective decision making is difficult. If agent 1 (left) observes flames in house H_1, it may be tempted to fight fire there rather than at house H_2. However, the efficacy of doing so depends on whether agent 2 (right) will fight fire in house H_2, which in turn depends on whether agent 2 observes flames in house H_3, a fact unknown to agent 1.

Such problems can be modeled as cooperative *Bayesian games (BGs)*, which extend traditional *strategic games* to model imperfect information. BGs can model a great variety of problems and are of great importance for solving sequential decision problems (Emery-Montemerlo et al., 2004; Oliehoek et al., 2008a; Kumar and Zilberstein, 2010; Spaan et al., 2011). In a BG, a *type* for each agent, specifying the private information it holds, is drawn from a distribution. Then, the agents simultaneously select actions conditioned on their individual type, and subsequently receive a team payoff based on the realized types and actions.

Unfortunately, solving cooperative BGs is NP-hard (Tsitsiklis and Athans, 1985). Just representing them

requires space exponential in the number of agents and solving them exactly requires time exponential in the number of agents and types. However, as in cooperative strategic games (Guestrin et al., 2002; Kok and Vlassis, 2006), many problems exhibit *agent independence*, i.e., the global payoff function can be decomposed as the sum of *local payoff functions*, each of which depends on the actions of only a few agents. The resulting *cooperative graphical Bayesian games (CG-BGs)* can be represented more compactly and solved more effectively using inference methods for graphical models such as *non-serial dynamic programming* (NDP) (Bertele and Brioschi, 1972) and the popular MAX-SUM algorithm (Pearl, 1988; Kok and Vlassis, 2005, 2006; Farinelli et al., 2008; Rogers et al., 2011).

This paper is motivated by the observation that BGs also exhibit another form of structure that we call *type independence*, in which the global payoff function can be decomposed as the sum of *contributions*, each of which depends on only one joint type. Such structure has been exploited when cooperative BGs are solved using heuristic search methods (Kumar and Zilberstein, 2010; Oliehoek et al., 2010), though the role of type independence has not been made explicit. However, in the worst case, heuristic search methods are no better than brute-force search and thus can perform much worse than inference-based methods, even when exploiting structure with *and/or search trees* (Marinescu and Dechter, 2009).[1] In addition, such methods do not exploit agent independence.

To address these shortcomings, this paper investigates the exploitation of type independence using inference methods. Specifically, we propose a novel *factor graph* representation that neatly captures *both* agent and type independence and thus enables the exploitation of both forms of structure. Our analysis of the computational complexity of both NDP and MAX-SUM applied to this factor graph reveals that the former cannot effectively exploit type independence; we prove that its computational complexity remains exponential in the number of types (although it still outperforms one of the search methods empirically). On the other hand, we prove that each iteration of MAX-SUM is tractable for problems with small local neighborhoods. Bounding the number of iterations thus yields a polynomial-time approximate method for such cooperative BGs.

In addition, we present extensive experimental results that demonstrate that MAX-SUM finds near-optimal solutions and that the simultaneous exploitation of both agent and type independence leads to dramatically better scalability than several state-of-the-art alternatives in the number of agents, actions, and types. This improved scalability enables the solution of cooperative BGs of unprecedented size.

[1] NDP, for example, is never slower than brute-force search, i.e., conditioning in graphical models (Koller and Friedman, 2009). When the *induced width* is small, NDP can be much faster (Dechter, 1999).

2 Background

We begin with some background on BGs and CGBGs.

Bayesian Games A Bayesian game, also called a *strategic game of imperfect information*, is an augmented strategic game in which the players hold private information (Harsanyi, 1967–1968; Osborne and Rubinstein, 1994). The private information of agent i defines its *type* $\theta_i \in \Theta_i$. The agents' payoffs depend not only on their actions, but also on their types.

Definition 1. A *Bayesian game (BG)* is a tuple $\langle \mathcal{D}, \mathcal{A}, \boldsymbol{\Theta}, \Pr(\boldsymbol{\Theta}), \langle u_1, ...u_n \rangle \rangle$, where $\mathcal{D}$ is the set of n agents, $\mathcal{A} = \mathcal{A}_1 \times \cdots \times \mathcal{A}_n$ is the set of joint actions $\mathbf{a} = \langle a_1, \ldots, a_n \rangle$, $\boldsymbol{\Theta} = \Theta_1 \times \cdots \times \Theta_n$ is the set of joint types $\boldsymbol{\theta} = \langle \theta_1, \ldots, \theta_n \rangle$, $\Pr(\boldsymbol{\Theta})$ is the distribution over joint types, and $u_i : \boldsymbol{\Theta} \times \mathcal{A} \to \mathbb{R}$ is the payoff function of agent i.

Since agents in a BG can condition their actions on their types, they select policies (as opposed to actions as in strategic games). A joint policy $\boldsymbol{\beta} = \langle \beta_1, ..., \beta_n \rangle$, consists of individual policies β_i for each agent i. Deterministic (pure) individual policies map each type θ_i to an action. Since we focus on *cooperative* Bayesian games, in which all agents share a single team payoff function $u = u_i$ for all i, only deterministic policies need be considered.

In a BG, the traditional Nash equilibrium is replaced by a *Bayesian Nash equilibrium (BNE).* A profile of policies $\boldsymbol{\beta} = \langle \beta_1, ..., \beta_n \rangle$ is a BNE when no agent i has an incentive to switch its policy β_i, given the policies of the other agents $\boldsymbol{\beta}_{\neq i}$. In cooperative BGs, the definition of a solution is simpler. Let the *value* of a joint policy be its expected payoff:

$$V(\boldsymbol{\beta}) = \sum_{\boldsymbol{\theta} \in \boldsymbol{\Theta}} \Pr(\boldsymbol{\theta}) u(\boldsymbol{\theta}, \boldsymbol{\beta}(\boldsymbol{\theta})), \tag{1}$$

where $\boldsymbol{\beta}(\boldsymbol{\theta}) = \langle \beta_1(\theta_1), ..., \beta_n(\theta_n) \rangle$ is the joint action specified by $\boldsymbol{\beta}$ for joint type $\boldsymbol{\theta}$. A solution of a cooperative BG is $\boldsymbol{\beta}^* = \arg\max_{\boldsymbol{\beta}} V(\boldsymbol{\beta})$, which is a Pareto-optimal Bayesian Nash equilibrium.

Cooperative Graphical Bayesian Games. A key difficulty in BGs is that the size of their payoff matrices is exponential in the number of agents. However, many BGs contain *agent independence*, i.e., not all agents directly influence each other, which allows for compact representations and efficient solutions.

Agent independence can be formalized in *graphical (strategic) games* (Kearns et al., 2001; Kearns, 2007) and *graphical Bayesian games* (Soni et al., 2007), in which each agent has an *individual* payoff function that depends on only a subset of agents. Unfortunately, such models are not useful in cooperative games since all agents share a single payoff function in which all agents participate (otherwise they would be irrelevant). Instead, we employ *cooperative graphical BGs (CGBGs)* (Oliehoek et al., 2008b), which use *coordination (hyper-)graphs* (Guestrin et al., 2002; Kok and Vlassis, 2006) to express conditional independence between agents. In CGBGs, the single team payoff function decomposes as the sum of several *local* payoff functions.

Definition 2. A *cooperative graphical Bayesian game (CGBG)* is a tuple $\langle \mathcal{D}, \mathcal{A}, \boldsymbol{\Theta}, \Pr(\boldsymbol{\Theta}), \mathcal{U} \rangle$ where $\mathcal{D}$, $\mathcal{A}$, $\boldsymbol{\Theta}$, and $\Pr(\boldsymbol{\Theta})$ are as before and $\mathcal{U} = \{u^1, \ldots, u^\rho\}$ is the set of *local payoff functions*, each of which involves only a subset of agents. Each u^e has *scope* $\mathbb{A}(u^e)$ specifying the subset of agents on which it depends.

When scopes are restricted, CGBGs can be represented much more compactly than regular cooperative BGs. In fact, if the largest scope has size k, then the representation size is exponential in k, but only linear in n. However, the joint type distribution must also be compact. A typical assumption is that the type probabilities factor as the product of individual type probabilities (Soni et al., 2007; Jiang and Leyton-Brown, 2010). More generally, it is common to represent $\Pr(\boldsymbol{\Theta})$ compactly (e.g., as in (Koller and Milch, 2003; Jiang and Leyton-Brown, 2010)) by means of Bayesian networks (Pearl, 1988; Bishop, 2006) or other graphical models.[2]

Agents in a CGBG aim to maximize the expected sum of local payoffs:

$$\boldsymbol{\beta}^* = \arg\max_{\boldsymbol{\beta}} \sum_{e \in \mathcal{E}} \sum_{\boldsymbol{\theta}_e \in \boldsymbol{\Theta}_e} \Pr(\boldsymbol{\theta}_e) u^e(\boldsymbol{\theta}_e, \boldsymbol{\beta}_e(\boldsymbol{\theta}_e)) \quad (2)$$

where $\boldsymbol{\theta}_e = \langle \theta_i \rangle_{i \in \mathbb{A}(u^e)}$ is the local joint type, $\boldsymbol{\beta}_e = \langle \beta_i \rangle_{i \in \mathbb{A}(u^e)}$ is the local joint policy, and $\boldsymbol{\beta}_e(\boldsymbol{\theta}_e)$ is the local joint action under $\boldsymbol{\beta}$ given $\boldsymbol{\theta}_e$.[3] The local value for the e-th payoff component is:

$$V^e(\boldsymbol{\beta}_e) = \sum_{\boldsymbol{\theta}_e \in \boldsymbol{\Theta}_e} \Pr(\boldsymbol{\theta}_e) u^e(\boldsymbol{\theta}_e, \boldsymbol{\beta}_e(\boldsymbol{\theta}_e)). \quad (3)$$

[2]While not all joint type distributions admit a compact representation, this is nonetheless a minimal assumption: there is no hope of solving other BGs efficiently, as they cannot even be represented efficiently. Fortunately, the class of real-world problems that admit a compact representation is likely to be quite large.

[3]We abuse notation such that e is an index into the set of local payoff functions and an element of the set of scopes.

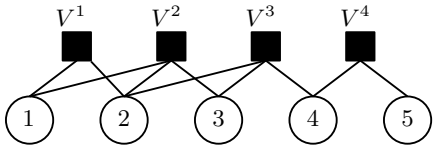

Figure 2: An AI factor graph with five agents. Circular nodes are agents and square nodes are local payoff functions, with edges indicating in which local payoff function each agent participates.

Each local value component can be interpreted as a factor in a *factor graph* (Kschischang et al., 2001; Loeliger, 2004), which generalizes a coordination graph to allow local payoff functions that depend on more than two agents. The resulting bipartite graph has one set of nodes for all the local value functions (the factors) and another set for all the agents (the variables, whose values correspond to policies), as shown in Fig. 2. A local value function V^e is connected to an agent i if and only if $i \in \mathbb{A}(u^e)$. We refer to this as an *agent independence (AI) factor graph*.

A naive solution approach is to simply enumerate all joint policies. However, the required time is $O(|\mathcal{A}_*|^{|\Theta_*|^n})$, where $|\mathcal{A}_*|$ and $|\Theta_*|$ are the size of the largest individual action and type set. Thus, it scales exponentially with the number of agents and types. Fortunately, the agent independence expressed in the factor graph of Fig. 2 can be exploited. For instance, Oliehoek et al. (2008b) apply NDP to this graph. Another option is to use Max-Sum message passing.

3 Representing Type Independence

Applying NDP or Max-Sum to an AI factor graph can reduce the exponential complexity with respect to the number of agents. However, it cannot reduce the exponential complexity with respect to the number of types because this complexity manifests itself in the number of values that the variables can take on.

The key observation motivating this work is that CGBGs also possess a second form of independence, which we call *type independence*, that enables solution approaches to avoid the exponential dependence on the number of types. Unlike agent independence, which only some BGs possess, type independence is an inherent property of all BGs because it is a direct consequence of the fact that the value of a joint policy is an expectation over joint types.

Type independence is expressed in terms of a *contribution* for each joint type:

$$C_{\boldsymbol{\theta}}(\mathbf{a}) \equiv \Pr(\boldsymbol{\theta}) u(\boldsymbol{\theta}, \mathbf{a}). \quad (4)$$

The value of a joint policy $\boldsymbol{\beta}$ can now be interpreted

as a sum of contributions, one for each joint type:

$$V(\boldsymbol{\beta}) = \sum_{\boldsymbol{\theta} \in \boldsymbol{\Theta}} C_{\boldsymbol{\theta}}(\boldsymbol{\beta}(\boldsymbol{\theta})). \quad (5)$$

Type independence results from the additive structure of a joint policy's value shown in (5). The key insight is that each contribution term depends only on the joint action selected when the corresponding joint type $\boldsymbol{\theta}$ occurs. Since that action is selected according to the joint policy $\boldsymbol{\beta}$, the contribution depends only on $\boldsymbol{\beta}(\boldsymbol{\theta})$, the part of the joint policy that specifies the joint action for $\boldsymbol{\theta}$.

Viewed from another perspective, type independence occurs because, in any game, only one individual type is realized for each agent, and that type affects only some contributions. In other words, the individual action $\beta_i(\theta_i)$ selected for type θ_i of agent i affects only those contributions whose joint types involve θ_i. For instance, in the firefighting problem illustrated in Fig. 1, one possible joint type is $\boldsymbol{\theta} = \langle N, N \rangle$ (neither agent observes flames). Clearly, the action $\beta_1(F)$ that agent 1 selects when it has type F (it observes flames), has no effect on the contribution of this joint type.

An optimal joint policy can also be described in terms of contributions, by simply maximizing the value as defined in (5):

$$\boldsymbol{\beta}^* = \arg\max_{\boldsymbol{\beta}} V(\boldsymbol{\beta}) = \arg\max_{\boldsymbol{\beta}} \sum_{\boldsymbol{\theta} \in \boldsymbol{\Theta}} C_{\boldsymbol{\theta}}(\boldsymbol{\beta}(\boldsymbol{\theta})). \quad (6)$$

Thus, the solution to a BG maximizes the sum of contributions, each of which has restricted scope. This is an important observation, since maximization of an additively factored function with components of restricted scope is exactly the operation that algorithms such as NDP and Max-Sum make more efficient.

To apply these methods, we represent type independence in a factor graph, by creating factors for all the contributions (corresponding to joint types) and variables for all the individual types of all the agents. Fig. 3 shows such a factor graph for the firefighting problem. Unlike the representation that results from reducing a BG to a strategic game played by *agent-type* combinations (Osborne and Rubinstein, 1994), this factor graph does not 'flatten' the utility function. On the contrary, it explicitly represents the contributions of each joint type, thereby capturing type independence.

However, while the factor graph in Fig. 3 represents type independence, it does not represent agent independence because the global payoff represented by the sum of contributions is not decomposed into local payoff functions. Conversely, the factor graph shown in Fig. 2 represents agent independence but not type independence because the value of each local payoff function is not decomposed into contributions. To solve CGBGs efficiently, we need a factor graph formulation that captures both agent and type independence.

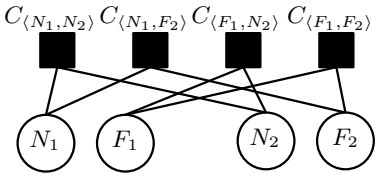

Figure 3: A factor graph for the firefighting problem that captures type independence, e.g., the action that agent 1 selects when it has type N affects only the contribution factors $C_{\langle N_1,N_2 \rangle}$ and $C_{\langle N_1,F_2 \rangle}$ in which it has that type.

To this end, we define a *local contribution* as follows:

$$C^e_{\boldsymbol{\theta}_e}(\mathbf{a}_e) \equiv \Pr(\boldsymbol{\theta}_e) u^e(\boldsymbol{\theta}_e, \mathbf{a}_e). \quad (7)$$

Using this notation, the solution of the CGBG is

$$\boldsymbol{\beta}^* = \arg\max_{\boldsymbol{\beta}} \sum_{e \in \mathcal{E}} \sum_{\boldsymbol{\theta}_e \in \boldsymbol{\Theta}_e} C^e_{\boldsymbol{\theta}_e}(\boldsymbol{\beta}_e(\boldsymbol{\theta}_e)). \quad (8)$$

Thus, the solution corresponds to the maximum of an additively decomposed function containing a contribution for each local joint type $\boldsymbol{\theta}_e$. This can be expressed in a factor graph in which an individual type θ_i of an agent i is connected to a contribution $C^e_{\boldsymbol{\theta}_e}$ if and only if i participates in u^e and $\boldsymbol{\theta}_e$ specifies θ_i for agent i, as illustrated in Fig. 4. We refer to this graph as the *agent and type independence (ATI) factor graph*. Contributions are separated, not only by the joint type to which they apply, but also by the local payoff function to which they contribute. Consequently, both agent and type independence are neatly expressed.

4 Solving ATI Factor Graphs

ATI factor graphs can be solved using existing methods such as NDP and Max-Sum. In this section, we analyze the computational complexity of doing so.

4.1 Non-Serial Dynamic Programming

NDP can compute the maximum configuration of a factor graph. In the *forward pass*, variables are eliminated one by one according to some prespecified order. Eliminating the kth variable v involves collecting all the factors in which it participates and replacing them with a new factor f^k that represents the sum of the removed factors, given that v selects a best response. Once all variables are eliminated, the *backward pass* iterates through the variables in reverse order of elimination. Each variable selects a best response to the

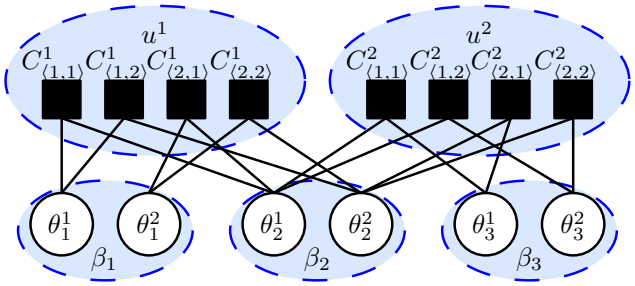

Figure 4: ATI factor graph for a CGBG with three agents, two types per agent, and two local payoff functions. Agents 1 and 2 participate in payoff function u^1 (corresponding to the first four contributions), while agents 2 and 3 participate in u^2 (corresponding to the last four contributions). The factor graph expresses both agent independence (e.g., agent 1 does not participate in u^2) and type independence (e.g, the action agent 1 selects when it receives observation θ^1_1 affects only the first 2 contributions).

variables already visited, eventually yielding an optimal joint policy.

The maximum number of agents participating in a factor encountered during NDP is known as the induced width w of the ordering. The induced width depends on the order in which the variables are eliminated and determining the optimal order is NP-complete (Arnborg et al., 1987). The following result is well-known (see for instance (Dechter, 1999)):

Theorem 1. NDP *requires exponential time and space in the induced width w.*

Though NDP is still exponential, for sparse problems the induced width is much smaller than the total number of variables V, i.e., $w \ll V$, leading to an exponential speedup over naively enumerating the joint variables. However, NDP scales poorly in practice on densely connected graphs (Kok and Vlassis, 2006). In addition, because of the particular shape that type independence induces on the ATI factor graph, we can establish the following:

Theorem 2. *The induced width of an ATI factor graph is lower bounded by the number of individual types and the size of the largest payoff function:*

$$w \geq (k-1) \cdot |\Theta_*|,$$

where k is the largest local scope $k = \max_{e \in \mathcal{E}} |\mathbb{A}(u^e)|$, and Θ_* denotes the smallest individual type set.

Proof. Assume u^e is a payoff function of maximal size k. At some point, NDP will eliminate the first variable connected to one of its contributions, i.e., a type of an agent $i \in \mathbb{A}(u^e)$. Since such a variable is connected to contributions for each profile $\boldsymbol{\theta}_{e \setminus i}$ of types of the other agents participating in u^e, the newly introduced factor will connect all the types of these $(k-1)$ other agents. The minimum number of types of an agent is $|\Theta_*|$ and thus the lower bound holds. □

Theorems 1 and 2 lead directly to the following observation:

Corollary 1. *The computational complexity of* NDP *applied to an ATI factor graph is exponential in the number of individual types.*

Therefore, even given the ATI factor graph formulation, it seems unlikely that NDP can effectively exploit type independence. In particular, we hypothesize that NDP will not perform significantly better when applied to the ATI factor graph instead of the AI factor graph. In fact, it is easy to construct an example where it performs worse.

4.2 Max-Sum

To more effectively exploit type independence, we can solve the ATI factor graph using the Max-Sum message passing algorithm. Max-Sum is an appealing choice for several reasons. First, it performs well in practice on structured problems (Murphy et al., 1999; Kschischang et al., 2001; Kok and Vlassis, 2006; Farinelli et al., 2008; Kuyer et al., 2008). Second, unlike NDP, it is an *anytime* algorithm that can provide results after each iteration, not only at the end (Kok and Vlassis, 2006). Third, as we show below, its computational complexity is exponential only in the size of the largest local payoff function's scope, which is fixed for many classes of CGBGs.

Max-Sum iteratively sends messages between the factors and variables. These messages encode how much payoff the sender expects to be able to contribute to the total payoff. In particular, a message sent from a type i to a contribution j encodes, for each possible action, the payoff it expects to contribute. This is computed as the sum of the incoming messages from other contributions. Similarly, a message sent from a contribution to a type i encodes the payoff it can contribute conditioned on each available action to the agent with type i.[4]

Max-Sum iteratively passes these messages over the edges of the factor graph. Within each iteration, the messages are sent either in parallel or sequentially with a fixed or random ordering. When run on an acyclic factor graph (i.e., a tree), it is guaranteed to converge to an optimal fixed point (Pearl, 1988; Wainwright

[4]For a detailed description of how the messages are computed, see Oliehoek (2010) or Rogers et al. (2011).

et al., 2004). In cyclic factor graphs, there are no guarantees that MAX-SUM will converge.[5] However, experimental results have demonstrated that it works well in practice even when cycles are present (Kschischang et al., 2001; Kok and Vlassis, 2006; Kuyer et al., 2008). This requires normalizing the messages to prevent them from growing ever larger, e.g., by taking a weighted sum of the new and old messages (damping).

Here we show that the computational complexity of one iteration of MAX-SUM on a CGBG is exponential only in the size of the largest local payoff function's scope. In general, it is not possible to bound the number of iterations, since MAX-SUM is not guaranteed to converge. However, MAX-SUM converges quickly in practice and, since it is an anytime algorithm, the number of iterations can be fixed in advance.

Theorem 3. *One iteration of* MAX-SUM *run on the factor graph constructed for a CGBG has cost*

$$O\left(|\mathcal{A}_*|^k \cdot k^2 \cdot \rho\rho_* |\Theta_*|^{2k-1}\right), \tag{9}$$

where ρ_* is the maximum number of edges in which an agent participates.

Proof. It follows directly from the cost of a message and the number of messages sent by factors and variables that the complexity of one iteration of MAX-SUM is

$$O\left(m^k \cdot k^2 \cdot l \cdot F\right), \tag{10}$$

where F is the number of factors, k is the maximum degree of a factor, l is the maximum degree of a variable, and m is the maximum number of values a variable can take.

Now, we interpret (10) for the CGBG setting. In this case, $m = |\mathcal{A}_*|$, $F = O(\rho \cdot |\Theta_*|^k)$ is the number of contributions, and $l = O(\rho_* \cdot |\Theta_*|^{k-1})$, since each edge $e \in \mathcal{E}$ in which a (type of an) agent participates induces $O(|\Theta_*|^{k-1})$ contributions to which it is connected. □

The implication of this theorem it that a MAX-SUM iteration is tractable for small k, the size of the largest local scope. For problems with bounded k, this therefore directly yields a polynomial-time approximate algorithm by bounding the number of iterations. Given these results, we expect that, in general, MAX-SUM will prove more effective than NDP at exploiting type independence. In particular, we hypothesize that MAX-SUM will outperform NDP when applied to an ATI factor graph and will outperform MAX-SUM when applied to an AI factor graph.

[5]However, some variants of the message passing approach have slight modifications that yield convergence guarantees (Globerson and Jaakkola, 2008). Since we found that regular MAX-SUM performs well in our experimental setting, we do not consider such variants here.

5 Experiments

To evaluate the efficacy of using ATI factor graphs, we compare **NDP-ATI**, NDP applied to an ATI factor graph and **Max-Sum-ATI**, MAX-SUM applied to an ATI factor graph with 10 restarts, to several state-of-the-art alternatives. In particular, we compare to: **BaGaBaB**, Bayesian Game Branch and Bound, a heuristic search method for optimally solving CBGs (Oliehoek et al., 2010); **AltMax**, Alternating maximization, starting with a random joint policy, each agent iteratively computes a best-response policy for each of its types, thus hill-climbing to a local optimum; **CE**, Cross Entropy optimization (de Boer et al., 2005) a randomized optimization method that maintains a distribution over joint policies; **MAID-CM**, the state-of-the-art continuation method for solving multiagent influence diagrams (Blum et al., 2006).[6] Apart from MAID-CM, methods were implemented using the MADP Toolbox (Spaan and Oliehoek, 2008); the NDP and MAX-SUM implementations also use LIBDAI (Mooij, 2008).

5.1 Random CGBG Experiments

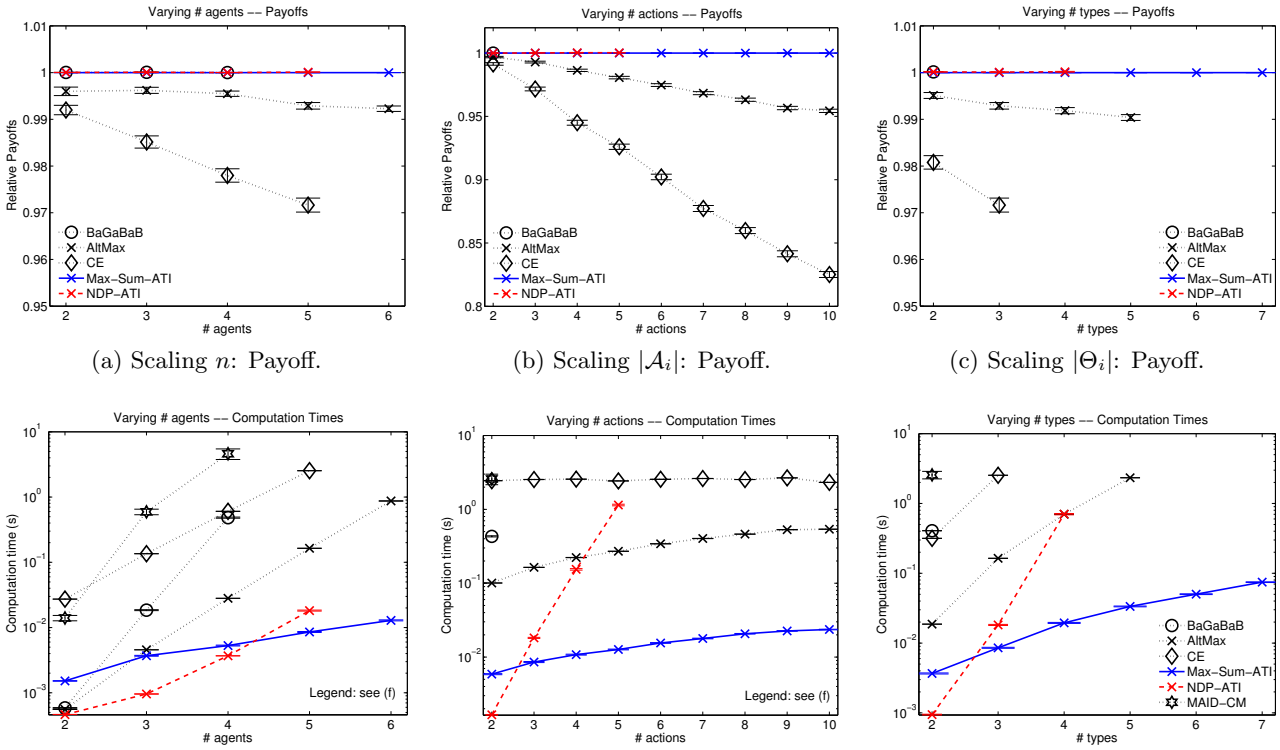
We first present experiments in randomly generated games following a procedure similar to that used by Kok and Vlassis (2006). We start with a set of n agents with no local payoff functions defined. As long as a path does not exist between every pair of agents, we add a local payoff function involving k agents. Payoffs $u^e(\boldsymbol{\theta}_e, \mathbf{a}_e)$ are drawn from a normal distribution $\mathcal{N}(0, 1)$, and the local joint type probabilities $\Pr(\boldsymbol{\theta}_e)$ are drawn from a uniform distribution and then normalized.

These random BGs enable testing on a range of problem parameters. In particular, we investigate the effect of scaling the number of agents n, the number of types for each agent $|\Theta_i|$, and the number of actions for each agent $|\mathcal{A}_i|$. We assume that the scopes of the local payoff functions, the individual action sets, and the individual type sets all have the same size for each agent. For each set of parameters, we generate 1,000 random CGBGs. Each method is run on these instances, limited by 1GB of memory and $5s$ computation time.[7] Payoffs are normalized with respect to those of MAX-SUM-ATI (whose payoff is always 1).

First, we compare NDP-ATI and MAX-SUM-ATI with other methods that do not exploit a factor graph rep-

[6]Since we use the implementation of Blum et al., which does not output the quality of the found solution, we report only computation times.

[7]A data point is not presented if the method exceeded the predefined resource limits on one or more test runs. MAID-CM was run on 30 games and given 30s.



(a) Scaling n: Payoff. (b) Scaling $|\mathcal{A}_i|$: Payoff. (c) Scaling $|\Theta_i|$: Payoff.

(d) Scaling n: Computation times. (e) Scaling $|\mathcal{A}_i|$: Computation times. (f) Scaling $|\Theta_i|$: Computation times.

Figure 5: Comparison of Max-Sum-ATI and NDP-ATI with other methods, scaling the number of agents ((a) and (d)), the number of actions ((b) and (e))), and the number of types ((c) and (f)). In all plots $k = 2$, and the parameters that are not being varied are set as follows: $n = 5, |\mathcal{A}_i| = 3, |\Theta_i| = 3$.

resentation explicitly, the results of which are shown in Fig. 5. These graphs show the payoff and computation time when increasing the number of agents (Fig. 5a and 5d), the number of actions (Fig. 5b and 5e), and the number of types (Fig. 5c and 5f). These results support a number of observations. 1) As predicted, NDP scales well with respect to the number of agents, but not types. It also scales poorly with the number of actions, which indicates that the encountered induced width is quite high in practice. 2) Though NDP cannot successfully exploit type independence, it is still consistently faster than BaGaBaB's heuristic search. 3) The approximate Max-Sum method always finds the optimum when we can compute it. 4) Max-Sum finds substantially better solutions than the other approximate methods AltMax and CE, while running faster than them for all but the smallest problems. 5) MAID-CM, the state-of-the-art for MAIDs, is significantly slower than the other methods.

To make explicit the advantage of exploiting type independence, Fig. 6 compares the performance of Max-Sum-ATI to that of Max-Sum-AI, i.e., Max-Sum applied to an AI factor graph, for games with $k = 2, |\Theta_i| = 4, |a_i| = 4$, larger numbers of agents, and $30s$ allowed per CGBG. Max-Sum-AI scales only to 50 agents, while Max-Sum-ATI scales to 725 (limited only by the allocated memory). While it is not possible to compute optimal solutions for these problems, values found by both methods are close and increase in proportion with the number of payoff components, indicating no degradation in performance.

While these results are for $k = 2$, experiments conducted for $k = 3$ were qualitatively similar, though lack of space prevents a detailed presentation. Note that there is no hope of efficiently solving problems with large k, since such problems cannot even be represented compactly. However, this not a serious practical limitation; on the contrary, even low values of k allow for complicated interactions since each agent may participate in many local payoff functions.

5.2 Generalized Firefighting Experiments

In this section, we aim to demonstrate that the advantages of Max-Sum-ATI extend to a more realistic problem, called Generalized Firefighting, which is like the two-agent firefighting problem of Fig. 1 but with N_H houses and n agents physically spread over a

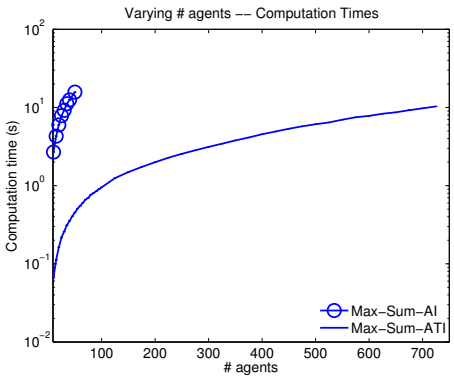


Figure 6: Comparison of the scaling behavior for many agents for MAX-SUM-AI and MAX-SUM-ATI.

2-dimensional area. Each agent observes the N_O nearest houses and may choose to fight fire at any of the N_A nearest houses.

Fig. 7 shows the results of our experiments in this domain, which corroborate our findings on random CGBGs by showing that MAX-SUM has the most desirable scaling behavior in a variety of different parameters.[8] We omit payoff plots because all methods computed solutions with the same payoff on all problem instances; MAX-SUM achieves the optimum in cases where we can compute it. Further investigation of solution quality (omitted due to lack of space) showed that solution quality decreases (there are only penalties in this problem) proportionally with the number of payoff components, again indicating that scalability does not come at the expense of solution quality.

6 Related Work

There is a large body of research that is related to the work presented in this paper. MAX-SUM has been used in decision making for teams of cooperative agents (Kok and Vlassis, 2006; Farinelli et al., 2008; Kuyer et al., 2008; Rogers et al., 2011). However, all of this work deals with cooperative games of perfect information, whereas we deal with imperfect information.

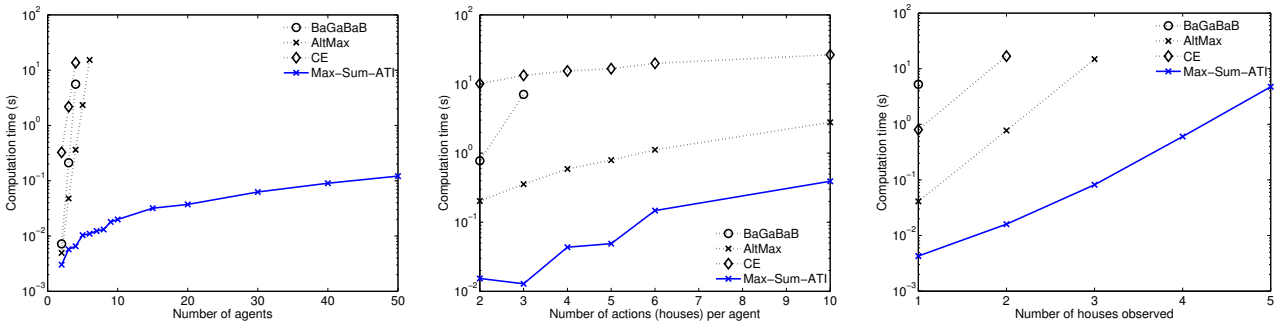
The CGBG model was introduced by Oliehoek et al. (2008b), who also used NDP to optimally solve CGBGs. However, NDP was applied only to the AI factor graph. Here we applied and analyzed application of NDP and MAX-SUM to a newly proposed ATI factor graph.

Two methods that are closely related to our approach are the heuristic search methods introduced by Oliehoek et al. (2010) and Kumar and Zilberstein (2010). The former propose BAGABAB for cooperative BGs, which we evaluated in our comparative experiments. It exploits additivity of the value function and can thus be interpreted as exploiting type independence. However, its performance depends heavily on the tightness of the heuristic used within BAGABAB (and, when problem sizes increase, the heuristic bounds tend to become looser, leading to disproportionate increases in runtime). Kumar and Zilberstein (2010) take a similar approach by performing search with a state-of-the-art heuristic (EDAC) for weighted constraint satisfaction problems to perform a point-based backup (as part of a solution method for sequential decision problems formalized as decentralized partially observable Markov decision processes, Dec-POMDPs). However, the EDAC heuristic provides leverage only in the two-agent case (de Givry et al., 2005). Furthermore, unlike our approach, neither of these methods exploits agent independence.

A closely related framework is the multiagent influence diagram (MAID), which extends decision diagrams to multiagent settings (Koller and Milch, 2003). A MAID represents a decision problem with a Bayesian network containing a set of chance nodes and, for each agent, a set of decision and utility nodes. As in a CGBG, the individual payoff function for each agent is defined as the sum of local payoffs. MAIDs are more general because they can represent sequential and non-identical payoff settings. Therefore, MAID solution methods are in principle applicable to CGBGs. However, these methods aim merely to find a sample Nash equilibrium, which is only guaranteed to be a local optimum. In contrast, our factor-graph formulation enables methods that find the global optimum. The MAID-CM method (Blum et al., 2006), which we also compared against, exploits the structure of the network in an inner loop to more efficiently compute the gradient of the payoff function. However, Blum et al. do not decompose the payoff into contributions and thus do not represent type independence. Moreover, since this inference is performed exactly using a clique-tree based approach, it cannot exploit type independence effectively, as the graphical argument made against NDP extends directly to this setting.

The framework of Bayesian action-graph games (BAGGs) can also model any BG (Jiang and Leyton-Brown, 2010). The BAGG solution method is similar to MAID-CM in that it exploits structure in an inner loop while searching for a sample equilibrium and thus suffers from the same limitations. This framework additionally allows the exploitation of anonymity and context-specific independence, but offers no advantages when these are not present.

[8] We omit NDP-ATI, since MAX-SUM-ATI outperformed it in random games, and MAID-CM, since it could not find solutions for any of these problems in 30s.



(a) Varying n. Each agent observes 2 houses (4 types per agent).

(b) Varying $|\mathcal{A}_i|$ when each agent observes 2 houses (4 types per agent).

(c) Varying number of houses that are observed per agent ($n = 4$, $|\mathcal{A}_i| = 5$).

7 Conclusions & Future Work

This paper considered the interaction of a team of agents under uncertainty modeled as cooperative graphical Bayesian games (CGBGs). We showed that CGBGs possess two different types of structure, agent and type independence, which can be neatly captured in a novel ATI factor graph formulation.

We considered two standard solution methods: non-serial dynamic programming (NDP) and Max-Sum message passing. The former has a computational complexity that is exponential in the induced tree width of the factor graph, which we proved to be lower bounded by the number of individual types. One iteration of the latter is tractable when there is enough independence between agents: we showed that it is exponential only in k, the maximum number of agents that participate in the same local payoff function.

By bounding the number of iterations, the combination of the ATI factor graph and Max-Sum yields, for any fixed k, a polynomial-time algorithm. While there are no quality guarantees, the complexity results suggest that any algorithm that scales polynomially with respect to the number of types (and thus, via our theorem, tree-width) *cannot* provide a solution within an arbitrary error bound (Kwisthout, 2011). It may be, however, be possible to obtain (non-adjustable) quality bounds for Max-Sum solutions via a technique that eliminates edges from the factor graph (Rogers et al., 2011).

An empirical evaluation showed that solution quality is high: in all our experiments Max-Sum found the optimal solution (when it could be computed). Moreover, the evaluation also revealed that exploiting both agent and type agent independence leads to significantly better performance than current state-of-the-art methods, providing scalability to much larger problems than was previously possible. In particular, we showed that this approach allows for the solution of coordination problems with imperfect information for up to 750 agents, limited only by a 1GB memory constraint. As such, we anticipate that the representation and exploitation of both agent and type independence will be a critical component in future solution methods for cooperative Bayesian games.

For future work, a possible extension of our approach could replace Max-Sum with message passing algorithms for belief propagation that are guaranteed to converge (Globerson and Jaakkola, 2008). In certain cases, such approaches can be shown to compute an optimal solution (Jebara, 2009). A different direction of study would be to use our approach to help solve Dec-POMDPs, by replacing the BG solving components used by Oliehoek et al. (2008b) and Kumar and Zilberstein (2010) with NDP or Max-Sum applied to the ATI factor graph. This can lead to huge scale-up in the number of agents approximate solutions can handle (Oliehoek, 2010). Similarly, it may be possible to improve methods like MAID-CM by performing the inference with Max-Sum in order to exploit type independence. Another avenue is to extend our algorithms to the non-cooperative case by rephrasing the task of finding a sample Nash equilibrium as one of minimizing regret, as suggested by Vickrey and Koller (2002).

Abstract

We study the problem of complexity estimation in the context of parallelizing an advanced Branch and Bound-type algorithm over graphical models. The algorithm's pruning power makes load balancing, one crucial element of every distributed system, very challenging. We propose using a statistical regression model to identify and tackle disproportionally complex parallel subproblems, the cause of load imbalance, ahead of time. The proposed model is evaluated and analyzed on various levels and shown to yield robust predictions. We then demonstrate its effectiveness for load balancing in practice.

1 INTRODUCTION

This paper explores the application of learning for improved load balancing in the context of distributed search for discrete combinatorial optimization over graphical models (e.g., Bayesian networks, weighted CSPs). Specifically, we consider one of the best exact search algorithms for solving the MPE task over graphical models, AND/OR Branch and Bound (AOBB) [12], ranked first and third, respectively, in the UAI'06 and '08 evaluations and winning all three MPE categories of the 2011 PASCAL Inference Challenge.

We adapt the established concept of parallel tree search [7], where a search tree is explored centrally up to a certain depth and the remaining subtrees are solved in parallel. In the graphical model context we explore the search space of partial instantiations up to a certain point and solve the resulting conditioned subproblems in parallel.

The distributed framework is built with a grid computing environment in mind, i.e., a set of autonomous, loosely connected systems – notably, we cannot assume any kind of shared memory or dynamic load balancing which most parallel or distributed algorithms build upon [1, 5, 7, 6]. The primary challenge is therefore to determine a priori a set of subproblems with balanced complexity, so that the overall parallel runtime will not be dominated by just a few of them. In the optimization context, however, the use of cost and heuristic functions for pruning makes it very hard to reliably predict and balance subproblem complexity ahead of time; in particular, structural parameters like the induced width are not sufficient to differentiate subproblems.

Our suggested approach and the main contribution of this paper is to estimate subproblem complexity by learning a regression model over several subproblem parameters, some static and structural (e.g., induced width, variable domain sizes), others dynamically extracted at runtime (e.g. upper and lower bounds on the subproblem solution based on the heuristic function).

A similar regression-based approach was developed in [11] to predict the problem complexity (called "empirical hardness") of combinatorial auction instances; similarly the successful SAT solver *SATzilla* uses linear regression models to choose among a set of component solvers the one that is predicted to be fastest for a given SAT instance [16].

Other general work on estimating search complexity goes back to [10] and more recently [9], which predict the size of general backtrack trees through random probing. Similar schemes were devised for Branch and Bound algorithms [2], where search is run for a limited time and the partially explored tree is extrapolated. These approaches typically require a substantial amount of probing, which is prohibitively expensive in our setup, where many hundreds, if not thousands of subproblems need to be evaluated quickly.

The contribution of the present paper lies in proposing and studying a general learning approach for estimating subproblem complexity. In particular, we frame the problem as statistical regression analysis, which allows us to leverage established, powerful techniques from machine learning and statistics. Motivated by different parallelization scenarios, we distinguish three distinct levels of learning: based on a single problem instance, based on a specific class of problems, and based on a combination of problem

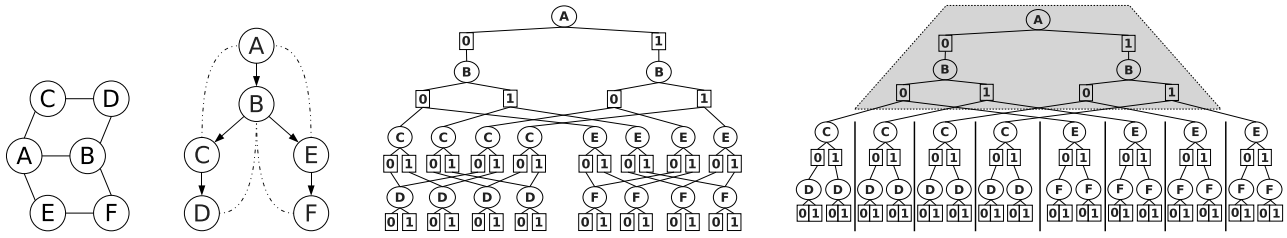

Figure 1: (a) Example primal graph with six variables, (b) its pseudo tree along ordering A, B, C, D, E, F, (c) the corresponding context-minimal AND/OR search graph, and (d) the parallel search space resulting from parallelizing at depth $d = 2$ with eight independent subproblems.

classes. We evaluate, analyze, and contrast these three levels on a sample set of more than 11,000 subproblem samples from four problem classes and demonstrate generally robust prediction performance. We also demonstrate empirically the model's potential for improved load balancing.

The remainder of the paper is organized as follows: Section 2 summarizes the necessary background and outlines the distributed AND/OR Branch and Bound algorithm. Section 3 introduces the proposed regression model for complexity estimation while Section 4 evaluates it on a variety of instances from several problem classes. Section 5 provides selected parallel results that highlight the benefits of the proposed model and Section 6 concludes.

2 BACKGROUND

We assume the usual definitions of a *graphical model* as a set of functions $F = \{f_1, \ldots, f_m\}$ over discrete variables $X = \{X_1, \ldots, X_n\}$, its *primal graph*, *induced graph*, and *induced width*.

2.1 AND/OR SEARCH SPACES

The concept of AND/OR search spaces has been introduced as a unifying framework for advanced algorithmic schemes for graphical models to better capture the structure of the underlying graph [3]. Its main virtue consists in exploiting conditional independencies between variables, which can lead to exponential speedups. The search space is defined using a *pseudo tree*, which captures problem decomposition:

DEFINITION **1 (pseudo tree)** *Given an undirected graph $G = (X, E)$, a* pseudo tree *of G is a directed, rooted tree $\mathcal{T} = (X, E')$ with the same set of nodes X, such that every arc of G that is not included in E' is a back-arc in $\mathcal{T}$, namely it connects a node in $\mathcal{T}$ to an ancestor in $\mathcal{T}$. The arcs in E' may not all be included in E.*

AND/OR Search Trees and Graphs : Given a graphical model instance with variables X and functions F, its primal graph (X, E), and a pseudo tree $\mathcal{T}$, the associated *AND/OR search tree* consists of alternating levels of OR and AND nodes. The structure of the AND/OR search tree is based on the underlying pseudo tree $\mathcal{T}$: the root of the AND/OR search tree is an OR node labeled with the root of $\mathcal{T}$. The children of an OR node X_i are AND nodes labeled with assignments $\langle X_i, x_i \rangle$; the children of an AND node $\langle X_i, x_i \rangle$ are OR nodes labeled with the children of X_i in $\mathcal{T}$, representing conditionally independent subproblems. Different nodes may root identical subproblems and can be merged through *caching*, yielding an *AND/OR search graph* of smaller size, at the expense of using additional memory during search.

Given a graphical model, its primal graph G, and a guiding pseudo tree $\mathcal{T}$ of height h, the size of the AND/OR search tree is $\mathcal{O}(n \cdot k^h)$, while $\mathcal{O}(n \cdot k^{w^*})$ bounds the AND/OR search graph, where w^* is the induced width of G over a depth-first traversal of $\mathcal{T}$ and k bounds the domain size [3]. Figure 1(a) shows an example problem primal graph with six variables, Figure 1(b) depicts a pseudo tree along ordering A, B, C, D, E, F. Figure 1(c) shows the corresponding AND/OR search graph.

AND/OR Branch and Bound : AND/OR Branch and Bound (AOBB) is a state-of-the-art algorithm for solving optimization problems over graphical models. Assuming maximization, it traverses the AND/OR graph in a depth-first manner while keeping track of a current lower bound on the optimal solution cost. During expansion of a node n, this lower bound l is compared with a heuristic upper bound $u(n)$ on the optimal solution below n – if $u(n) \leq l$ the algorithm can prune the subproblem below n [12].

Mini-Bucket Heuristics : The heuristic $h(n)$ that we use in our experiments is the Mini-Bucket heuristic. It is based on Mini-Bucket elimination, an approximate variant of a variable elimination scheme that computes approximations to reasoning problems over graphical models [4]. A control parameter i allows to trade accuracy of the heuristic against its time and space requirements. It was shown that the intermediate functions generated by the Mini-Bucket algorithm MBE(i) can be used to derive a heuristic function that un-

derestimates the minimal cost solution to a subproblem in the AND/OR search graph [12].

2.2 DISTRIBUTED AOBB & LOAD BALANCING

Our distributed implementation of AND/OR Branch and Bound draws from the notion of parallel tree search [7, 6], where a search tree is explored centrally up to a certain depth and the remaining subtrees are solved in parallel. Applied to the search graph from Figure 1(c), for instance, we could obtain eight independent subproblems as shown in Figure 1(d), with a conditioning search space (in gray) spanning the first two levels (variables A and B).

We refer to the boundary between conditioning search space and parallel subproblems as the *parallelization frontier*. Its choice determines the shape and the number of subproblems and is thus crucial for effective parallel *load balancing*. Namely, it is known that for best parallel performance we should spread the parallel workload evenly across all available CPUs, while minimizing overhead. Note that we assume independent worker machines, with limited or very costly communication, hence dynamic load balancing at runtime (cf. [6]) is not applicable.

Algorithm 1 shows pseudo code for our parallelization policy: the parallelization frontier is generated in a breadth-first manner by iteratively selecting the current most complex subproblem, estimated by a complexity estimator $\hat{N}$, and splitting it into its immediate "sub-subproblems", which are in turn added to the frontier. This process is repeated until a desired number of subproblems is obtained, at which point all subproblems are submitted to the distributed environment.

In the context of depth-first Branch and Bound, however, determining the most complex subproblem is extremely difficult and elusive. Due to the pruning power of the algorithm, subproblem runtimes can differ greatly, even when the underlying subgraph structure and the associated asymptotic complexity guarantees (exponential in the induced width of the AND/OR subspace) are identical.

To illustrate, consider the subproblem statistics of two parallel runs shown in Figure 2, where instead the parallelization frontier is placed at a fixed depth $d = 5$ and $d = 4$, respectively, yielding 64 and 144 subproblems (the horizontal axis). In each case we see significant variance in subproblem runtime. In fact, the overall runtime is dominated exclusively by the handful of longest-running subproblems, with most other subproblems finishing long before (note the log scale). Detecting and mitigating this imbalance ahead of time constitutes the central challenge in this line of work, as we elaborate in the next sections.

Algorithm 1 Finding the parallelization frontier

Input: Pseudo tree $\mathcal{T}$ with root X_0, subproblem count p, subproblem complexity estimator $\hat{N}$.
Output: Set F of subproblem root nodes with $|F| \geq p$.

```
1: F ← {⟨X_0⟩}
2: while |F| < p :
3:     n' ← arg max_{n∈F} N̂(n)
4:     F ← F \ {n'}
5:     F ← F ∪ children(n')
```

3 LEARNING COMPLEXITIES THROUGH REGRESSION

This section introduces our learning approach to subproblem complexity prediction through regression analysis. Previous work has investigated and evaluated various methods for balancing subproblem complexity, directly formulating metrics using human expert knowledge [13, 14]. These metrics were relative in nature, i.e., they only allowed comparison of one subproblem to another within a given overall problem instance. In contrast, the present work does not depend as heavily on expert knowledge and gives absolute complexity estimates.

3.1 GENERAL METHODOLOGY

We identify a subproblem by its search space root node n. We further measure the complexity of the subproblem rooted at n through the size of its explored search space, which is the number of node expansions required for its solution, denoted $N(n)$. We then aim to capture the exponential nature of the search space size by modeling $N(n)$

as an exponential function of various subproblem features $\phi_i(n)$ as follows:

$$N(n) = \exp(\sum_i \lambda_i \phi_i(n)) \quad (1)$$

The exponent has been chosen as a sum so that we can consider the log complexity and obtain the following:

$$\log N(n) = \sum_i \lambda_i \phi_i(n) \quad (2)$$

Given a set of m sample subproblems, finding suitable parameter values λ_j can thus be formulated as a well-known *linear regression* problem, with the *mean squared error* (MSE) as the loss function $L(\lambda)$ we aim to minimize:

$$L(\lambda) = \frac{1}{m} \sum_{k=1}^{m} \Big(\sum_i \lambda_i \phi_i(n_k) - \log N(n_k) \Big)^2 \quad (3)$$

The MSE captures how well the learned regression model fits the training data. In the context of load balancing for parallelism we can consider a secondary metric, the *Pearson correlation coefficient* (PCC), which is simply the normalized covariance between the vector of subproblem complexities and their estimates, normalized by the product of each vector's standard deviation. It is bounded by $[-1, 1]$, where 1 implies perfect linear correlation and -1 anticorrelation. Hence a value close to 1 is desirable, as it signifies a model likely to correctly identify the hardest subproblems.

3.2 SUBPROBLEM FEATURES

Table 1 lists the full set of basic subproblem features ϕ_i that we consider. This list was compiled based on our prior knowledge of what aspects can affect problem complexity. Features can be divided into two distinct classes: "static", which can be precompiled from the problem graph and pseudo tree, and "dynamic" which are computed at runtime, as the parallelization frontier decision is made (note that none of the dynamic features are costly to compute).

Subproblem variable statistics (static):	
1:	Number of variables in subproblem.
2-6:	Min, Max, mean, average, and std. dev. of variable domain sizes in subproblem.
Pseudotree depth/leaf statistics (static):	
7:	Depth of subproblem root in overall search space.
8-12:	Min, max, mean, average, and std. dev. of depth of subproblem pseudo tree leaf nodes, counted from subproblem root.
13:	Number of leaf nodes in subproblem pseudo tree.
Pseudo tree width statistics (static):	
14-18:	Min, max, mean, average, and std. dev. of induced width of variables within subproblem.
19-23:	Min, max, mean, average, and std. dev. of induced width of variables within subproblem, *when conditioning on subproblem root conditioning set*.
Subproblem cost bounds (dynamic):	
24:	Lower bound L on subproblem solution cost, derived from current best overall solution.
25:	Upper bound U on subproblem solution cost, provided by mini bucket heuristics.
26:	Difference $U - L$ between upper and lower bound, expressing "constrainedness" of the subproblem.
Pruning ratios (dynamic), based on running 5000 node expansion probe of AOBB:	
27:	Ratio of nodes pruned using the heuristic.
28:	Ratio of nodes pruned due of determinism (zero probabilities, e.g.)
29:	Ratio of nodes corresponding to pseudo tree leaf.
Sample statistics (dynamic), based on running 5000 node expansion probe of AOBB:	
30:	Average depth of terminal search nodes within probe.
31:	Average node depth within probe (denoted $\bar{d}$).
32:	Average branching degree, defined as $\sqrt[\bar{d}]{5000}$.
Various (static):	
33:	Mini bucket i-bound parameter.
34:	Max. subproblem variable context size minus mini bucket i-bound.

Table 1: Subproblem features for complexity estimation.

3.3 SUBPROBLEM SAMPLE DOMAINS

In order to evaluate training and prediction error of the proposed complexity model from a statistical learning perspective, we need to specify the sample domain over which we will make predictions, for which we aim to generate a model, and from which subproblem samples are assumed to be drawn. In fact, in the following we consider three incrementally more general levels of sample domains and learning, corresponding to three different designs in the context of parallelizing AOBB:

1. **Learning per problem instance:** The sample domain is all subproblems from a single problem instance. This corresponds to learning a new complexity model for every problem instance the parallel scheme encounters (e.g., we would learn separate models for the two instances in Figure 2).

2. **Learning per problem class:** Take the domain to be all subproblems of problems from a specific class. In the parallelization context we learn a separate model for every problem class we consider. For example, we would learn a single model for all pedigree problems, but a different model for other problem classes like protein sidechain prediction.

3. **Learning across problem classes:** Take the sample domain to be all subproblems of all problems from several classes. Ultimately this could translate to a parallel scheme that uses a single complexity model for all problem classes under consideration.

These three levels are increasingly more general and thus potentially more challenging for robust estimation. On the other hand, they require increasingly less computational ef-

fort, since fewer distinct models need to be learned. Lastly, they can present different trade-offs between pre-compiled off-line learning and learning at runtime.

3.4 REGRESSION ALGORITHMS

We investigated a number of algorithms for fitting a linear model. Ordinary least squares (OLS) regression was problematic due to numerical issues (near-singular matrix inversion) and prone to overfitting (due to lack of regularization) and we did not consider if further. Standard ridge regression adds the L_2-norm of the parameter vector λ to the regularized loss function through a term $\alpha(\sum_i \lambda_i^2)^{\frac{1}{2}}$; similarly, lasso regression [15], places an L_1-penalty on the parameter vector by adding the term $\alpha \sum_i |\lambda_i|$. The so-called "Elastic Net" combines both penalty terms [18]. In each case we followed the common approach of determining the regularization parameter α once through initial cross validation and held it fixed subsequently.

In our experiments we found all methods to perform similarly in terms of training and prediction errors, with a slight advantage for the lasso method. We will therefore focus on lasso learning. This method has the additional benefit of "built-in" feature selection: learned models are relatively sparse and thus compact, because the L_1-regularization pushes many parameters λ_i to zero [15].

3.5 NON-LINEAR REGRESSION

In addition to the purely linear regression analysis proposed above, we also explored non-linear approaches. In particular, we took inspiration from [11], which reports improved prediction performance using *quadratic feature expansion*, albeit in the context of combinatorial auctions. Quadratic feature expansion, also referred to as "quadratic regression", works by adding new features in the form of pairwise products of the original features; namely, for every pair of subproblem features ϕ_i, ϕ_j with $i \leq j$, we create a new feature $\phi_i \cdot \phi_j$. We then perform linear regression on the expanded feature set (629 in our case), thereby effectively fitting a polynomial of 2nd degree. Results will be outlined in Section 4.5.

Next we evaluate the proposed regression model on a variety of instances from several different problem classes.

4 EVALUATION AND ANALYSIS

The basis for our evaluation are 31 hard problem instances from four classes: pedigree haplotyping problems, protein side-chain prediction ([17], named "pdb"), "large family" genetic linkage instances, and grid networks ("75-2x-x"). Summary statistics of the different problem classes are given in Table 2. We note that all instances each take several hours, if not days to solve using sequential AOBB.

domain	M	n	k	w	h
pedigree	13	437 – 1272	3 – 7	17 – 39	47 – 102
pdb	5	103 – 172	81	10 – 15	24 – 43
largeFam	8	2569 – 3730	3 – 4	28 – 37	73 – 108
grid	5	624 – 675	2	37 – 39	111 – 124

Table 2: Summary statistics for problem classes used, M gives the number of instances in the class. n denotes number of problem variables, k max. domain size, w induced width, h pseudo tree height.

To compile a set of subproblem samples we revisit experiments with fixed-depth parallelization (cf. Section 2.2): we randomly choose not more than 500 subproblems from a previously recorded fixed-depth parallel run for each instance. This leaves us with about 11,500 sample subproblems (approx. 40% pedigree, 25% protein, 25% largeFam, 10% grids), which is very reasonable for the number of features we have (the variance of the trained linear model scales with p/m, where p is the number of features and m the number of samples, cf. Section 7.3 in [8]).

The empirical evaluation is organized as follows: Sections 4.1 through 4.3 assess the prediction power of our proposed linear regression complexity model according to the three levels of learning outlined in Section 3.3. Section 4.4 inspects feature informativeness and Section 4.5 briefly investigates performance of the quadratic model. Section 4.6 provides a summary of the learning results.

Throughout this section results are presented as a log-log scatter plot of actual versus predicted complexities, each also containing mean squared prediction error ("MSE", on the test set) and Pearson correlation coefficient ("PCC") as well as mean squared training error ("TER").

4.1 LEARNING PER PROBLEM INSTANCE

This first set of experiments is meant to determine the prediction quality of a regression model that is learned for a single instance only. To that end, we consider all subproblem samples from a given problem instance and apply 5-fold cross validation (i.e., partition the samples into 5 subsets, then predict the complexities of each subset by learning a model on the remaining four).

Figure 3 presents scatter plots for six problem instances from the different problem classes considered. We see that results are good for the protein and largeFam instance and still acceptable for *pedigree19* with slightly higher MSE. *Pedigree41* has a relatively low MSE and good PCC, in spite of the plot's flat appearance. In case of the grid instance *75-26-9* the model's discriminatory power is likely limited by the small number of subproblem samples in this case. Finally, we note that the training error ("TER") is very close to the prediction error ("MSE") in all cases, indicating the absence of overfitting.

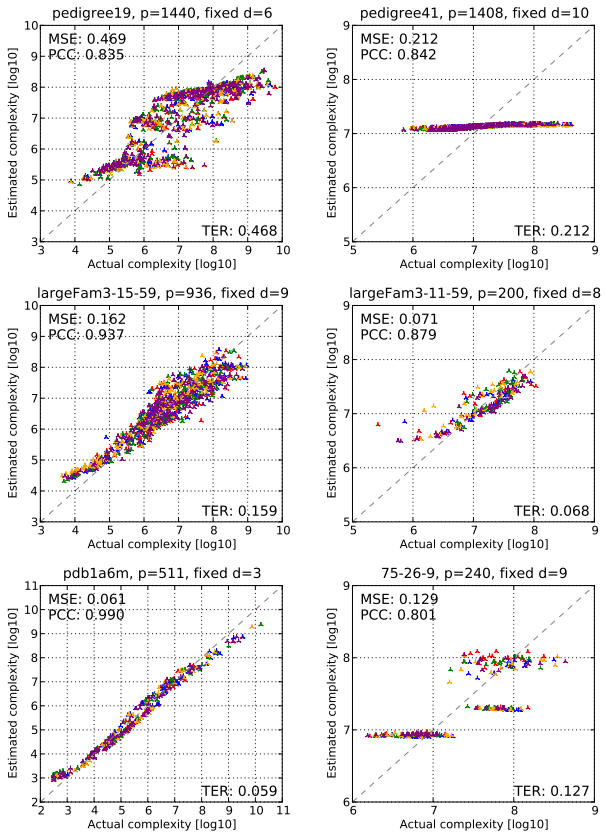

Figure 3: Actual vs. predicted subproblem complexity when learning per problem instance, using 5-fold cross validation.

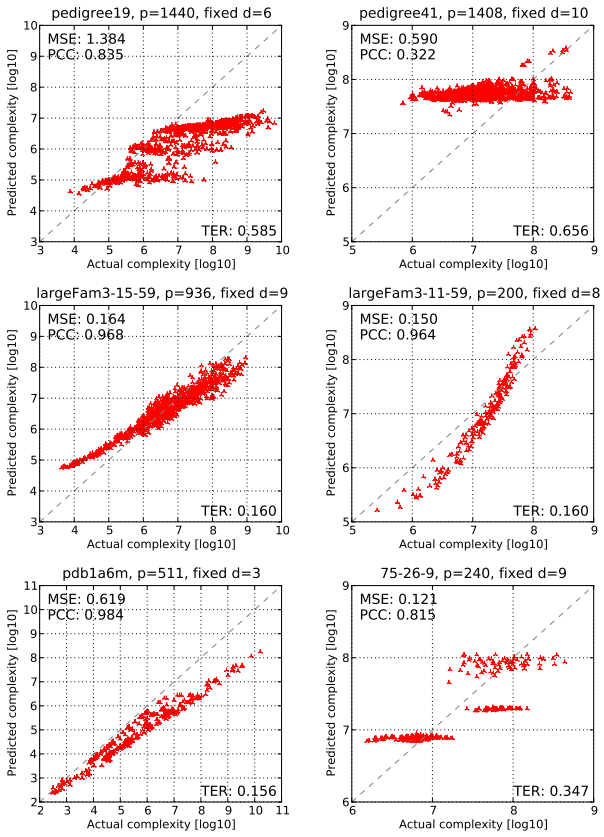

Figure 4: Actual vs. predicted subproblem complexity when learning per problem class.

4.2 LEARNING PER PROBLEM CLASS

Secondly, we aim to assess how well we can learn a model for an entire problem class. That is, we learn only once from sample subproblems of instances from the problem class in question. For testing we perform cross validation on the level of problem instances. Namely, we predict the subproblems of a given instance by fitting a model using subproblem samples of other instances from the same class – but not of the test instance itself.

Results are shown in Figure 4. Compared to Figure 3 in the previous section, estimates for the grid and largeFam instance are very similar and yield almost the same mean squared error. MSE increases for the pedigree and largeFam instances, but the PCC and overall shape of the predictions also remain similar, with the exception of *pedigree41* which sees both MSE and PCC deteriorate.

4.3 LEARNING MULTIPLE PROBLEM CLASSES

Lastly, we investigate how good a model we can learn from subproblems of instances across multiple problem classes. In particular, given a problem instance we learn a regression model on the subproblems of all other instances, regardless of their problem class.

Results are given in Figure 5, analogous to Figures 3 and 4. The two pedigree problems see an improved MSE and PCC (significantly for *pedigree41*), but the other instances suffer from a slightly larger prediction error. However, we again note that the overall shape of the plots remains roughly linear, which is also captured by high PCC values.

4.4 MOST INFORMATIVE FEATURES

Linear regression has the advantage that the resulting models can be straightforward to interpret. Namely, to assess the informativeness of feature ϕ_i we simply look at the absolute value of its coefficient λ_i in the regression model. Assuming a normalized sample set, features with larger absolute values contribute more to the predictions and are thus intuitively more informative.

In addition, recall that the L_1-regularization in lasso regression implicitly performs feature selection by assigning $\lambda_i = 0$ for some i. In our case, training on the entire sample set (11,500 subproblem instances, regularization parameter through cross-validation) yielded non-zero λ_i for nine features, as shown in in Table 3. In addition each feature's

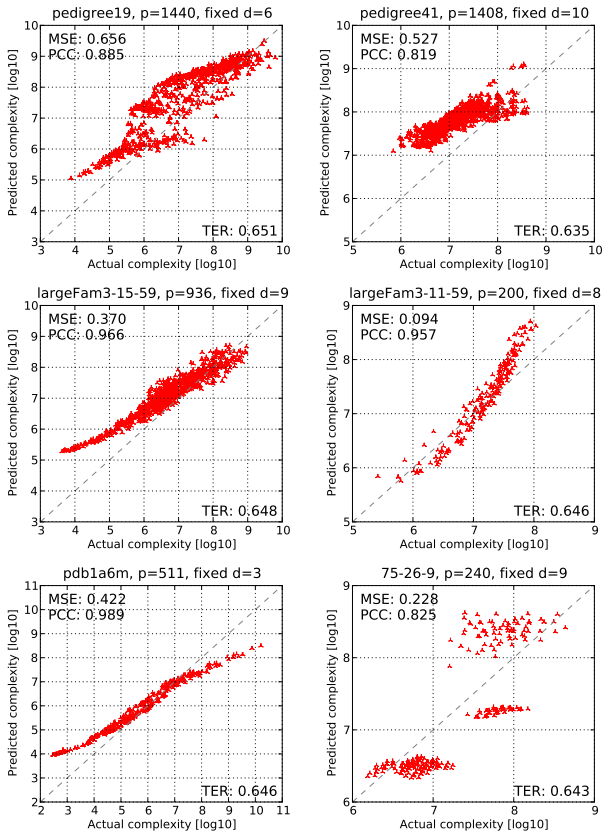

Figure 5: Actual vs. predicted subproblem complexity when learning across problem classes.

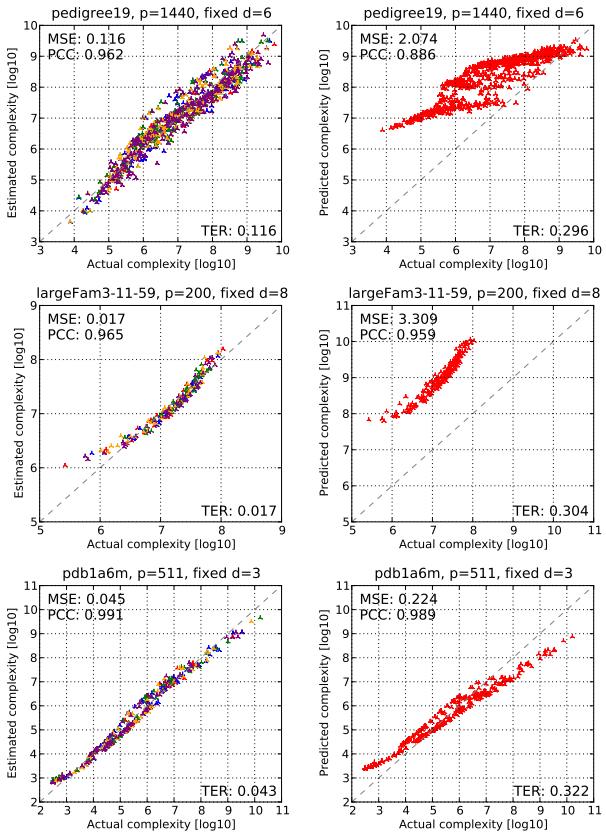

Figure 6: Example prediction results using a quadratic regression model. Left: learning per problem instance, using 5-fold cross validation (cf. Fig. 3). Right: learning from all problem classes (cf. Fig. 5).

cost of omission ("coo") as defined in [11] is given, which measures the normalized difference between the prediction error of the model with all nine features and the prediction error of a model trained with the respective feature omitted (using 5-fold cross-validation in all cases).

The particular set of features can be somewhat misleading, however, since lasso regression tends to pick only one of several highly correlated features. Yet it is useful to gain a conceptual understanding. In particular, we observe that the most informative features are dynamic, extracted from a limited AOBB probe or based on the initial subproblem bounds. Only the fifth feature, max. subproblem context size minus mini-bucket i-bound, is static, with a normalized cost of omission of only 16. This ties in to Section 2.2, where we observed that the asymptotic complexity bound of AOBB (based on static parameters) yields little information in this context.

Feature ϕ_i	$\lvert\lambda_i\rvert$	coo
Average branching degree in probe	0.57	100
Average leaf node depth in probe	0.39	87
Subproblem upper bound minus lower bound	0.22	17
Ratio of nodes pruned by heuristic in probe	0.20	27
Max. context size minus mini bucket i-bound	0.19	16
Ratio of leaf nodes in probe	0.18	10
Subproblem upper bound	0.11	7
Std. dev. of subproblem pseudo tree leaf depth	0.06	2
Depth of subproblem root node in overall space	0.05	2

Table 3: Features present in the linear model trained by lasso regression, with their model coefficients λ_i and their cost of omission "coo" (normalized).

4.5 NON-LINEAR REGRESSION

Here we briefly summarize results from our investigation of quadratic feature expansion, as detailed in Section 3.5. Selected prediction results for three instances are shown in Figure 6. On the left are results of learning per problem instances, on the right we plot the prediction accuracy when learning from all problem classes.

Comparing the plots on the left (per-problem learning) with Figure 3, we note that quadratic regression does a bit better than linear regression in terms of MSE and very similarly with regards to PCC. In contrast to [11], however, we find deteriorated prediction performance when comparing the plots on the right with Figure 5: while the PCC value is

similar, the mean squared prediction error when learning from multiple problem classes increases considerably for *pedigree19* and *largeFam3-11-59*. Notably, however, the training error remains fairly low in both cases, which is indicative of overfitting. And indeed, with over 600 subproblem features and just 31 different instances, the quadratic regression model is likely to pick up specific characteristics of each instance that hurt its predictive performance.

Since quadratic models are also more expensive to train and lack the straightforward interpretability of a linear model, we feel that the latter is better-suited for our purposes.

4.6 INTERPRETATION OF RESULTS

We have trained and evaluated our proposed regression model on the three levels of learning laid out in Section 3.3, trading off between the wider applicability of the learned models and the challenges of capturing increasingly general sample sets. Learning per problem instance provided a good baseline but has limited relevance in practice, since each new instance requires extensive sampling of subproblems to train on. Learning per problem class is more reasonable as the learned model can be reused within the given problem class; our experiments showed good performance. Finally, learning across classes is the most challenging as the sample set is likely to be more diverse and have higher variance, requiring more training samples; however, once we learn a model it can be used throughout.

And indeed, our results in Section 4.3 show that, given our

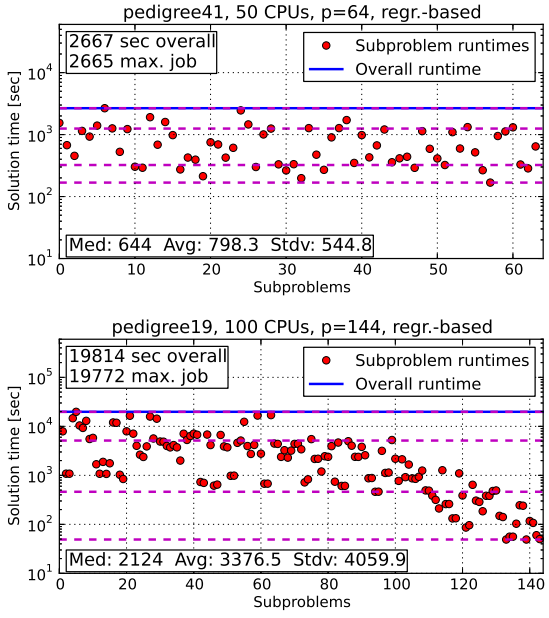

Figure 7: Subproblem statistics for regression-based parallelization (cf. fixed-depth parallelization in Fig. 2), p denotes the number of subproblems.

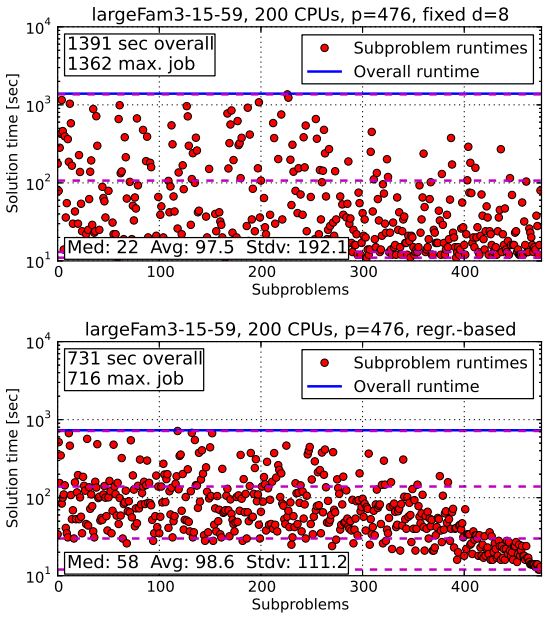

Figure 8: Subproblem statistics for fixed-depth (top) and regression-based (bottom) parallelization on *largeFam3-15-59* instance.

substantial set of 11,500 subproblem samples, the model can accommodate this most general level of learning across problem classes without a noticeable penalty, at least for the current collection of problem classes. A model learned across classes is therefore also the basis for the next section, where we demonstrate the benefit of robust complexity estimates in the context of distributed AOBB.

5 REGRESSION-BASED LOAD BALANCING IN PRACTICE

In this section we present selected experimental results that show the potential of the proposed regression models in guiding the parallelization process, as described in Section 2.2 – a comprehensive empirical evaluation of Distributed AOBB is beyond the scope of this paper. As noted above, the regression model used for experiments in this section was learned at the most general level, using all available problem classes as discussed in Section 4.3 (but always excluding the test problem instance).

5.1 IMPROVING LOAD BALANCING

To demonstrate the profound impact the complexity predictions can have on the load balancing of the parallel scheme, we revisit the two parallel experiments presented in Section 2.2, Figure 2. In both cases the overall performance was heavily dominated by very few long-running subproblems.

Figure 7 shows runtime statistics for parallel execution on

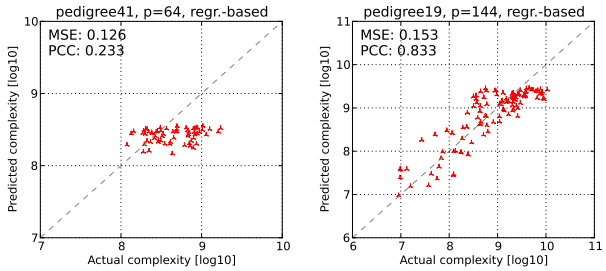

Figure 9: Actual vs. predicted subproblem complexity from the two parallel executions in Figure 7.

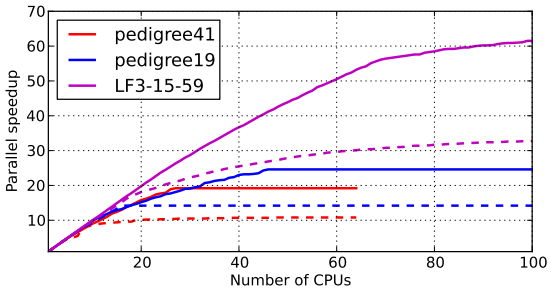

Figure 10: Parallel speedup for *pedigree41*, *pedigree19*, and *largeFam3-15-59* (cf. Figures 2, 7, and 8) as a function of the number of parallel CPUs. Dashed lines represent fixed-depth parallelization, solid lines correspond to parallel runs guided by our regression model.

these instances, using the regression model for load balancing. Figure 8 gives an additional example on a largeFam instance. In all cases we see that the max. subproblem runtime has been reduced greatly, close to 50% for *largeFam3-15-59* (1,362 to 716 seconds for "max. job" in Figure 8). We also note the drastically lower standard deviation in subproblem runtimes.

In addition, Figure 9 compares the complexity estimates obtained during the parallel execution with the actual recorded values. In both cases we observe good prediction error and *pedigree19* in particular also shows good PCC.

5.2 FACILITATING PARALLEL SPEEDUP

Figure 10 plots the parallel speedup for the three problem instances considered in Section 5.1 over the number of parallel CPUs. For each instance we show (as a dashed line) the speedup when using fixed-depth parallelization and (with a solid line) the speedup of the parallel execution guided by the regression model.

Comparing each instance's two entries reveals a clear advantage for the regression-based parallelization: it achieves higher speedups, roughly by a factor of two, and seems to plateau later, i.e. it is able to utilize a larger number of parallel resources.

On the other hand, most curves appear to level off well before their theoretical limit. This indicates that further improvements are possible, even though "perfect" speedup is unattainable in practice, since splitting a given subproblem often yields components of widely varying size and large jumps in complexity.

One way to mitigate these issues lies in increasing the subproblem granularity, i.e., setting the number of subproblems to match several times the number of parallel CPUs. However, this may add overhead in the general distributed context and redundancies in the particular graphical model context, which can negate potential gains in extreme cases. Indeed, finding the right balance in granularity is a central research issue in the field of distributed computing.

6 CONCLUSION & FUTURE WORK

We have presented a case study of complexity estimation in the context of parallelizing the state-of-the-art sequential optimization algorithm AND/OR Branch and Bound. The pruning power of the algorithm makes parallel load balancing very challenging, leading to inefficiencies in practice.

To address these symptoms we have proposed to employ statistical regression analysis in order to identify bottlenecks for parallel performance ahead of time. In particular, we developed a linear regression model that uses a variety of static as well as dynamic features to predict a subproblem's complexity, enabling us to detect and split problematic subproblems.

We identified three distinct levels of learning and evaluated our proposed model accordingly, using more than 11,000 subproblem samples from 31 problem instances and four problem classes. Results were good throughout, with generally low prediction error and high correlation coefficients.

In the context of our parallel scheme, we have shown how the regression model can enable more effective load balancing and improved parallel speedup. This last set of results, however, also outlined opportunities for further improvements and future research, including varying the parallel granularity.

Future work with respect to learning of complexity estimates will expand to more instances and additional problem classes. In that context we also plan to investigate how our learned models perform on instances from previously unseen problem classes. Furthermore, we are trying to devise more subproblem features, for instance extracted directly from the cost function tables within a subproblem.

Abstract

Latent variable models are an elegant framework for capturing rich probabilistic dependencies in many applications. However, current approaches typically parametrize these models using conditional probability tables, and learning relies predominantly on local search heuristics such as Expectation Maximization. Using tensor algebra, we propose an alternative parameterization of latent variable models (where the model structures are junction trees) that still allows for computation of marginals among observed variables. While this novel representation leads to a moderate increase in the number of parameters for junction trees of low treewidth, it lets us design a local-minimum-free algorithm for learning this parameterization. The main computation of the algorithm involves only tensor operations and SVDs which can be orders of magnitude faster than EM algorithms for large datasets. To our knowledge, this is the first provably consistent parameter learning technique for a large class of low-treewidth latent graphical models beyond trees. We demonstrate the advantages of our method on synthetic and real datasets.

1 Introduction

Latent variable models such as Hidden Markov Models (HMMs) (Rabiner & Juang, 1986), and Latent Dirichlet Allocation (Blei et al., 2003) have become a popular framework for modeling complex dependencies among variables. A latent variable can represent an abstract concept (such as topic or state), thus enriching the dependency structure among the observed variables while simultaneously allowing for a more tractable representation. Typically, a latent variable model is parameterized by a set of conditional probability tables (CPTs) each associated with an edge in the latent graph structure. For instance, an HMM can be parametrized compactly by a transition probability table and an observation probability table. By summing out the latent variables in the HMM, we obtain a fully connected graphical model for the observed variables.

Although the parametrization of latent variable models using CPTs is very compact, parameters in this representation can be difficult to learn. Compared to parameter learning in fully observed models which is either of closed form or convex (Koller & Friedman, 2009), most parameter learning algorithms for latent variable models resort to maximizing a non-convex objective via Expectation Maximization (EM) (Dempster et al., 1977). EM can get trapped in local optima and has slow convergence.

While EM explicitly learns the CPTs of a latent variable model, in many cases the goal of the model is primarily for prediction and thus the actual latent parameters are not needed. One example is determining splicing sites in DNA sequences (Asuncion & Newman, 2007). One can build a different latent variable model, such as an HMM, for each type of splice site from training data. A new sequence is then classified by determining which model it is most likely to have been generated by. Other examples include supervised topic modelling such as (Blei & McAuliffe, 2007; Lacoste-Julien et al., 2008; Zhu et al., 2009) and collaborative filtering (Su & Khoshgoftaar, 2009).

In these cases, it is natural to ask whether there exists an alternative representation/parameterization of a latent variable model where parameter learning can be done consistently and the representation remains tractable for inference among the observed variables. This question has been tackled recently by Hsu et al. (2009), Balle et al. (2011), and Parikh et al. (2011) who proposed spectral algorithms for local-minimum-free learning of HMMs, finite state transducers, and latent tree graphical models respectively. Unlike traditional parameter learning algorithms such as EM, spectral algorithms do not directly learn the CPTs of

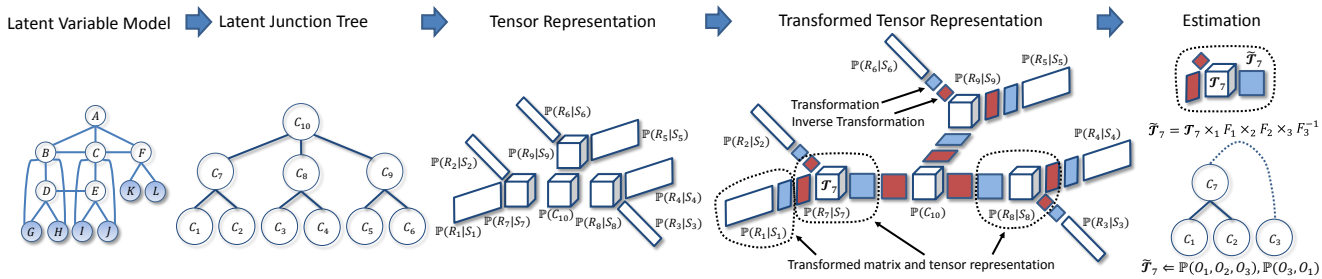

Figure 1: Our algorithm for local-minimum-free learning of latent variable models consist of four major steps. (1) First, we transform a model into a junction tree, such that each node in the junction tree corresponds to a maximal clique of variables in the triangulated graph of the original model. (2) Then we embed the clique potentials of the junction tree into higher order tensors and express the marginal distribution of the observed variables as a tensor-tensor/matrix multiplication according to the message passing algorithm. (3) Next we transform the tensor representation by inserting a pair of transformations between those tensor-tensor/matrix operations. Each pair of transformations is chosen so that they are inversions of each other. (4) Lastly, we show that each transformed representation is a function of only observed variables. Thus, we can estimate each individual transformed tensor quantity using samples from observed variables.

a latent variable model. Instead they learn an alternative parameterization (called the *observable representation*) which generally contains a larger number of parameters than the CPTs, but where computing observed marginals is still tractable. Moreover, these alternative parameters have the advantage that they only depend on observed variables and can therefore be directly estimated from data. Thus, parameter learning in the alternative representation is fast, local-minimum-free, and provably consistent. Furthermore, spectral algorithms can be generalized to nonparametric latent models (Song et al., 2010, 2011) where it is difficult to run EM.

However, existing spectral algorithms apply only to restricted latent structures (HMMs and latent trees), while latent structures beyond trees, such as higher order HMMs (Kundu et al., 1989), factorial HMMs (Ghahramani & Jordan, 1997) and Dynamic Bayesian Networks (Murphy, 2002), are needed and have been proven useful in many real world problems. The challenges for generalizing spectral algorithms to general latent structured models include the larger factors, more complicated conditional independence structures, and the need to sum out multiple variables simultaneously.

The goal of this paper is to develop a new representation for latent variable models with structures beyond trees, and design a spectral algorithm for learning this representation. We will focus on latent junction trees; thus the algorithm is suitable for both directed and undirected models which can be transformed into junction trees. Concurrently to our work, Cohen et al. (2012) proposed a spectral algorithm for Latent Probabilistic Context Free Grammars (PCFGs). Latent PCFGs are not trees, but have many tree-like properties, and so the representation Cohen et al. (2012) propose does not easily extend to other non-tree models such as higher order/factorial HMMs that we consider here. Our more general approach requires more complex tensor operations, such as multi-mode inversion, that are not used in the latent PCFG case.

The key idea of our approach is to embed the clique potentials of the junction tree into higher order tensors such that the computation of the marginal probability of observed variables can be carried out via tensor operations. While this novel representation leads only to a moderate increase in the number parameters for junction trees of low treewidth, it allows us to design an algorithm that can recover a transformed version of the tensor parameterization and ensure that the joint probability of observed variables are computed correctly and consistently. The main computation of the algorithm involves only tensor operations and singular value decompositions (hence the name "spectral") which can be orders of magnitude faster than EM algorithms in large datasets. To our knowledge, this is the first provably consistent parameter learning technique for a large class of low-treewidth latent graphical models beyond trees. In our experiments with large scale synthetic datasets, we show that our spectral algorithm can be almost 2 orders of magnitude faster than EM while at the same achieving considerably better accuracy. Our spectral algorithm also achieves comparable accuracy to EM on real data.

Organization of paper. A high level overview of our approach is given in Figure 1. We first provide some background on tensor algebra and latent junction trees. We then derive the spectral algorithm by representing junction tree message passing with tensor operations, and then transform this representation into one that only depends on observed variables. Finally, we analyze the sample complexity of our method and evaluate it on synthetic and real datasets.

2 Tensor Notation

We first give an introduction to the tensor notation tailored to this paper. An Nth order tensor is a multiway array with N "modes", *i.e.*, N indices

$\{i_1, i_2, \ldots, i_N\}$ are needed to access its entries. Subarrays of a tensor are formed when a subset of the indices is fixed, and we use a colon to denote all elements of a mode. For instance, $\boldsymbol{\mathcal{A}}(i_1, \ldots, i_{n-1}, :, i_{n+1}, \ldots, i_N)$ are all elements in the nth mode of a tensor $\boldsymbol{\mathcal{A}}$ with indices from the other $N-1$ modes fixed to $\{i_1, \ldots, i_{n-1}, i_{n+1}, \ldots, i_N\}$ respectively. Furthermore, we also use the shorthand $\boldsymbol{i}_{p:q} = \{i_p, i_{p+1}, \ldots, i_{q-1}, i_q\}$ for consecutive indices, *e.g.*, $\boldsymbol{\mathcal{A}}(i_1, \ldots, i_{n-1}, :, i_{n+1}, \ldots, i_N) = \boldsymbol{\mathcal{A}}(\boldsymbol{i}_{1:n-1}, :, \boldsymbol{i}_{n+1:N})$.

Labeling tensor modes with variables. In contrast to the conventional tensor notation such as the one described in Kolda & Bader (2009), the ordering of the modes of a tensors will not be essential in this paper. We will use random variables to *label* the modes of a tensor: each mode will correspond to a random variable and what is important is to keep track of this correspondence. Therefore, we think two tensors are equivalent if they have the same set of labels and they can be obtained from each other by a permutation of the modes for which the labels are aligned.

In the matrix case this translates to $\boldsymbol{A}$ and $\boldsymbol{A}^\top$ being equivalent in the sense that $\boldsymbol{A}^\top$ carries the same information as $\boldsymbol{A}$, as long as we remember that the rows of $\boldsymbol{A}^\top$ are the columns of $\boldsymbol{A}$ and vice versa. We will use the following notation to denote this equivalence

$$\boldsymbol{A} \cong \boldsymbol{A}^\top \tag{1}$$

Under this notation, the dimension (or the size) of a mode labeled by variable X will be the same as the number of possible values for variable X. Furthermore, when we multiply two tensors together, we will always carry out the operation along (a set of) modes with matching labels.

Tensor multiplication with mode labels. Let $\boldsymbol{\mathcal{A}} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ be an Nth order tensor and $\boldsymbol{\mathcal{B}} \in \mathbb{R}^{J_1 \times J_2 \times \cdots \times J_M}$ be an Mth order tensor. If X is a common mode label for both $\boldsymbol{\mathcal{A}}$ and $\boldsymbol{\mathcal{B}}$ (w.l.o.g. we assume that this is the first mode, implying also that $I_1 = J_1$), multiplying along this mode will give

$$\boldsymbol{\mathcal{C}} = \boldsymbol{\mathcal{A}} \times_X \boldsymbol{\mathcal{B}} \quad \in \quad \mathbb{R}^{I_2 \times \cdots \times I_N \times J_2 \times \cdots \times J_M}, \tag{2}$$

where the entries of $\boldsymbol{\mathcal{C}}$ is defined as

$$\boldsymbol{\mathcal{C}}(\boldsymbol{i}_{2:N}, \boldsymbol{j}_{2:M}) = \sum\nolimits_{i=1}^{I_1} \boldsymbol{\mathcal{A}}(i, \boldsymbol{i}_{2:N})\, \boldsymbol{\mathcal{B}}(i, \boldsymbol{j}_{2:M})$$

Similarly, we can multiply two tensors along multiple modes. Let $\boldsymbol{\sigma} = \{X_1, \ldots, X_k\}$ be an arbitrary set of k modes (k variables) shared by $\boldsymbol{\mathcal{A}}$ and $\boldsymbol{\mathcal{B}}$ (w.l.o.g. we assume these labels correspond to the first k modes, and $I_1 = J_1, \ldots, I_k = J_k$ holds for the corresponding dimensions). Then multiplying $\boldsymbol{\mathcal{A}}$ and $\boldsymbol{\mathcal{B}}$ along $\boldsymbol{\sigma}$ results in

$$\boldsymbol{\mathcal{D}} = \boldsymbol{\mathcal{A}} \times_{\boldsymbol{\sigma}} \boldsymbol{\mathcal{B}} \quad \in \quad \mathbb{R}^{I_{k+1} \times \ldots \times I_N \times J_{k+1} \times \ldots \times J_M}, \tag{3}$$

where the entries of $\boldsymbol{\mathcal{D}}$ are defined as

$$\boldsymbol{\mathcal{D}}(\boldsymbol{i}_{k+1:N}, \boldsymbol{j}_{k+1:M}) = \sum_{\boldsymbol{i}_{1:k}} \boldsymbol{\mathcal{A}}(\boldsymbol{i}_{1:k}, \boldsymbol{i}_{k+1:N}) \boldsymbol{\mathcal{B}}(\boldsymbol{i}_{1:k}, \boldsymbol{j}_{k+1:M}).$$

Multi-mode multiplication can also be interpreted as reshaping the $\boldsymbol{\sigma}$ modes of $\boldsymbol{\mathcal{A}}$ and $\boldsymbol{\mathcal{B}}$ into a single mode and doing single-mode tensor multiplication. Furthermore, tensor multiplication with labels is symmetric in its arguments, *i.e.*, $\boldsymbol{\mathcal{A}} \times_{\boldsymbol{\sigma}} \boldsymbol{\mathcal{B}} \cong \boldsymbol{\mathcal{B}} \times_{\boldsymbol{\sigma}} \boldsymbol{\mathcal{A}}$.

Mode-specific identity tensor. We now define our notion of identity tensor with respect to a set of modes $\boldsymbol{\sigma} = \{X_1, \ldots, X_K\}$. Let $\boldsymbol{\mathcal{A}}$ be a tensor with mode labels containing $\boldsymbol{\sigma}$, and $\boldsymbol{\mathcal{I}}_{\boldsymbol{\sigma}}$ be a tensor with $2K$ modes with mode labels $\{X_1, \ldots, X_K, X_1, \ldots, X_K\}$. Then $\boldsymbol{\mathcal{I}}_{\boldsymbol{\sigma}}$ is an identity tensor with respect to modes $\boldsymbol{\sigma}$ if

$$\boldsymbol{\mathcal{A}} \times_{\boldsymbol{\sigma}} \boldsymbol{\mathcal{I}}_{\boldsymbol{\sigma}} \cong \boldsymbol{\mathcal{A}}. \tag{4}$$

One can also understand $\boldsymbol{\mathcal{I}}_{\boldsymbol{\sigma}}$ using its matrix representation: flattening $\boldsymbol{\mathcal{I}}_{\boldsymbol{\sigma}}$ with respect to $\boldsymbol{\sigma}$ (the first $\boldsymbol{\sigma}$ modes mapped to rows and the second $\boldsymbol{\sigma}$ modes mapped to columns) results in an identity matrix.

Mode-specific tensor inversion. Let $\boldsymbol{\mathcal{F}}, \boldsymbol{\mathcal{F}}^{-1} \in \mathbb{R}^{I_1 \times \cdots \times I_K \times I_{K+1} \times \cdots \times I_{K+K'}}$ be tensors of order $K + K'$, and both have two sets of mode labels $\boldsymbol{\sigma} = \{X_1, \ldots, X_K\}$ and $\boldsymbol{\omega}' = \{X_{K+1}, \ldots, X_{K+K'}\}$. Then $\boldsymbol{\mathcal{F}}^{-1}$ is the inverse of $\boldsymbol{\mathcal{F}}$ w.r.t. modes $\boldsymbol{\omega}$ if and only if

$$\boldsymbol{\mathcal{F}} \times_{\boldsymbol{\omega}} \boldsymbol{\mathcal{F}}^{-1} \cong \boldsymbol{\mathcal{I}}_{\boldsymbol{\sigma}}. \tag{5}$$

Multimode inversion can also be interpreted as reshaping $\boldsymbol{\mathcal{F}}$ with respect to $\boldsymbol{\omega}$ into a matrix of size $(I_1 \ldots I_K) \times (I_{K+1} \ldots I_{K+K'})$, taking the inverse, and then rearranging back into a tensor. Thus the existence and uniqueness of this inverse can be characterized by the rank of the matricized version of $\boldsymbol{\mathcal{F}}$.

Mode-specific diagonal tensors. We use $\boldsymbol{\delta}$ to denote an N-way relation: its entry $\boldsymbol{\delta}(\boldsymbol{i}_{1:N})$ at position $\boldsymbol{i}_{1:N}$ equals 1 when all indexes are the same ($i_1 = i_2 = \ldots = i_N$), and 0 otherwise. We will use $\oslash_d$ to denote repetition of an index d times. For instance, we use $\mathbb{P}(\oslash_d X)$ to denote a dth order tensor where its entries at $(\boldsymbol{i}_{1:d})$th position are specified by $\boldsymbol{\delta}(\boldsymbol{i}_{1:d})\mathbb{P}(X = x_{i_1})$. A diagonal matrix with its diagonal equal to $\mathbb{P}(X)$ is then denoted as $\mathbb{P}(\oslash_2 X)$. Similarly, we can define a $(d + d')$th order tensor $\mathbb{P}(\oslash_d X | \oslash_{d'} Y)$ where its $(\boldsymbol{i}_{1:d}\boldsymbol{j}_{1:d'})$th entry corresponds to $\boldsymbol{\delta}(\boldsymbol{i}_{1:d})\boldsymbol{\delta}(\boldsymbol{j}_{1:d'})\mathbb{P}(X = x_{i_1} | Y = y_{j_1})$.

3 Latent Junction Trees

In this paper, we will focus on discrete latent variable models where the number of states, k_h, for each hidden variable is much smaller than the number of states, k_o, for each observed variable. Uppercase letters denote random variables (*e.g.*, X_i) and lowercase letters their instantiations (*e.g.*, x_i). A latent variable model defines a joint probability distribution over a set of variables $\mathscr{X} = \mathscr{O} \cup \mathscr{H}$. Here, $\mathscr{O}$ denotes the set of observed variables, $\{X_1, \ldots, X_{|\mathscr{O}|}\}$. $\mathscr{H}$ denotes the set of hidden variables, $\{X_{|\mathscr{O}|+1}, \ldots, X_{|\mathscr{H}|+|\mathscr{O}|}\}$.

We will focus on latent variable models where the

structure of the model is a junction tree of low treewidth (Cowell et al., 1999). Each node C_i in a junction tree corresponds to a subset (clique) of variables from the original graphical model. We will also use C_i to denote the collection of variables contained in the node, *i.e.* $C_i \subset \mathscr{X}$. Let $\mathbb{C}$ denote the set of all clique nodes. The treewidth is then the size of a largest clique in a junction tree minus one, that is $t = \max_{C_i \in \mathbb{C}} |C_i| - 1$. Furthermore, we associate each edge in a junction tree with a separator set $S_{ij} := C_i \cap C_j$ which contains the common variables of the two cliques C_i and C_j it is connected to. If we condition on all variables in any S_{ij}, the variables on different sides of S_{ij} will become independent.

Without loss of generality, we assume that each internal clique node in the junction tree has exactly 3 neighbors.[1] Then we can pick a clique C_r as the root of the tree and reorient all edges away from the root to induce a topological ordering of the clique nodes. Given the ordering, the root node will have 3 children nodes, denoted as C_{r_1}, C_{r_2} and C_{r_3}. Each other internal node C_i will have a unique parent node, denoted as C_{i_0}, and 2 children nodes denoted as C_{i_1} and C_{i_2}. Each leaf node C_l is only connected with its unique parent node C_{l_0}. Furthermore, we can simplify the notation for the separator set between a node C_i and its parent C_{i_0} as $S_i = C_i \cap C_{i_0}$, omitting the index for the parent node. Then the remainder set of a node is defined as $R_i = C_i \setminus S_i$. We also assume w.l.o.g. that if C_i is a leaf in the junction tree, R_i consists of only observed variables. We will use r_i to denote an instantiation of the set of variables in R_i. See Figure 2 for an illustration of notation.

Given a root and a topological ordering of the nodes in a junction tree, the joint distribution of all variables $\mathscr{X}$ can be factorized according to

$$\mathbb{P}(\mathscr{X}) = \prod_{i=1}^{|\mathscr{X}|} \mathbb{P}(R_i|S_i), \tag{6}$$

where each CPT $\mathbb{P}(R_i|S_i)$, also called a clique potential, corresponds to a node C_i. The number of parameters needed to specify the model is $O(|\mathbb{C}|k_o^t)$, linear in the number of cliques but exponential in the tree width t. Then the marginal distribution of the observed variables can be obtained by summing over the latent variables,

$$\mathbb{P}(\mathscr{O}) = \sum_{X_{|\mathscr{O}|+1}} \cdots \sum_{X_{|\mathscr{O}|+|\mathscr{H}|}} \left[\prod_{i=1}^{|\mathscr{X}|} \mathbb{P}(R_i|S_i) \right], \tag{7}$$

where we use $\sum_X \phi(X)$ to denote summation over all possible instantiations of $\phi(x)$ w.r.t. variable X. Note that each (non-leaf) remainder set R_i contains a small subset of all latent variables. The presence of latent variables introduces complicated dependency between observed variables, while at the same time only a small number of parameters corresponding to the entries in the CPTs are needed to specify the model.

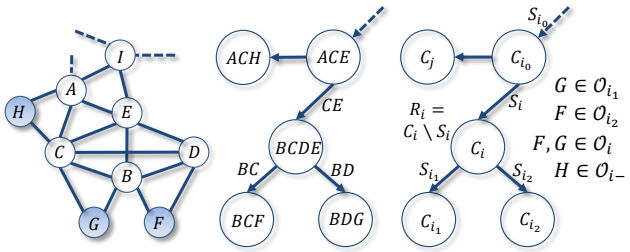

Figure 2: Example latent variable models with variables $\mathscr{X} = \{A, B, C, D, E, F, G, H, I, \ldots\}$, the observed variables are $\mathscr{O} = \{F, G, H, \ldots\}$ (only partially drawn). Its corresponding junction tree is shown in the middle panel. Corresponding to this junction tree, we also show the general notation for it in the rightmost panel.

The process of eliminating the latent variables in (7) can be carried out efficiently via message passing. More specifically, the summation can be broken up into local computation for each node in the junction tree. Each node only needs to sum out a small number of variables and then the intermediate result, called the message, is passed to its parent for further processing. In the end the root node incorporates all messages from its children and produces the final result $P(\mathscr{O})$. The local summation step, called the message update, can be generically written as[2]

$$\boldsymbol{\mathcal{M}}(S_i) = \sum_{R_i} \mathbb{P}(R_i|S_i)\boldsymbol{\mathcal{M}}(S_{i_1})\boldsymbol{\mathcal{M}}(S_{i_2}) \tag{8}$$

where we use $\boldsymbol{\mathcal{M}}(S_i)$ to denote the intermediate results of eliminating variables in the remainder set R_i. This message update is then carried out recursively according the reverse topological order of the junction tree until we reach the root node. The local summation step for the leaf nodes and root node can be viewed as special cases of (8). For a leaf node C_l, there is no incoming message from children nodes, and hence $\boldsymbol{\mathcal{M}}(S_l) = \mathbb{P}(r_l|S_l)$; for the root node C_r, $S_r = \emptyset$ and $R_i = C_i$, and hence $\mathbb{P}(\mathscr{O}) = \boldsymbol{\mathcal{M}}(\emptyset) = \sum_{\forall X \in C_r} \mathbb{P}(C_r)\boldsymbol{\mathcal{M}}(S_{r_1})\boldsymbol{\mathcal{M}}(S_{r_2})\boldsymbol{\mathcal{M}}(S_{r_3})$.

Example. The message update at the internal node C_{BCDE} in Figure 2 is
$\boldsymbol{\mathcal{M}}(\{C, E\}) = \sum_{B,D} \mathbb{P}(B, D|C, E)\mathbb{P}(f|B, C)\mathbb{P}(g|B, D)$.

4 Tensor Representation for Message Passing

Although the parametrization of latent junction trees using CPTs is very compact and inference (message passing) can be carried out efficiently, parameters in this representation can be difficult to learn. Since the likelihood of the observed data is no longer convex in the latent parameters, local search heuristics, such as

[1] If this is not the case, the derivation is similar but notationally much heavier.

[2] For simplicity of notation, assume $C_i = S_i \cup S_{i_1} \cup S_{i_2}$.

EM, are often employed to learning the parameters. Therefore, our goal is to design a new representation for latent junction trees, such that subsequent learning can be carried out in a local-minimum-free fashion.

In this section, we will develop a new representation for the message update in (8) by embedding each CPT $\mathbb{P}(R_i|S_i)$ into a higher order tensor $\mathcal{P}(C_i)$. As we will see, there will be two advantages to the tensor form. The first is that tensor multiplication can be used to compactly express the sum and product steps involved in message passing. As a very simplistic example, let $\boldsymbol{P}_{A|B} = \mathbb{P}(A|B)$ be a conditional probability matrix and $\boldsymbol{P}_B = \mathbb{P}(B)$ be a marginal probability vector. Then matrix-vector multiplication, $\boldsymbol{P}_{A|B}\boldsymbol{P}_B = P(A)$, sums out variable B. However, if we put the marginal probability of B on the diagonal of a matrix, then B will not be summed out: *e.g.*, if $\boldsymbol{P}_{\oslash_2 B} = \mathbb{P}(\oslash_2 B)$, then $\boldsymbol{P}_{A|B}\boldsymbol{P}_{\oslash_2 B} = \mathbb{P}(A, B)$ (but now B is no longer on the diagonal). We will leverage these facts to derive our tensor representation for message passing.

Moreover, we can then utilize tensor inversion to construct an alternate parameterization. In the very simplistic (matrix) example, note that $\mathbb{P}(A, B) = \boldsymbol{P}_{A|B}\boldsymbol{P}_{\oslash_2 B} = \boldsymbol{P}_{A|B}\boldsymbol{F}\boldsymbol{F}^{-1}\boldsymbol{P}_{\oslash_2 B}$. The invertible transformations $\boldsymbol{F}$ will give us an extra degree of freedom to allow us to design an alternate parameterization of the latent junction tree that is only a function of observed variables. This would not be possible in the traditional representation (Eq. 8).

4.1 Embed CPTs to higher order tensors

As we can see from (6), the joint probability distribution of all variables can be represented by a set of conditional distributions over just subsets of variables. Each one of this conditionals is a low order tensor. For example in Figure 2, the CPT corresponding to the clique node C_{BCDE} would be a 4th order tensor $\mathbb{P}(B, D|C, E)$ where each variable corresponds to a different mode of the tensor. However, this representation is not suitable for deriving the observable representation since message passing cannot be defined easily using the tensor multiplication/sum connection shown above. Instead we will embed these tensors into even higher order tensors to facilitate the computation. The key idea is to introduce duplicate indexes using the mode-specific identity tensors, such that the sum-product steps in message updates can be expressed as tensor multiplications.

More specifically, the number of times a mode of the tensor is duplicated will depend on how many times the corresponding variable in the clique C_i appears in the separator sets incident to C_i. We can define the count for a variable $X_j \in C_i$ as

$$d_{j,i} = \mathbb{I}[X_j \in S_i] + \mathbb{I}[X_j \in S_{i_1}] + \mathbb{I}[X_j \in S_{i_2}], \quad (9)$$

where $\mathbb{I}[\cdot]$ is an indicator function taking value 1 if its argument is true and 0 otherwise. Then the tensor representation of the node C_i is

$$\boldsymbol{\mathcal{P}}(C_i) := \mathbb{P}(\underbrace{\ldots, (\oslash_{d_{j,i}} X_j), \ldots}_{\forall X_j \in R_i} | \underbrace{\ldots, (\oslash_{d_{j',i}} X_{j'}), \ldots}_{\forall X_{j'} \in S_i}), \quad (10)$$

where the labels for the modes of the tensor are the combined labels of the separator sets, *i.e.*, $\{S_i, S_{i_1}, S_{i_2}\}$. The number of times a variable is repeated in the label set is exactly equal to $d_{j,i}$.

Essentially, tensor $\boldsymbol{\mathcal{P}}(C_i)$ contains exactly the same information as the original CPT $\mathbb{P}(R_i|S_i)$. Furthermore, $\boldsymbol{\mathcal{P}}(C_i)$ has a lot of zero entries, and the entries from $\mathbb{P}(R_i|S_i)$ are simply embedded in the higher order tensor $\boldsymbol{\mathcal{P}}(C_i)$. Suppose all variables in node C_i are latent variables each taking k_h values. Then the number of entries needed to specify $\mathbb{P}(R_i|S_i)$ is $k_h^{|C_i|}$, while the high order tensor $\boldsymbol{\mathcal{P}}(C_i)$ has $k_h^{d_i}$ entries where $d_i := \sum_{j:X_j \in C_i} d_{j,i}$ which is never smaller than $k_h^{|C_i|}$. In a sense, the parametrization using higher order tensor $\boldsymbol{\mathcal{P}}(C_i)$ is less compact than the parametrization using the original CPTs. However, constructing the tensor $\boldsymbol{\mathcal{P}}$ this way allows us to express the junction tree message update step in (8) as tensor multiplications (more details in the next section), and then we can leverage tools from tensor analysis to design a local-minimum-free learning algorithm.

The tensor representation for the leaf nodes and the root node are special cases of the representation in (10). The tensor representation at a leaf node C_l is simply equal to its CPT $\boldsymbol{\mathcal{P}}(C_l) = \mathbb{P}(R_l|S_l)$. The root node C_r has no parent, so $\boldsymbol{\mathcal{P}}(C_r) = \mathbb{P}(\ldots, (\oslash_{d_{j,r}} X_j), \ldots)$, $\forall X_j \in C_r$. Furthermore, since $d_{j,i}$ is simply a count of how many times a variable in C_i appears in each of the incident separators, the size of each tensor does not depend on which clique node was selected as the root.

Example. In Figure 2, node C_{BCDE} corresponds to CPT $\mathbb{P}(B, D|C, E)$. Its high order tensor representation is $\boldsymbol{\mathcal{P}}(C_{BCDE}) = \mathbb{P}(\oslash_2 B, D| \oslash_2 C, E)$, since both B and C occur twice in the separator sets incident to C_{BCDE}. Therefore the tensor $\boldsymbol{\mathcal{P}}(\{B, C, D, E\})$ is a 6th order tensor with mode labels $\{B, B, D, C, C, E\}$.

4.2 Tensor message passing

With the higher order tensor representation for clique potentials in the junction tree as in (10), we can express the message update step in (8) as tensor multiplications. Consequently, we can compute the marginal distribution of the observed variables $\mathscr{O}$ in equation (7) recursively using a sequence of tensor multiplications. More specifically the general message update equation

for a node in a junction tree can be expressed as

$$\boldsymbol{\mathcal{M}}(S_i) = \boldsymbol{\mathcal{P}}(C_i) \times_{S_{i_1}} \boldsymbol{\mathcal{M}}(S_{i_1}) \times_{S_{i_2}} \boldsymbol{\mathcal{M}}(S_{i_2}). \quad (11)$$

Here the modes of the tensor $\boldsymbol{\mathcal{P}}(C_i)$ are labeled by the variables, and the mode labels are used to carry out tensor multiplications as explained in Section 2. Essentially, multiplication with respect to the duplicated modes of the tensor $\boldsymbol{\mathcal{P}}(C_i)$ will implement some kind of element-wise multiplication for the incoming messages and then summation over the variables in the remainder set R_i.

The tensor message passing steps in leaf nodes and the root node are special cases of the tensor message update in equation (11). The outgoing message $\boldsymbol{\mathcal{M}}(S_l)$ at a leaf node C_l can be computed by simply setting all variables in R_l to the actual observed values r_l, *i.e.*,

$$\boldsymbol{\mathcal{M}}(S_l) = \mathcal{P}(C_l)_{R_l=r_l} = \mathbb{P}(R_l = r_l | S_l). \quad (12)$$

In this step, there is no difference between the augmented tensor representation and the standard message passing in junction tree. At the root, we arrive at the final results of the message passing algorithm, and we obtain the marginal probability of the observed variables by aggregating all incoming messages from its 3 children, *i.e.*,

$$\mathbb{P}(\mathscr{O}) = \quad (13)$$
$$\boldsymbol{\mathcal{P}}(C_r) \times_{S_{r_1}} \boldsymbol{\mathcal{M}}(S_{r_1}) \times_{S_{r_2}} \boldsymbol{\mathcal{M}}(S_{r_2}) \times_{S_{r_3}} \boldsymbol{\mathcal{M}}(S_{r_3}).$$

Example. For Figure 2, using the following tensors

$$\boldsymbol{\mathcal{P}}(\{B,C,D,E\}) = \mathbb{P}(\oslash_2 B, D \mid \oslash_2 C, E)$$
$$\boldsymbol{\mathcal{M}}(\{B,C\}) = \mathbb{P}(f|B,C)$$
$$\boldsymbol{\mathcal{M}}(\{B,D\}) = \mathbb{P}(g|B,D),$$

we can write the message update for node C_{BCDE} in the form of equation (11) as

$$\boldsymbol{\mathcal{M}}(\{C,E\}) = \boldsymbol{\mathcal{P}}(\{B,C,D,E\}) \times_{\{B,C\}} \boldsymbol{\mathcal{M}}(\{B,C\}) \times_{\{B,D\}} \boldsymbol{\mathcal{M}}(\{B,D\}).$$

Note how the tensor multiplication sums out B and D: $\boldsymbol{\mathcal{P}}(\{B,C,D,E\})$ has two B labels, and it appears in the subscripts of tensor multiplication twice; D appears once in the label and in the subscript of tensor multiplication respectively. Similarly, C is not summed out since there are two C labels but it appears only once in the subscript of tensor multiplication.

5 Transformed Representation

Explicitly learning the tensor representation in (10) is still an intractable problem. Our key observation is that we do not need to recover the tensor representation explicitly if our focus is to perform inference using the message passing algorithm as in (11)–(13). As long as we can recover the tensor representation up to some invertible transformation, we can still obtain the correct marginal probability $\mathbb{P}(\mathscr{O})$.

More specifically, we can insert a mode-specific identity tensor $\boldsymbol{\mathcal{I}}_{\boldsymbol{\sigma}}$ into the message update equation in (11) without changing the outgoing message. Subsequently, we can then replace the mode-specific identity tensor by a pair of tensors, $\boldsymbol{\mathcal{F}}$ and $\boldsymbol{\mathcal{F}}^{-1}$, which are mode-specific inversions of each other ($\boldsymbol{\mathcal{F}} \times_{\boldsymbol{\omega}} \boldsymbol{\mathcal{F}}^{-1} \cong \boldsymbol{\mathcal{I}}_{\boldsymbol{\sigma}}$). Then we can group these inserted tensors with the representation $\boldsymbol{\mathcal{P}}(C)$ from (10), and obtain a transformed version $\widetilde{\boldsymbol{\mathcal{P}}}(C)$ (also see Figure 1). Furthermore, we have the freedom in choosing these collections of tensor inversion pairs. We will show that if we choose them systematically, we will be able to estimate each transformed tensor $\widetilde{\boldsymbol{\mathcal{P}}}(C)$ using the marginal probability of a small set of observed variables (observable representation). In this section, we will first explain the transformed tensor representation.

As an illustration, consider a sequence of matrix multiplications with two identity matrices $\boldsymbol{I}_1 = \boldsymbol{F}_1\boldsymbol{F}_1^{-1}$ and $\boldsymbol{I}_2 = \boldsymbol{F}_2\boldsymbol{F}_2^{-1}$ inserted

$$\begin{aligned}\boldsymbol{ABC} &= \boldsymbol{A}(\boldsymbol{F}_1\boldsymbol{F}_1^{-1})\boldsymbol{B}(\boldsymbol{F}_2\boldsymbol{F}_2^{-1})\boldsymbol{C} \\ &= \underbrace{(\boldsymbol{AF}_1)}_{\widetilde{\boldsymbol{A}}} \underbrace{(\boldsymbol{F}_1^{-1}\boldsymbol{BF}_2)}_{\widetilde{\boldsymbol{B}}} \underbrace{(\boldsymbol{F}_2^{-1}\boldsymbol{C})}_{\widetilde{\boldsymbol{C}}}.\end{aligned}$$

We see that we can equivalently compute $\boldsymbol{ABC}$ using their transformed versions, *i.e.*, $\boldsymbol{ABC} = \widetilde{\boldsymbol{A}}\widetilde{\boldsymbol{B}}\widetilde{\boldsymbol{C}}$.

Moving to the tensor case, let us first consider a node C_i and its parent node C_{i_0}. Then the outgoing message of C_{i_0} can be computed recursively as

$$\boldsymbol{\mathcal{M}}(S_{i_0}) = \boldsymbol{\mathcal{P}}(C_{i_0}) \times_{S_i} \underbrace{\boldsymbol{\mathcal{M}}(S_i)}_{\boldsymbol{\mathcal{P}}(C_i)\times_{S_{i_1}}\boldsymbol{\mathcal{M}}(S_{i_1})\times_{S_{i_2}}\boldsymbol{\mathcal{M}}(S_{i_2})} \times \dots$$

Inserting a mode specific identity tensor $\boldsymbol{\mathcal{I}}_{S_i}$ with labels $\{S_i, S_i\}$ and similarly defined mode specific identity tensors $\boldsymbol{\mathcal{I}}_{S_{i_1}}$ and $\boldsymbol{\mathcal{I}}_{S_{i_2}}$ into the above two message updates, we obtain

$$\boldsymbol{\mathcal{M}}(S_{i_0}) = \boldsymbol{\mathcal{P}}(C_{i_0}) \times_{S_i} (\boldsymbol{\mathcal{I}}_{S_i} \times_{S_i} \underbrace{\boldsymbol{\mathcal{M}}(S_i)}_{\boldsymbol{\mathcal{P}}(C_i)\times_{S_{i_1}}(\boldsymbol{\mathcal{I}}_{S_{i_1}}\times_{S_{i_1}}\boldsymbol{\mathcal{M}}(S_{i_1}))\times_{S_{i_2}}(\boldsymbol{\mathcal{I}}_{S_{i_2}}\times_{S_{i_2}}\boldsymbol{\mathcal{M}}(S_{i_1}))}) \times \dots$$

Then we can further expand $\boldsymbol{\mathcal{I}}_{S_i}$ using tensor inversion pairs $\boldsymbol{\mathcal{F}}_i$, $\boldsymbol{\mathcal{F}}_i^{-1}$, *i.e.*, $\boldsymbol{\mathcal{I}}_{S_i} = \boldsymbol{\mathcal{F}}_i \times_{\boldsymbol{\omega}_i} \boldsymbol{\mathcal{F}}_i^{-1}$. Note that both $\boldsymbol{\mathcal{F}}$ and $\boldsymbol{\mathcal{F}}^{-1}$ have two set of mode labels, S_i and another set $\boldsymbol{\omega}_i$ which is related to the observable representation and explained in the next section. Similarly, we expand $\boldsymbol{\mathcal{I}}_{S_{i_1}}$ and $\boldsymbol{\mathcal{I}}_{S_{i_2}}$ using their corresponding tensor inversion pairs.

After expanding tensor identities $\boldsymbol{\mathcal{I}}$, we can regroup terms, and at node C_i we have

$$\begin{aligned}\boldsymbol{\mathcal{M}}(S_i) =& (\boldsymbol{\mathcal{P}}(C_i) \times_{S_{i_1}} \boldsymbol{\mathcal{F}}_{i_1} \times_{S_{i_2}} \boldsymbol{\mathcal{F}}_{i_2}) \\ &\times_{\boldsymbol{\omega}_{i_1}} (\boldsymbol{\mathcal{F}}_{i_1}^{-1} \times_{S_{i_1}} \boldsymbol{\mathcal{M}}(S_{i_1})) \\ &\times_{\boldsymbol{\omega}_{i_2}} (\boldsymbol{\mathcal{F}}_{i_2}^{-1} \times_{S_{i_2}} \boldsymbol{\mathcal{M}}(S_{i_2}))\end{aligned} \quad (14)$$

and at the parent node C_{i_0} of C_i

$$\begin{aligned}\boldsymbol{\mathcal{M}}(S_{i_0}) =& (\boldsymbol{\mathcal{P}}(C_{i_0}) \times_{S_i} \boldsymbol{\mathcal{F}}_i \times \dots) \\ &\times_{\boldsymbol{\omega}_i} (\boldsymbol{\mathcal{F}}_i^{-1} \times_{S_i} \boldsymbol{\mathcal{M}}(S_i)) \times \dots\end{aligned} \quad (15)$$

Now we can define the transformed tensor representation for $\boldsymbol{\mathcal{P}}(C_i)$ as

$$\widetilde{\boldsymbol{\mathcal{P}}}(C_i) := \boldsymbol{\mathcal{P}}(C_i) \times_{S_{i_1}} \boldsymbol{\mathcal{F}}_{i_1} \times_{S_{i_2}} \boldsymbol{\mathcal{F}}_{i_2} \times_{S_i} \boldsymbol{\mathcal{F}}_i^{-1}, \quad (16)$$

where the two transformations $\boldsymbol{\mathcal{F}}_{i_1}$ and $\boldsymbol{\mathcal{F}}_{i_2}$ are ob-

tained from the children side and the transformation $\boldsymbol{\mathcal{F}}_i^{-1}$ is obtained from the parent side. Similarly, we can define the transformed representation for a leaf node and for the root node as

$$\widetilde{\boldsymbol{\mathcal{P}}}(C_l) = \boldsymbol{\mathcal{P}}(C_l) \times_{S_l} \boldsymbol{\mathcal{F}}_l^{-1} \tag{17}$$

$$\widetilde{\boldsymbol{\mathcal{P}}}(C_r) = \boldsymbol{\mathcal{P}}(C_r) \times_{S_{r_1}} \boldsymbol{\mathcal{F}}_{r_1} \times_{S_{r_2}} \boldsymbol{\mathcal{F}}_{r_2} \times_{S_{r_3}} \boldsymbol{\mathcal{F}}_{r_3} \tag{18}$$

Applying these definitions of the transformed representation recursively, we can perform message passing based purely on these transformed representations

$$\widetilde{\boldsymbol{\mathcal{M}}}(S_{i_0}) = \widetilde{\boldsymbol{\mathcal{P}}}(C_{i_0}) \times_{\boldsymbol{\omega}_i} \underbrace{\widetilde{\boldsymbol{\mathcal{M}}}(S_i)}_{\widetilde{\boldsymbol{\mathcal{P}}}(C_i) \times_{\boldsymbol{\omega}_{i_1}} \widetilde{\boldsymbol{\mathcal{M}}}(S_{i_1}) \times_{\boldsymbol{\omega}_{i_2}} \widetilde{\boldsymbol{\mathcal{M}}}(S_{i_2})} \times \dots \tag{19}$$

6 Observable Representation

In the transformed tensor representation in (16)-(18), we have the freedom of choosing the collection of tensor pairs $\boldsymbol{\mathcal{F}}$ and $\boldsymbol{\mathcal{F}}^{-1}$. We will show that if we choose them systematically, we can recover each transformed tensor $\widetilde{\boldsymbol{\mathcal{P}}}(C)$ using the marginal probability of a small set of observed variables (observable representation).

We will focus on the transformed tensor representation in (16) for an internal node C_i (other cases follow as special cases). Due to the recursive way the transformed representation is defined, we only have the freedom of choosing $\boldsymbol{\mathcal{F}}_{i_1}$ and $\boldsymbol{\mathcal{F}}_{i_2}$ in this formula; the choice of $\boldsymbol{\mathcal{F}}_i$ will be fixed by the parent node of C_i. The idea is to choose

- $\boldsymbol{\mathcal{F}}_{i_1} = \mathbb{P}(\mathscr{O}_{i_1}|S_{i_1})$ as the conditional distribution of some set of observed variables $\mathscr{O}_{i_1} \subset \mathscr{O}$ in the subtree rooted at child node C_{i_1} of node C_i, conditioning on the corresponding separator set S_{i_1}.
- Similarly, we choose $\boldsymbol{\mathcal{F}}_{i_2} = \mathbb{P}(\mathscr{O}_{i_2}|S_{i_2})$ where $\mathscr{O}_{i_2} \subset \mathscr{O}$ and it lies in subtree rooted at C_{i_2}.
- Following this convention, $\boldsymbol{\mathcal{F}}_i$ is chosen by the parent node C_{i_0} and is fixed to $\mathbb{P}(\mathscr{O}_i|S_i)$.

Therefore, we have

$$\begin{aligned}\widetilde{\boldsymbol{\mathcal{P}}}(C_i) = \boldsymbol{\mathcal{P}}(C_i) &\times_{S_{i_1}} \mathbb{P}(\mathscr{O}_{i_1}|S_{i_1}) \times_{S_{i_2}} \mathbb{P}(\mathscr{O}_{i_2}|S_{i_2}) \\ &\times_{S_i} \mathbb{P}(\mathscr{O}_i|S_i)^{-1},\end{aligned} \tag{20}$$

where the first two tensor multiplications essentially eliminate the latent variables in S_{i_1} and S_{i_2}.[3] With these choices, we also fix the mode labels $\boldsymbol{\omega}_i$, $\boldsymbol{\omega}_{i_1}$ and $\boldsymbol{\omega}_{i_2}$ in (14) (15) and (19). That is $\boldsymbol{\omega}_i = \mathscr{O}_i$, $\boldsymbol{\omega}_{i_1} = \mathscr{O}_{i_1}$ and $\boldsymbol{\omega}_{i_2} = \mathscr{O}_{i_2}$.

To remove all dependencies on latent variables in $\widetilde{\boldsymbol{\mathcal{P}}}(C_i)$ and relate it to observed variables, we need to eliminate the latent variables in S_i and the tensor $\mathbb{P}(\mathscr{O}_i|S_i)^{-1}$. For this, we multiply the transformed tensor $\widetilde{\boldsymbol{\mathcal{P}}}(C_i)$ by $\mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-})$, where $\mathscr{O}_{i-}$ denotes some set of observed variables which do *not* belong to the subtree rooted at node C_i. Furthermore, $\mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-})$ can be re-expressed using the conditional distribution of $\mathscr{O}_i$ and $\mathscr{O}_{i-}$ respectively, conditioning on the separator set S_i, *i.e.*,

$$\mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-}) = \mathbb{P}(\mathscr{O}_i|S_i) \times_{S_i} \mathbb{P}(\oslash_2 S_i) \times_{S_i} \mathbb{P}(\mathscr{O}_{i-}|S_i).$$

Therefore, we have

$$\mathbb{P}(\mathscr{O}_i|S_i)^{-1} \times_{\mathscr{O}_i} \mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-}) = \mathbb{P}(\oslash_2 S_i) \times_{S_i} \mathbb{P}(\mathscr{O}_{i-}|S_i),$$

and plugging this into (20), we have

$$\begin{aligned}&\widetilde{\boldsymbol{\mathcal{P}}}(C_i) \times_{\mathscr{O}_i} \mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-}) \\ =&\boldsymbol{\mathcal{P}}(C_i) \times_{S_{i_1}} \mathbb{P}(\mathscr{O}_{i_1}|S_{i_1}) \times_{S_{i_2}} \mathbb{P}(\mathscr{O}_{i_2}|S_{i_2}) \\ &\times_{S_i} \mathbb{P}(\oslash_2 S_i) \times_{S_i} \mathbb{P}(\mathscr{O}_{i-}|S_i) \\ =&\mathbb{P}(\mathscr{O}_{i_1}, \mathscr{O}_{i_2}, \mathscr{O}_{i-}),\end{aligned} \tag{21}$$

where $\widetilde{\boldsymbol{\mathcal{P}}}(C_i)$ is now related to only marginal probabilities of observed variables. From the equivalent relation, we can inverting $\mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-})$, and obtain the observable representation for $\widetilde{\boldsymbol{\mathcal{P}}}(C_i)$

$$\widetilde{\boldsymbol{\mathcal{P}}}(C_i) = \mathbb{P}(\mathscr{O}_{i_1}, \mathscr{O}_{i_2}, \mathscr{O}_{i-}) \times_{\mathscr{O}_{i-}} \mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-})^{-1}. \tag{22}$$

Example. For node C_{BCDE} in Figure 2, the choices of $\mathscr{O}_i, \mathscr{O}_{i_1}, \mathscr{O}_{i_2}$ and $\mathscr{O}_{i-}$ are $\{F, G\}$, G, F and H respectively.

There are many valid choices of $\mathscr{O}_{i-}$. In the supplementary, we describe how these different choices can be combined via a linear system using Eq. 21. This can substantially increase performance.

For the leaf nodes and the root node, the derivation for their observable representations can be viewed as special cases of that for the internal nodes. We provide the results for their observable representation below:

$$\widetilde{\boldsymbol{\mathcal{P}}}(C_r) = \mathbb{P}(\mathscr{O}_{r_1}, \mathscr{O}_{r_2}, \mathscr{O}_{r_3}), \tag{23}$$

$$\widetilde{\boldsymbol{\mathcal{P}}}(C_l) = \mathbb{P}(\mathscr{O}_l, \mathscr{O}_{l-}) \times_{\mathscr{O}_{l-}} \mathbb{P}(\mathscr{O}_l, \mathscr{O}_{l-})^{-1}. \tag{24}$$

If $\mathbb{P}(\mathscr{O}_l, \mathscr{O}_{l-})$ is invertible, then $\widetilde{\boldsymbol{\mathcal{P}}}(C_l) = \boldsymbol{\mathcal{I}}_{\mathscr{O}_l}$. Otherwise we need to project $\mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-})$ using a tensor $\boldsymbol{\mathcal{U}}_i$ to make it invertible, as discussed in the next section. The overall algorithm is given in Algorithm 1. Given N *i.i.d.* samples of the observed nodes, we simply replace $\mathbb{P}(\cdot)$ by the empirical estimate $\widehat{\mathbb{P}}(\cdot)$.

Algorithm 1 Spectral algorithm for latent junction tree

In: Junction tree topology and N *i.i.d.* samples $\{x_1^s, \dots, x_{|\mathscr{O}|}^s\}_{s=1}^N$

Out: Estimated marginal $\widehat{\mathbb{P}}(\mathscr{O})$

1: Estimate $\widehat{\boldsymbol{\mathcal{P}}}(C_i)$ for the root, leaf and internal nodes

$$\widehat{\boldsymbol{\mathcal{P}}}(C_r) = \widehat{\mathbb{P}}(\mathscr{O}_{r_1}, \mathscr{O}_{r_2}, \mathscr{O}_{r_3}) \times_{\mathscr{O}_{r_1}} \boldsymbol{\mathcal{U}}_{r_1} \times_{\mathscr{O}_{r_2}} \boldsymbol{\mathcal{U}}_{r_2} \times_{\mathscr{O}_{r_3}} \boldsymbol{\mathcal{U}}_{r_3}$$

$$\widehat{\boldsymbol{\mathcal{P}}}(C_l) = \widehat{\mathbb{P}}(\mathscr{O}_l, \mathscr{O}_{l-}) \times_{\mathscr{O}_{l-}} (\widehat{\mathbb{P}}(\mathscr{O}_l, \mathscr{O}_{l-}) \times_{\mathscr{O}_l} \boldsymbol{\mathcal{U}}_l)^{-1}$$

$$\widehat{\boldsymbol{\mathcal{P}}}(C_i) = \widehat{\mathbb{P}}(\mathscr{O}_{i_1}, \mathscr{O}_{i_2}, \mathscr{O}_{i-}) \times_{\mathscr{O}_{i_1}} \boldsymbol{\mathcal{U}}_{i_1} \times_{\mathscr{O}_{i_2}} \boldsymbol{\mathcal{U}}_{i_2} \times_{\mathscr{O}_{i-}} (\widehat{\mathbb{P}}(\mathscr{O}_i, \mathscr{O}_{i-}) \times_{\mathscr{O}_i} \boldsymbol{\mathcal{U}}_i)^{-1}$$

2: In reverse topological order, leaf and internal nodes send messages

$$\widehat{\boldsymbol{\mathcal{M}}}(S_l) = \widehat{\boldsymbol{\mathcal{P}}}(C_l)_{\mathscr{O}_l = o_l}$$

$$\widehat{\boldsymbol{\mathcal{M}}}(S_i) = \widehat{\boldsymbol{\mathcal{P}}}(C_i) \times_{\mathscr{O}_{i_1}} \widehat{\boldsymbol{\mathcal{M}}}(S_{i_1}) \times_{\mathscr{O}_{i_2}} \widehat{\boldsymbol{\mathcal{M}}}(S_{i_2})$$

3: At the root, obtain $\widehat{\mathbb{P}}(\mathscr{O})$ by

$$\widehat{\boldsymbol{\mathcal{P}}}(C_r) \times_{\mathscr{O}_{r_1}} \widehat{\boldsymbol{\mathcal{M}}}(S_{r_1}) \times_{\mathscr{O}_{r_2}} \widehat{\boldsymbol{\mathcal{M}}}(S_{r_2}) \times_{\mathscr{O}_{r_3}} \widehat{\boldsymbol{\mathcal{M}}}(S_{r_3})$$

[3] If a latent variable in $S_{i_1} \cup S_{i_2}$ is also in S_i, it is not eliminated in this step but in another step.

7 Discussion

The observable representation exists only if there exist tensor inversion pairs $\boldsymbol{\mathcal{F}}_i = \mathbb{P}(\mathscr{O}_i|S_i)$, and $\boldsymbol{\mathcal{F}}_i^{-1}$. This is equivalent to requiring that the rank of the matricized version of $\boldsymbol{\mathcal{F}}_i$ (rows corresponds to modes $\mathscr{O}_i$ and column to modes S_i) has rank $\tau_i := k_h \times |S_i|$. Similarly. the matricized version of $\mathbb{P}(\mathscr{O}_{-i}|S_i)$ also needs to have rank τ_i, so that the matricized version of $\mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-})$ has rank τ_i and is invertible. Thus, it is required that $\#\text{states}(\mathscr{O}_i) \geq \#\text{states}(S_i)$. This can be achieved by either making $\mathscr{O}_i$ consist of a few high dimensional observations, or of many smaller dimensional ones. In the case when $\#\text{states}(\mathscr{O}_i) > \#\text{states}(S_i)$, we need to project $\boldsymbol{\mathcal{F}}_i$ to a lower dimensional space using a tensor $\boldsymbol{\mathcal{U}}_i$ so that it can be inverted. In this case, we define $\boldsymbol{\mathcal{F}}_i := \mathbb{P}(\mathscr{O}_i|S_i) \times_{\mathscr{O}_i} \boldsymbol{\mathcal{U}}_i$. For example, following this through the computation for the leaf gives us that $\widetilde{\boldsymbol{\mathcal{P}}}(C_l) = \mathbb{P}(\mathscr{O}_l, \mathscr{O}_{l-}) \times_{\mathscr{O}_{l-}} (\mathbb{P}(\mathscr{O}_l, \mathscr{O}_{l-}) \times_{\mathscr{O}_l} \boldsymbol{\mathcal{U}}_l)^{-1}$. A good choice of $\boldsymbol{\mathcal{U}}_i$ can be obtained by performing a singular value decomposition of the matricized version of $\mathbb{P}(\mathscr{O}_i, \mathscr{O}_{i-})$ (variables in $\mathscr{O}_i$ are arranged to rows and those in $\mathscr{O}_{i-}$ to columns).

For HMMs and latent trees, this rank condition can be expressed simply as requiring the conditional probability tables of the underlying model to not be rank-deficient. However, junction trees encode more complex latent structures that introduce subtle considerations. A general characterization of the existence condition for observable representation with respect to the graph topology will be our future work. In the appendix, we give some intuition using a couple of examples where observable representations do not exist.

8 Sample Complexity

We analyze the sample complexity of Algorithm 1 and show that it depends on the junction tree topology and the spectral properties of the true model. Let d_i be the order of $\boldsymbol{\mathcal{P}}(C_i)$ and e_i be the number of modes of $\boldsymbol{\mathcal{P}}(C_i)$ that correspond to observed variables.

Theorem 1 *Let $\tau_i = k_h \times |S_i|$, $d_{\max} = \max_i d_i$, and $e_{\max} = \max_i e_i$. Then, for any $\epsilon > 0, 0 < \delta < 1$, if*

$$N \geq O\left(\left(\frac{4k_h^2}{3\beta^2}\right)^{d_{\max}} \frac{k_o^{e_{\max}} \ln \frac{|\mathbb{C}|}{\delta} |\mathbb{C}|^2}{\epsilon^2 \alpha^4}\right)$$

where $\sigma_\tau(*)$ returns the τ^{th} largest singular value and

$$\alpha = \min_i \ \sigma_{\tau_i}(\mathbb{P}(\mathscr{O}_i, \mathscr{O}_{-i})), \quad \beta = \min_i \ \sigma_{\tau_i}(\boldsymbol{\mathcal{F}}_i)$$

Then with probability $1 - \delta$,

$$\sum_{x_1,\ldots,x_{|\mathscr{O}|}} \left|\widehat{\mathbb{P}}(x_1, \ldots, x_{|\mathscr{O}|}) - \mathbb{P}(x_1, \ldots, x_{|\mathscr{O}|})\right| \leq \epsilon \ .$$

See the supplementary for a proof. The result implies that the estimation problem depends exponentially on d_{max} and e_{max}, but note that $e_{max} \leq d_{max}$. Furthermore, d_{max} is always greater than or equal to the treewidth. Note the dependence on the singular values of certain probability tensors. In fully observed models, the accuracy of the learned parameters depends only on how close the empirical estimates of the factors are to the true factors. However, our spectral algorithm also depends on how close the inverses of these empirical estimates are to the true inverses, which depends on the spectral properties of the matrices (Stewart & Sun, 1990).

9 Experiments

We now evaluate our method on synthetic and real data and compare it with both standard EM (Dempster et al., 1977) and stepwise online EM (Liang & Klein, 2009). All methods were implemented in C++, and the matrix library Eigen (Guennebaud et al., 2010) was used for computing SVDs and solving linear systems. For all experiments, standard EM is given 5 random restarts. Online EM tends to be sensitive to the learning rate, so it is given one restart for each of 5 choices of the learning rate $\{0.6, 0.7, 0.8, 0.9, 1\}$ (the one with highest likelihood is selected). Convergence is determined by measuring the change in the log likelihood at iteration t (denoted by $f(t)$) over the average: $\frac{|f(t)-f(t-1)|}{\text{avg}(f(t),f(t-1))} \leq 10^{-4}$ (the same precision as used in Murphy (2005)).

For large sample sizes our method is almost two orders of magnitude faster than both EM and online EM. This is because EM is iterative and every iteration requires inference over all the training examples which can become expensive. On the other hand, the computational cost of our method is dominated by the SVD/linear system. Thus, it is primarily dependent only on the number of observed states and maximum tensor order, and can easily scale to larger sample sizes.

In terms of accuracy, we generally observe 3 distinct regions, low-sample size, mid-sample size, and large sample size. In the low sample size region, EM/online EM tend to overfit to the training data and our spectral algorithm usually performs better. In the mid-sample size region EM/online EM tend to perform better since they benefit from a smaller number of parameters. However, once a certain sample size is reached (the large sample size region), our spectral algorithm consistently outperforms EM/online EM which suffer from local minima and convergence issues.

9.1 Synthetic Evaluation

We first perform a synthetic evaluation. 4 different latent structures are used (see Figure 3): a second order nonhomogenous (NH) HMM, a third order NH HMM, a 2 level NH factorial HMM, and a complicated synthetic junction tree. The second/third order HMMs have $k_h = 2$ and $k_o = 4$, while the factorial HMM and synthetic junction tree have $k_h = 2$, and $k_o = 16$. For each latent structure, we generate 10 sets of model parameters, and then sample N training points and 1000

test points from each set, where N is varied from 100 to 100,000. For evaluation, we measure the accuracy of joint estimation using $error = \frac{|\widehat{\mathbb{P}}(x_1,\ldots,x_O) - \mathbb{P}(x_1,\ldots,x_O)|}{\mathbb{P}(x_1,\ldots,x_O)}$. We also measure the training time of both methods.

Figure 3 shows the results. As discussed earlier, our algorithm is between one and two orders of magnitude faster than both EM and online EM for all the latent structures. EM is actually slower for very small sample sizes than for mid-range sample sizes because of overfitting. Also, in all cases, the spectral algorithm has the lowest error for large sample sizes. Moreover, critical sample size at which spectral overtakes EM/online EM is largely dependent on the number of parameters in the observable representation compared to that in the original parameterization of the model. In higher order/factorial HMM models, this increase is small, while in the synthetic junction tree it is larger.

9.2 Splice dataset

We next consider the task of determining splicing sites in DNA sequences (Asuncion & Newman, 2007). Each example consists of a DNA sequence of length 60, where each position in the sequence is either an A, T, C, or G. The goal is to classify whether the sequence is an Intron/Exon site, Exon/Intron site, or neither. During training, for each class a different second order nonhomogeneous HMM with $k_h = 2$ and $k_o = 4$ is trained. At test, the probability of the test sequence is computed for each model, and the one with the highest probability is selected (which we found to perform better than a homogeneous one).

Figure 4, shows our results, which are consistent with our synthetic evaluation. Spectral performs the best in low sample sizes, while EM/online EM perform a little better in the mid-sample size range. The dataset is not large enough to explore the large sample size regime. Moreover, we note that spectral algorithm is much faster for all the sample sizes.

10 Conclusion

We have developed an alternative parameterization that allows fast, local minima free, and consistent parameter learning of latent junction trees. Our approach generalizes spectral algorithms to a much wider range of structures such as higher order, factorial, and semi-hidden Markov models. Unlike traditional non-convex optimization formulations, spectral algorithms allow us to theoretically explore latent variable models in more depth. The spectral algorithm depends not only on the junction tree topology but also on the spectral properties of the parameters. Thus, two models with the same structure may pose different degrees of difficulty based on the underlying singular values. This is very different from learning fully observed junction trees, which is primarily dependent on only the topology/treewidth. Future directions include learning discriminative models and structure learning.

Abstract

In spectral clustering, one defines a similarity matrix for a collection of data points, transforms the matrix to get the Laplacian matrix, finds the eigenvectors of the Laplacian matrix, and obtains a partition of the data using the leading eigenvectors. The last step is sometimes referred to as *rounding*, where one needs to decide how many leading eigenvectors to use, to determine the number of clusters, and to partition the data points. In this paper, we propose a novel method for rounding. The method differs from previous methods in three ways. First, we relax the assumption that the number of clusters equals the number of eigenvectors used. Second, when deciding the number of leading eigenvectors to use, we not only rely on information contained in the leading eigenvectors themselves, but also use subsequent eigenvectors. Third, our method is model-based and solves all the three subproblems of rounding using a class of graphical models called *latent tree models*. We evaluate our method on both synthetic and real-world data. The results show that our method works correctly in the ideal case where between-clusters similarity is 0, and degrades gracefully as one moves away from the ideal case.

1 Introduction

Clustering is a data analysis task where one assigns similar data points to the same cluster and dissimilar data points to different clusters. There are many different clustering algorithms, amongst which *spectral clustering* [14] is one approach that has gained prominence in recent years. The idea is to convert clustering into a graph cut problem. More specifically, one first builds a *similarity graph* over the data points using data similarity as edge weights and then partitions the graph by cutting some of the edges. Each connected component in the resulting graph is a cluster. The cut is done so as to simultaneously minimize the cost of cut and balance the sizes of the resulting clusters [12]. The graph cut problem is NP-hard and is hence relaxed. The solution is given by the leading eigenvectors of the so-called Laplacian matrix, which is a simple transformation of the original data similarity matrix. In a post-processing step called rounding [2], a partition of the data points is obtained from those real-valued eigenvectors.

In this paper we focus on rounding. In general, rounding is considered an open problem. There are three subproblems: (1) decide which leading eigenvectors to use; (2) determine the number of clusters; and (3) determine the members in each cluster. Previous rounding methods fall into two groups depending on whether they assume the number of clusters is given. When the number of clusters is known to be k, rounding is usually done based on the k leading eigenvectors. The data points are projected onto the subspace spanned by those eigenvectors and then the K-means algorithm is run on that space to get k clusters [14]. Bach and Jordan [2] approximate the subspace using a space spanned by k piecewise constant vectors and then run K-means on the latter space. Zhang and Jordan [19] observe a link between rounding and the orthogonal Procrustes problem and iteratively use an analytical solution for the latter problem to build a method for rounding. Rebagliati and Verri [10] ask the user to provide a number K that is larger than k and obtain k clusters based on the K leading eigenvectors using a randomized algorithm.

When the number of clusters is not given, one needs to estimate it. A common method is to manually examine the difference between every two consecutive eigenvalues starting from the first two. If a big gap appears for the first time between the k-th and $(k+1)$-

th eigenvalues, then one uses k as an estimate of the number of clusters. Zelnik-Manor and Perona [17] propose an automatic method. For a particular integer k, it tries to rotate the k leading eigenvectors so as to align them with the canonical coordinate system for the eigenspace spanned by those vectors. A cost function is defined in terms of how well the alignment can be achieved. The k with the lowest cost is chosen as an estimate for the number of clusters. Xiang and Gong [16] and Zhao et al. [20] relax the assumption that clustering should be based on a continuous block of eigenvectors at the beginning of the eigenvector spectrum. They use heuristics to choose eigenvectors which do not necessarily form a continuous block, and use Gaussian mixture models to determine the clusters. Socher et al. [13] assume the number of leading eigenvectors to use is given. Based on those leading eigenvectors, they determine the number of clusters and the membership of each cluster using a non-parametric Bayesian clustering method.

In this paper, we propose a model-based approach to rounding. The novelty lies in three aspects. First, we relax the assumption that the number of clusters equals the number of eigenvectors used for rounding. While the assumption is reasonable in the *ideal case* where between-cluster similarity is 0, it is not appropriate in non-ideal cases. Our method allows the number of clusters to differ from the number of eigenvectors. Second, we choose a continuous block of leading eigenvectors for rounding just as [17]. The difference is that, when deciding the appropriateness of the k leading eigenvectors, Zelnik-Manor and Perona [17] use only information contained in those eigenvectors, whereas we also use information in subsequent eigenvectors. So our method uses more information and hence the choice is expected to be more robust. Third, we solve all the three subproblems of rounding within one class of models, namely latent tree models [18]. In contrast, most previous methods either assume that the first two subproblems are solved and focus only on the third subproblem, or do not solve all the subproblems within one class of models [17, 20].

The remaining paper is organized as follows. In Section 2 we review the basics of spectral clustering and point out two key properties of the eigenvectors of the Laplacian matrix in the ideal case. In Section 3 we describe a straightforward method for rounding that takes advantage of the two properties. This method is fragile and breaks down as soon as we move away from the ideal case. In Sections 4 and 5 we propose a model-based method that exploits the same two properties. In Section 6 we evaluate the method on both synthetic and real-world data sets and also on real-world image segmentation tasks. The paper concludes in Section 7.

2 Background

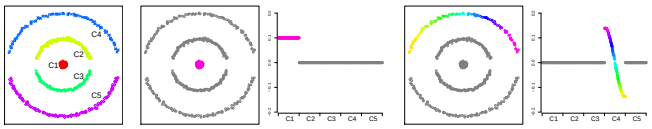
To cluster a set of n data points $X = \{x_1, \ldots, x_n\}$, one starts by defining a non-negative similarity measure s_{ij} for each pair x_i and x_j of data points. In this paper we consider two measures. The *k-NN similarity measure* sets s_{ij} to 1 if x_i is one of the k nearest neighbors of x_j, or vice verse, and 0 otherwise. The *Gaussian similarity measure* sets $s_{ij} = \exp(\frac{-\|x_i - x_j\|^2}{\sigma^2})$, where σ controls the width of neighborhood of each data point. The $n \times n$ matrix $S = [s_{ij}]$ is called the *similarity matrix*. The *similarity graph* is an undirected graph over the data points where the edge is added between x_i and x_j, with weight s_{ij}, if and only if $s_{ij} > 0$.

In spectral clustering, one transforms the similarity matrix to get the *Laplacian matrix*. There are several Laplacian matrices to choose from [14]. We use the *normalized Laplacian matrix* $L_{rw} = I - D^{-1}S$, where I is the identity matrix, and $D = (d_{ij})$ is the diagonal *degree matrix* given by $d_{ii} = \sum_{j=1}^{n} s_{ij}$. Next one computes the eigenvectors of L_{rw} and sorts them in ascending order of their corresponding eigenvalues. Denote those eigenvectors as $e_1, \ldots, e_n$. To obtain k clusters, one forms an $n \times k$ matrix U using the k leading eigenvectors $e_1, \ldots, e_k$ as columns. Each row y_i of U is a point in $\mathbb{R}^k$ and corresponds to an original data point x_i. One partitions the points $\{y_1, \ldots, y_n\}$ into k clusters using the K-means algorithm and obtains k clusters of the original data points accordingly.

Suppose the data consist of k_t true clusters $C_1, \ldots, C_{k_t}$. In the *ideal case*, the similarity graph has k_t connected components, where each of them corresponds to a true cluster. Assume that the data points are ordered based on their cluster memberships. Then the Laplacian matrix L_{rw} has a block diagonal form, with each block corresponding to one true cluster [14]. Moreover, L_{rw} has exactly k_t eigenvalues that equal 0, and the eigenspace of eigenvalue 0 is spanned by the indicator vectors $\vec{1}_{C_1}, \ldots, \vec{1}_{C_{k_t}}$. Create an $n \times k_t$ matrix U_c using those indicator vectors as columns. It is known that, when $k = k_t$, $U = U_c R$ for some orthogonal matrix $R \in \mathbb{R}^{k \times k}$ [8]. For simplicity, assume the non-zero eigenvalues of L_{rw} are distinct. Call those eigenvectors for eigenvalue 0 the *primary eigenvectors* and the others the *secondary eigenvectors*. The facts reviewed in this paragraph imply the following:

Proposition 1. *In the ideal case, eigenvectors of L_{rw} have the following properties:*

1. *The primary eigenvectors are piecewise constant, with each value identifying one true cluster or the union of several true clusters.*
2. *The support (non-zero elements) of each secondary eigenvector is contained by one of the true clusters.*



(a) Data (b) Eigenvector e_1 (c) Eigenvector e_6

Figure 1: Example eigenvectors: There are five true clusters $C_1, \ldots, C_5$ in the data set shown in (a). The 10-NN similarity measure is used to produce the ideal case. Two eigenvectors are shown in (b) and (c). Each eigenvector is depicted in two diagrams. In the first diagram, the values of the eigenvector are indicated by different colors, with grey meaning 0. In the second diagram, the x-axis indexes the data points and the y-axis shows the values of the eigenvector.

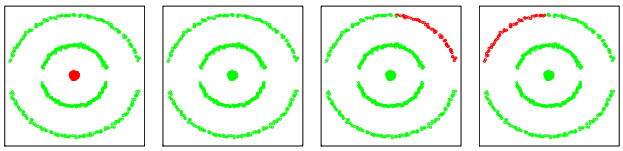
The two properties are illustrated in Fig 1. The primary eigenvector e_1 has two different values, 0.1 and 0. The value 0.1 identifies the cluster C_1, whereas 0 corresponds to the union of the other clusters. The eigenvector e_6 is a secondary eigenvector. Its support is contained by the true cluster C_4.

3 A Naive Method for Rounding

In the original graph cut formulation of spectral clustering [12], an eigenvector has two different values. It partitions the data points into two clusters. In the relaxed problem, an eigenvector can have many different values (see Fig 1(c)). The first step of our method is to obtain, from each eigenvector e_i, two clusters using a confidence parameter δ that is between 0 and 1. Let e_{ij} be the value of e_i at the j-th data point. One of the clusters consists of the data points x_j that satisfy $e_{ij} > 0$ and $e_{ij} > \delta \max_j e_{ij}$, while the other cluster consists of the data points x_j that satisfy $e_{ij} < 0$ and $e_{ij} < \delta \min_j e_{ij}$. The indicator vectors of those two clusters are denoted as e_i^+ and e_i^- respectively. We refer to the process of obtaining e_i^+ and e_i^- from e_i as *binarization*. Applying binarization to the eigenvectors e_1 and e_6 of Fig 1 results in the binary vectors shown in Fig 2. Note that e_1^- is a degenerated binary vector in the sense that it is all 0. We still refer to it as a binary vector for convenience. The following proposition follows readily from Proposition 1.

Proposition 2. *Let e^b be a vector obtained from an eigenvector e of the Laplacian matrix L_{rw} via binarization. In the ideal case:*

1. *If e is a primary eigenvector, then the support of e^b is either a true cluster or the union of several true clusters.*
2. *If e is a secondary eigenvector, then the support of e^b is contained by one of the true clusters.*



(a) e_1^+ (b) e_1^- (c) e_6^+ (d) e_6^-

Figure 2: Binary vectors obtained from eigenvectors e_1 and e_6 through binarization with $\delta = 0.1$. Data points have values 1 (red) or 0 (green).

Each binary vector gives a partition of the data points, with one cluster comprising points with value 1 and another comprising points with value 0. Consider two partitions where one divides the data into two clusters C_1 and C_2 and the other into P_1 and P_2. *Overlaying* the two partitions results in a new partition consisting of clusters $C_1 \cap P_1$, $C_1 \cap P_2$, $C_2 \cap P_1$, and $C_2 \cap P_2$. Note that there are not necessarily exactly 4 clusters in the new partition as some of the 4 intersections might be empty. It is evident how to overlay multiple partitions.

Consider the case when the number q of leading eigenvectors to use is given. Here is a straightforward method for rounding:

NAIVE-ROUNDING1(q)

1. Compute the q leading eigenvectors of L_{rw}.
2. Binarize the q eigenvectors.
3. Obtain a partition of the data using each binary vector from the previous step.
4. Overlay all the partitions to get the final partition.

Note that the number of clusters obtained by NAIVE-ROUNDING1 is determined by q, but it is not necessarily the same as q. The following proposition is an easy corollary of Proposition 2.

Proposition 3. *In the ideal case and when q is smaller than or equal to the number of true clusters, the clusters obtained by* NAIVE-ROUNDING1 *are either true clusters or unions of true clusters.*

Now consider how to determine the number q of leading eigenvectors to use. We do so by making use of Proposition 2. The idea is to gradually increase q in NAIVE-ROUNDING1 and test the partition P_q obtained for each q to see whether it satisfies the condition of Proposition 2 (2).

Suppose K is a sufficiently large integer. Denote a subroutine that tests the partition P_q by `cTest`(P_q, q, K). To perform this test, we use the binary vectors obtained from the eigenvectors from the range $[q+1, K]$. If the support of every such binary vector is contained by some cluster in P_q, we say that P_q satisfies the *containment condition* and `cTest` returns `true`. Oth-

erwise, P_q violates the condition and `cTest` returns `false`.

Let k_t be the number of true clusters. When $q = k_t$, $\texttt{cTest}(P_q, q, K)$ passes because of Proposition 2. When $q = k_t + 1$, P_q is likely to be finer than the true partition. Consequently, $\texttt{cTest}(P_q, q, K)$ may fail. The probability of this happening increases with the number of binary vectors used in the test. To make the probability high, we pick K such that $K/2$ is safely larger than k_t and let q run from 2 to $\lfloor K/2 \rfloor$. When $q < k_t$, $\texttt{cTest}(P_q, q, K)$ usually passes.

The above discussions suggest that if $\texttt{cTest}(P_q, q, K)$, for the first time, passes for some $q = k$ and fails for $q = k + 1$, we can use k as an estimate of k_t. Consequently, we can use the k leading eigenvectors for clustering and return P_k as the final clustering result. This leads to the following algorithm:

NAIVE-ROUNDING2(K)

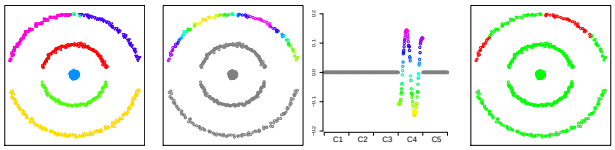
1. For $q = 2$ to $\lfloor K/2 \rfloor$,
   (a) $P \leftarrow$ NAIVE-ROUNDING1(q).
   (b) $P' \leftarrow$ NAIVE-ROUNDING1($q + 1$).
   (c) If $\texttt{cTest}(P, q, K) = \texttt{true}$ and $\texttt{cTest}(P', q + 1, K) = \texttt{false}$, return P.
2. Return P.

Suppose an integer K is given such that $K/2$ is safely larger than the number of true clusters. The algorithm NAIVE-ROUNDING2 automatically decides how many leading eigenvectors to use and automatically determines the number of clusters. Consider running it on the data set shown in Fig 1(a) with $K = 40$. It loops q through 2 to 4 without terminating because both the two tests at Step 1(c) return `true`. When $q = 5$, P is the true partition and P' is shown in Fig 3(a). At Step 1(c), the first test for P passes. However, the second test for P' fails, because the support of the binary vector e_{16}^+ is not contained by any cluster in P' (Fig 3). So, NAIVE-ROUNDING2 terminates at Step 1(c) and returns P (the true partition) as the final result.

4 Latent Class Models for Rounding

NAIVE-ROUNDING2 is fragile. It can break down as soon as we move away from the ideal case. In this and the next section, we describe a model-based method that also exploits Proposition 2 and is more robust.

In the model-based method, the binary vectors are regarded as features and the problem is to cluster the data points based on those features. So what we face is a *problem of clustering discrete data*. As in the previous section, there is a question of how many leading eigenvectors to use. In this section, we assume the number q of leading eigenvectors to use is given. In the next section, we will discuss how to determine q.



(a) 7 clusters (b) e_{16} (c) e_{16}^+

Figure 3: Illustration of NAIVE-ROUNDING2: (a) shows the 7 clusters given by the first 6 pairs of binary vectors. (b) and (c) show eigenvector e_{16} and one of the binary vectors obtained from e_{16}. The support of e_{16}^+ (the red region) is not contained by any of the clusters in (a).

The problem we address in this section is how to cluster the data points based on the first q pairs of binary vectors e_1^+, e_1^-, ..., e_q^+, e_q^-. We solve the problem using latent class models (LCMs) [3]. LCMs are commonly used to cluster discrete data, just as Gaussian mixture models are used to cluster continuous data. Technically they are the same as the Naive Bayes model except that the class variable is not observed.

The LCM for our problem is shown in Fig 4(a). So far we have been using the notations e_s^+ and e_s^- to denote vectors of n elements or functions over the data points. In this and the next sections, we overload the notations to denote random variables that take different values at different data points. The latent variable Y represents the partition to find and each state of Y represents a cluster. So the number of states of Y, often called the *cardinality* of Y, is the number of clusters. To learn an LCM from data means to determine: (1) the cardinality of Y, i.e., the number of clusters; and (2) the probability distributions $P(Y)$, $P(e_s^+|Y)$, and $P(e_s^-|Y)$, i.e., the characterization of the clusters.

After an LCM is learned, one can compute the posterior distribution of Y for each data point. This gives a *soft partition* of the data. To get a *hard partition*, one can assign each data point to the state of Y that has the maximum posterior probability. This is called *hard assignment*.

There are two cases with the LCM learning problem, depending on whether the number of clusters is known. When that number is known, we only need to determine the probability distributions $P(Y)$, $P(e_s^+|Y)$, and $P(e_s^-|Y)$. This is done using the EM algorithm [5].

Proposition 4. *It is possible to set the probability parameter values of the LCM in Fig 4(a) in such a way that it gives the same partition as* NAIVE-ROUDING1. *Moreover, those parameter values maximize the likelihood of the model.*

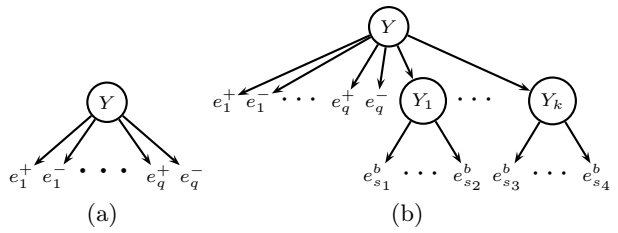


Figure 4: (a) Latent class model and (b) latent tree model for rounding: The binary vectors e_1^+, e_1^-, ..., e_q^+, e_q^- are regarded as random variables. The discrete latent variable Y represents the partition to find.

The proof is omitted due to space limit. It is well known that the EM algorithm aims at finding the maximum likelihood estimate (MLE) of the parameters. So the LCM method for rounding actually tries to find the same partition as NAIVE-ROUNDING1.

Now consider the case when the number of clusters is not known. We determine it using the BIC score [11]. Given a model m, the score is defined as $BIC(m) = \log P(D|m,\theta) - \frac{d}{2}\log n$, where D is the data, θ is the MLE of the parameters, and d is the number of free parameters in the model. We start by setting the number k of clusters to 2 and increase it gradually. We stop the process as soon as the BIC score of the model starts to decrease, and use the k with the maximum BIC score as the estimate of the number of clusters. Note that the number of clusters determined using the BIC score might not be the same as the number of clusters found by NAIVE-ROUNDING1.

5 Latent Tree Models for Rounding

In this section we present a method for determining the number q of leading eigenvectors to use. Consider an integer q between 2 and $K/2$. We first build an LCM using the first q pairs of binary vectors and obtain a hard partition of the data using the LCM. Suppose k clusters C_1, ..., C_k are obtained. Each cluster C_r corresponds to a state r of the latent variable Y.

We extend the LCM model to obtain the model shown in Fig 4(b). We do this in three steps. First, we introduce k new latent variables Y_1, ..., Y_k into the model and connect them to Y. Each Y_r is a binary variable and its conditional distribution is set as follows:

$$P(Y_r = 1|Y = r') = \begin{cases} 1 & \text{if } r' = r, \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

So the state $Y_r = 1$ means the cluster C_r and $Y_r = 0$ means the union of all the other clusters.

Next, we add binary vectors from the range $[q+1, K]$ to the model by connecting them to the new latent variables. For convenience we call those vectors *secondary binary vectors*. This is not to be confused with the secondary eigenvectors mentioned in Proposition 1. For each secondary binary vector e_s^b, let D_s be its support. When determining to which Y_r to connect e_s^b, we consider how well the cluster C_r covers D_s. We connect e_s^b to the Y_r such that C_r covers D_s the best, in the sense that the quantity $|D_s \cap C_r|$ is maximized, where $|.|$ stands for the number of data points in a set. We break ties arbitrarily.

Finally, we set the conditional distribution $P(e_s^b|Y_r)$ as follows:

$$P(e_s^b = 1|Y_r = 1) = \frac{|D_s \cap C_r|}{|C_r|} \quad (2)$$

$$P(e_s^b = 1|Y_r = 0) = \frac{|D_s - C_r|}{n - |C_r|} \quad (3)$$

What we get after the extension is a tree structured probabilistic graphical model, in which the variables at the leaf nodes are observed and the variables at the internal nodes are latent. Such models are known as *latent tree models (LTMs)* [4, 15], sometimes also called hierarchical latent class models [18]. The LCM part of the model is called its *primary part*, while the newly added part is called the *secondary part*. The parameter values for the primary part is determined during LCM learning, while those for the secondary part are set manually by Equations (1–3).

To determine the number q of leading eigenvectors to use, we examine all integers in the range $[2, K/2]$. For each such integer q, we build an LTM as described above and compute its BIC score. We pick the q with the maximum BIC score as the answer. After q is determined, we use the primary part of the LTM to partition the data. In other words, the secondary part is used only to determine q. We call this method *LTM-Rounding*.

Here are the intuitions behind the LTM method. If the support D_s of e_s^b is contained in cluster C_r, it fits the situation to connect e_s^b to Y_r. The model construction no longer fits the data well if D_s is not contained in any of the clusters. The worst case is when two different clusters C_r and $C_{r'}$ cover D_s equally well and better than other clusters. In this case, e_s^b can be either connected to Y_r or to $Y_{r'}$. Different choices here lead to different models. As such, neither choice is 'ideal'. Even when there is only one cluster C_r that covers D_s the best, connecting e_s^b to Y_r is still intuitively not 'perfect' as long as C_r does not cover D_s completely.

So when the support of every secondary binary vector is contained by one of the clusters C_1, ..., C_k, the

LTM we build would fit the data well. However, when the supports of some secondary binary vectors are not completely covered by any of the clusters, the LTM would not fit the data well. In the ideal case, the fit would be good if q is the number k_t of eigenvectors for eigenvalue 0 according to Proposition 2. The fit would not be as good otherwise. This is why the likelihood of the LTM contains information that can be used to choose q.

We now summarize the LTM method for rounding:

LTM-ROUNDING(K,δ)

1. Compute the K leading eigenvectors of L_{rw}.
2. Binarize the eigenvectors with confidence parameter δ as in Section 3.
3. $S^* \leftarrow -\infty$.
4. For $q = 2$ to $\lfloor K/2 \rfloor$,
   (a) $m_{lcm} \leftarrow$ the LCM learnt using the first q pairs of binary vectors as shown in Section 4.
   (b) $P \leftarrow$ hard partition obtained using m_{lcm}.
   (c) $m_{ltm} \leftarrow$ the LTM extended from m_{lcm} as explained in Section 5.
   (d) $S \leftarrow$ the BIC score of m_{ltm}.
   (e) If $S > S^*$, then $P^* \leftarrow P$ and $S^* \leftarrow S$.
5. Return P^*.

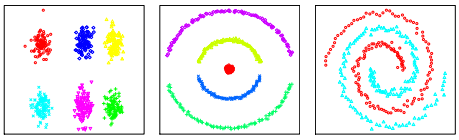
An implementation of LTM-ROUNDING can be obtained from `http://www.cse.ust.hk/~lzhang/ltm/index.htm`.

The choice of K should be such that $K/2$ is safely larger than the number of true clusters. We do not allow q to be larger than $K/2$, so that there is sufficient information in the secondary part of the LTM to determine the appropriateness of using the q leading eigenvectors for rounding. The parameter δ should be picked from the range $(0, 1)$. We recommend to set δ at 0.1. The sensitivity of LTM-ROUNDING with respect to those parameters will be investigated in Section 6.3.

6 Empirical Evaluations

Our empirical investigations are designed to: (1) show that LTM-ROUNDING works perfectly in the ideal case and its performance degrades gracefully as we move away from the ideal case, and (2) compare LTM-ROUNDING with alternative methods. Synthetic data are used for the first purpose, while both synthetic and real-world data are used for the second purpose.

LTM-ROUNDING has two parameters δ and K. We set $\delta = 0.1$ and $K = 40$ in all our experiments except in sensitivity analysis (Section 6.3). For each set of synthetic data, 10 repetitions were run.



(a) 6 clusters (b) 5 clusters (c) 2 clusters

Figure 5: Synthetic data set for the ideal case. Each color and shape of the data points identifies a cluster. Clusters were recovered by LTM-ROUNDING correctly.

6.1 Performance in the Ideal Case

Three data sets were used for the ideal case (Fig 5). They vary in the number and the shape of clusters. Intuitively the first data set is the easiest, while the third one is the hardest. To produce the ideal case, we used the 10-NN similarity measure for the first two data sets. For the third one, the same measure gave a similarity graph with one single connected component. So we used the 3-NN similarity measure instead.

LTM-ROUNDING produced the same results on all 10 runs. The results are shown in Fig 5 using colors and shapes of data points. Each color identifies a cluster. LTM-ROUNDING correctly determined the numbers of clusters and recovered the true clusters perfectly.

6.2 Graceful Degrading of Performance

To demonstrate that the performance of LTM-ROUNDING degrades gracefully as we move away from the ideal case, we generated 8 new data sets by adding different levels of noise to the second data set in Fig 5. The Gaussian similarity measure was adopted with $\sigma = 0.2$. So the similarity graphs for all the data sets are complete.

We evaluated the quality of an obtained partition by comparing it with the true partition using Rand index (RI) [9] and variation of information (VI) [7]. Note that higher RI values indicate better performance, while the opposite is true for VI. The performance statistics of LTM-ROUNDING are shown in Table 1. We see that RI is 1 for the first three data sets. This means that the true clusters have been perfectly recovered. The index starts to drop from the 4th data set onwards in general. It falls gracefully with the increase in the level of noise in data. Similar trend can also be observed on VI.

The partitions produced by LTM-ROUNDING at the best run (in terms of BIC score) are shown in Fig 7(a) using colors and shapes of the data points. We see that on the first four data sets, LTM-ROUNDING correctly determined the number of clusters and the members of each cluster. On the next three data sets, it also

Table 1: Performances of various methods on the 8 synthetic data sets in terms of Rand index (RI) and variation of information (VI). Higher values of RI or lower values of VI indicate better performance. K-MEANS and GMM require extra information for rounding and should not be compared with the other two methods directly.

	Data	1	2	3	4	5	6	7	8
RI	LTM	**1.0±.00**	**1.0±.00**	**1.0±.00**	**.99±.01**	**.97±.02**	**.98±.01**	**.94±.01**	.88±.01
	ROT	.92±.00	.92±.00	**1.0±.00**	.98±.00	.52±.00	.52±.00	.88±.00	**.90±.00**
	K-MEANS	1.0±.00	1.0±.00	1.0±.00	1.0±.00	.85±.00	.72±.00	.71±.00	.75±.00
	GMM	1.0±.00	1.0±.00	1.0±.00	1.0±.00	.94±.00	.88±.00	.91±.00	.88±.00
VI	LTM	**.00±.00**	**.00±.00**	**.00±.00**	**.06±.09**	**.29±.19**	**.28±.14**	**.79±.12**	1.64±.10

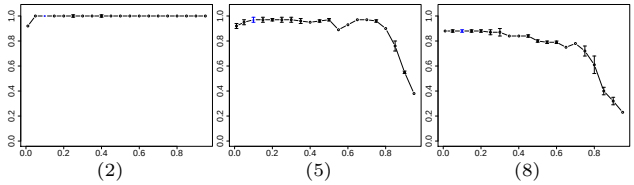
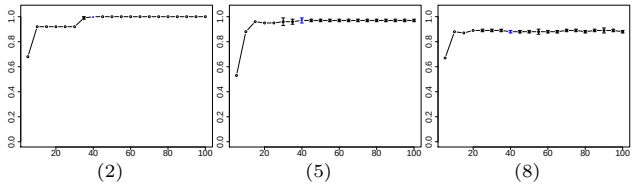
	K-MEANS	.00±.00	.00±.00	.00±.00	.00±.00	1.04±.00	1.41±.00	1.52±.00	1.97±.00
	GMM	.00±.00	.00±.00	.00±.00	.00±.00	.85±.00	.91±.00	1.25±.00	1.74±.00

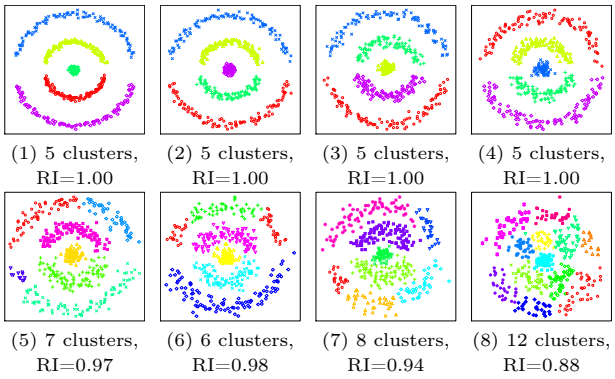


(a) $K = 40$ with varying δ (x-axis)

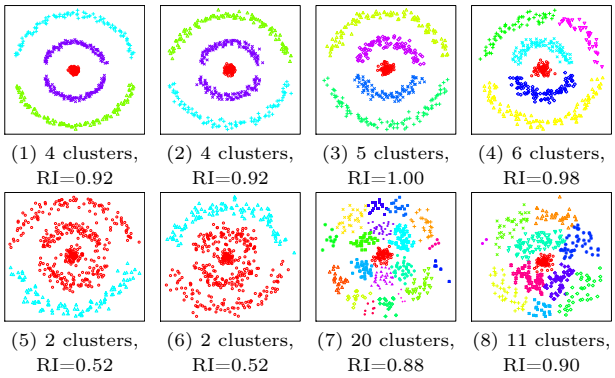


(b) $\delta = 0.1$ with varying K (x-axis)

Figure 6: Sensitivity analysis on parameters δ and K in LTM-ROUNDING. The y-axis denotes Rand index. We recommend $\delta = 0.1$ and $K = 40$ in general.



(a) Partitions produced by LTM-ROUNDING



(b) Partitions produced by ROT-ROUNDING

Figure 7: The 8 synthetic data sets.

correctly recovered the true clusters except that the top and the bottom crescent clusters might have been broken into two or three parts. Given the gaps between the different parts, the results are probably the best one can hope for. The result on the last data set is less ideal but still reasonable.

Putting together, the above discussions indicate that the performance of LTM-ROUNDING degrades gracefully as we move away from the ideal case.

6.3 Sensitivity Analysis

We now study the sensitivity of the parameters δ and K in LTM-ROUNDING. Experiments were conducted on the 2nd, 5th, and 8th data sets in Fig 7. Those data sets contain different levels of noise and hence are at different distances from the ideal case.

To determine the sensitivity of LTM-ROUNDING with respect to δ, we fix $K = 40$ and let δ vary between 0.01 and 0.95. The RI statistics are shown in Fig 6(a). We see that on data set (2) the performance of LTM-ROUNDING is insensitive to δ except when $\delta = 0.01$. On data set (5), the performance of LTM-ROUNDING is more or less robust when $0.1 \leq \delta \leq 0.3$. Its performance gets particularly worse when $\delta \geq 0.8$. Similar behavior can be observed on data set (8). Those results suggest that the performance of LTM-ROUNDING is robust with respect to δ in situations close to the ideal case and it becomes sensitive in situations that are far away from the ideal case. In general, we recommend $\delta = 0.1$.

To determine the sensitivity of LTM-ROUNDING with respect to K, we fix $\delta = 0.1$ and let K vary between 5 and 100. The RI statistics are shown in Fig 6(b). It is clear that the performance of LTM-ROUNDING is

robust with respect to K as long as it is not too small.

6.4 Running Time

LTM-ROUNDING deals with tree-structured models. It is deterministic everywhere except at Step 4(a), where the EM algorithm is called to estimate the parameters of LCM. EM is an iterative algorithm and is computationally expensive in general. However, it is efficient on LCMs. So the running time of LTM-ROUNDING is relatively short. To process one of the data sets in Fig 7, it took around 10 minutes on a laptop computer.

6.5 Alternative Methods for Rounding

To compare with LTM-ROUNDING, we included the method by Zelnik-Manor and Perona [17] in our experiments. The latter method determines the appropriateness of using the q leading eigenvectors by checking how well they can be aligned with the canonical coordinates through rotation. So we name it ROT-ROUNDING. Both LTM-ROUNDING and ROT-ROUNDING can determine the number q of eigenvectors and the number k of clusters automatically. Therefore, they are directly comparable. The method by Xiang and Gong [16] is also related to our work. However, its implementation is not available to us and hence it is excluded from comparison.

K-MEANS and GMM can also be used for rounding. However, both methods cannot determine q, and K-MEANS cannot even determine k. We therefore gave the number k_t of true clusters for K-MEANS and used $q = k_t$ for both methods. Since the two methods required additional information, they are included in our experiments only for reference. They should not be compared with LTM-ROUNDING directly.

ROT-ROUNDING and GMM require the maximum allowable number of clusters. We set that number to 20.

6.6 Comparison on Synthetic Data

Table 1 shows the performance statistics of the three other methods on the 8 synthetic data sets. LTM-ROUNDING performed better than ROT-ROUNDING on all but two data sets. The differences were substantial on 5 of those data sets.

The partitions produced by ROT-ROUNDING at one run are shown in Fig 7(b).[1] We see that on the first two data sets, ROT-ROUNDING underestimated the number of clusters and merged the two smaller crescent clusters. This is serious under-performance given the easiness of those data sets. On the 3rd data set, it recovered the true clusters correctly. On the 4th data set, it broke the top crescent cluster into two. On the 5th data set, it recovered the bottom cluster correctly but merged all the other clusters incorrectly. This leads to a much lower RI. The story on the 6th data set is similar. On the 7th data set, it produced many more clusters than the number of true clusters. Therefore, its RI is also lower. On the last data set, the clustering obtained by ROT-ROUNDING is not visually better than the one produced by LTM-ROUNDING, even though RI suggests otherwise. Given all the evidence presented, we conclude that the performance of LTM-ROUNDING is significantly better than that of ROT-ROUNDING.

[1]Same results were obtained for all 10 repetitions.

Table 2: Comparison on MNIST digits data.

Method	#clusters	RI	VI
LTM	**9.3±.82**	.91±.00	**2.17±.07**
ROT	19.0±.00	**.92±.00**	2.40±.00
K-MEANS	(10)	.90±.00	1.83±.00
GMM	16.0±.00	.91±.00	2.14±.00
SD-CRP	9.3±.96	.89±.00	2.72±.08

Like LTM-ROUNDING, both K-MEANS and GMM recovered clusterings correctly on the first three data sets (Table 1). They performed slightly better than LTM-ROUNDING on the 4th data set. However, their performances were considerably worse on the next three data sets. They were also worse on the last one in terms of VI. It happened even though K-MEANS and GMM were given additional information for rounding. This shows the superior performance of LTM-ROUNDING.

6.7 MNIST Digits Data

In the next two experiments, we used real-world data to compare the rounding methods. The MNIST digits data were used in this subsection. The data consist of 1000 samples of handwritten digits from 0 to 9. They were preprocessed by the deep belief network as described in [6] using their accompanying code.[2] Table 2 shows the results averaged over 10 runs.

We see that the number of clusters estimated by LTM-ROUNDING is close to the ground truth (10), but that by ROT-ROUNDING is considerably larger than 10. In terms of quality of clusterings, the results are inconclusive. RI suggests that ROT-ROUNDING performed slightly better, but VI suggests that LTM-ROUNDING performed significantly better.

Compared with LTM-ROUNDING, K-MEANS obtained

[2]We thank Richard Socher for sharing the preprocessed data with us. The original data can be found at `http://yann.lecun.com/exdb/mnist/`.

a better clustering (in terms of VI), whereas GMM obtained one with similar quality. However, K-MEANS was given the number of true clusters and GMM the number of eigenvectors. GMM also overestimated the number of clusters even with the extra information.

A non-parametric Bayesian clustering method, called SD-CRP, has recently been proposed for rounding [13]. Although we obtained the same data from their authors, we could not get a working implementation for their method. Therefore, we simply copied their reported performance to Table 2. Note that SD-CPR can determine the number clusters automatically. However, it requires the number of eigenvectors as input, and the number was set to 10 in this experiment. Hence, SD-CPR requires more information than LTM-ROUNDING. Table 2 shows that it estimated a similar number of clusters as LTM-ROUNDING. However, its clustering was significantly worse in terms of RI or VI. This shows that LTM-ROUNDING performed better than SD-CPR even with less given information.

6.8 Image Segmentation

The last part of our empirical evaluation was conducted on real-world image segmentation tasks. Five images from the Berkeley Segmentation Data Set (BSDS500) were used. They are shown in the first column of Fig 8. The similarity matrices were built using the method proposed by Arbeláez et al. [1].

The segmentation results obtained by ROT-ROUNDING and LTM-ROUNDING are shown in the second and third columns of Fig 8 respectively. On the first two images, ROT-ROUNDING did not identify any meaningful segments. In contrast, LTM-ROUNDING identified the polar bear and detected the boundaries of the river on the first image. It identified the bottle, the glass and a lobster on the second image.

An obvious undesirable aspect of the results is that some uniform regions are broken up. Examples include the river bank and the river itself in the first image, and the background and the table in the second image. This is a known problem of spectral clustering when applied to image segmentation and can be dealt with using image analysis techniques [1]. We do not deal with the problem in this paper.

On the third image the performance of LTM-ROUNDING was better because the lizard was identified and the segmentation lines follow leaf edges more closely. On the fourth image LTM-ROUNDING did a better job at detecting the edges around the lady's hands and skirt and on the left end of the silk scarf. However, ROT-ROUNDING did a better job at the last image because it produced a cleaner segmentation.

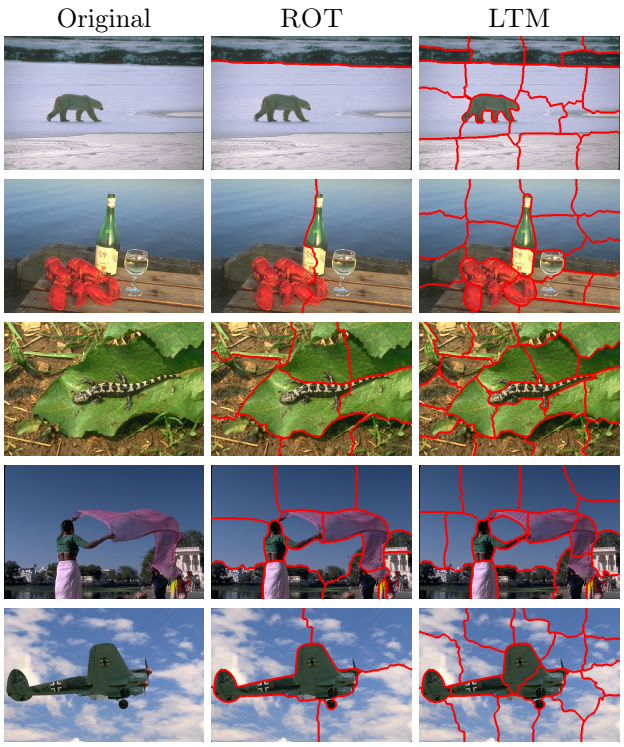


Figure 8: Image segmentation results.

Overall, the performance of LTM-ROUNDING was better than that of ROT-ROUNDING. The objective of this section has been to compare LTM-ROUNDING and ROT-ROUNDING on the same collection of eigenvectors. The conclusion is meaningful even if the final segmentation results are not as good as the best that can be achieved by image analysis techniques.

7 Conclusion

Rounding is an important step of spectral clustering that has not received sufficient attention. Not many papers have been published on the topic, especially on the issues of determining the number of leading eigenvectors to use. In this paper, we have proposed a novel method for the task. The method is based on latent tree models. It can automatically select an appropriate number of eigenvectors to use, determine the number of clusters, and finally assign data points to clusters. We have shown that the method works correctly in the ideal case and its performance degrades gracefully as we move away from the ideal case.

Abstract

We consider the problem of selecting a subset of alternatives given noisy evaluations of the relative strength of different alternatives. We wish to select a k-subset (for a given k) that provides a maximum likelihood estimate for one of several objectives, e.g., containing the strongest alternative. Although this problem is $\mathcal{NP}$-hard, we show that when the noise level is sufficiently high, intuitive methods provide the optimal solution. We thus generalize classical results about singling out one alternative and identifying the hidden ranking of alternatives by strength. Extensive experiments show that our methods perform well in practical settings.

1 Introduction

The initial motivation for this paper stemmed from discussions with the inventors of EteRNA (http://eterna.cmu.edu). Similarly to Foldit [9], EteRNA is a scientific discovery game where the goal is to design RNA molecules that fold into stable structures. Thousands of human players propose RNA designs weekly, but only a relatively small number k of them can be synthesized in a laboratory to discover whether they actually fold well. To choose k designs to synthesize, players vote over the proposed designs using a voting rule known as *k-approval*: each player reports up to k favorite designs, each of which is awarded one point. The k designs that receive the most points are synthesized, and the best design is identified.

The aggregation of opinions via k-approval has several shortcomings. For example, players typically do not consider all proposed designs, and in particular designs that receive votes early in the voting process gain visibility and therefore usually accumulate more votes, leading to a snowball effect. One alternative is to elicit players' opinions about pairs of designs, making sure that each proposed design is compared with at least several others. Regardless of how players' opinions are elicited, one would need to answer the question: *what is our objective in aggregating opinions?* For EteRNA, the answer is simple; since biochemists are seeking a stable design for a specific molecule, but will only use a single proposed design, we would like to select a set of k designs that includes at least one great design. Including one great design is sufficient, as it will be singled out when the k selected designs are synthesized.

Of course, this setup is not confined to the realm of human computation; it also arises naturally, for example, in the process of *new product development (NPD)*. A product can have many different potential designs. A k-subset of these designs is selected based on a market survey, and (possibly costly) prototypes are manufactured for the selected designs. The prototypes are then evaluated by a focus group that definitively singles out the best design. Again, the goal is to include at least one great design among the prototypes that are evaluated.

A natural approach views elicited opinions over alternatives (designs, in the examples) as noisy estimates of a true, hidden ranking of the alternatives in terms of quality. Given such a noise model, the examples presented above call for the selection of the subset of alternatives that is most likely to contain the top alternative of the true ranking, that is, the truly strongest alternative. However, other settings may require the selection of a subset of alternatives that is most likely to possess a different property. In this paper we study this maximum likelihood estimation (MLE) framework under several objectives and noise models.

1.1 Our model and results

Our model consists of two components: the noise model and the objective function. We are interested

in two basic noise models (see, e.g, [4]) that govern how the dataset is obtained given a hidden true ranking. The first model—the *noisy comparisons* model—corresponds to independent evaluations of pairs of alternatives, where each evaluation is consistent with the true ranking with a fixed probability $p \in (1/2, 1)$. For the second model—the *noisy orders* model (also known as the *Mallows* model [14])—we imagine voters submitting complete rankings over the alternatives. The probability of observing a ranking is exponentially small in its Kendall Tau distance to the true ranking, i.e., the number of pairs of alternatives on which the two rankings disagree. The second model is consistent with EteRNA's current voting method, where in theory players are expected to consider all designs, but it is much more natural when the number of alternatives (e.g., product designs) is small. Our positive results hold with respect to a general noise model—the *noisy choice model*—that includes both basic models as special cases.

For the second component, we focus on three objective functions. Objective 1 is the one discussed above: select a subset that maximizes the probability of including the top alternative of the true ranking. Objective 2 aims to select a k-subset of alternatives that coincides with the top k alternatives of the true ranking; this objective is natural, for example, when choosing a team of workers to carry out a task that requires multiple workers with identical skills (here the alternatives are the workers). Objective 3 seeks to select an ordered tuple of alternatives of length k that maximizes the probability of coinciding with the k-prefix of the true ranking. In other words, we are trying to single out the k top alternatives as before, but in the correct order; this objective is closely aligned with web search applications. Note that the three objectives coincide when $k = 1$. We consider Objective 1 to be the most natural and important among the three, and indeed our exposition concentrates on this objective.

We prove that computing the optimal solution under all three objectives is $\mathcal{NP}$-hard for any nontrivial value of k (for Objectives 1 and 2, the case of $k = m$, where m is the number of alternatives, is trivial). However, our analytical results indicate that the optimal solutions for special cases correspond to intuitive (and sometimes tractable) methods. In particular, our analytical results focus on the case where the level of noise is very high. There are two compelling reasons for considering such noisy settings. First, if the level of noise is not very high, any reasonable method would be able to single out the true ranking with relatively little data and high confidence, and therefore maximizing our objectives becomes a nonissue. Second, as we discuss below, our experiments clearly indicate that methods that perform well in theory with respect to a very high noise level also perform well in practice.

For Objective 1, we introduce the *extended scoring method* to single out a k-subset of alternatives. We prove that under the noisy choice model, when the noise level is sufficiently high, any optimal solution is in the solution space provided by the extended scoring method.[1] Interestingly, under noisy orders the extended scoring method reduces to a well-known voting rule (which maps a vector of rankings submitted by voters to a selected alternative) called *Borda count*, and its special case for noisy comparisons also provides a highly intuitive and tractable method. To our surprise, it turns out that the extended scoring method also yields the optimal solution for Objective 2 when the noise level is sufficiently high.

For Objective 3 we present the *scored tuples* method, and prove that it gives the optimal solution when the noise level is high. Interestingly, under the noisy orders model, this method coincides with Borda count when $k = 1$, and with another famous rule known as the *Kemeny* rule when $k = m$. Intermediate values of k give a sequence of optimal voting rules that connects Borda count with Kemeny; we believe that this insight is of independent interest to social choice theory.

Finally, we conduct extensive experiments that compare the extended scoring method (for Objectives 1 and 2) and the scored tuples method (for Objective 3) with other methods. Our experiments indicate that the proposed methods, which are theoretically optimal under high noise, also outperform other methods under practical noise levels. Moreover, in cases where we are able to compute the MLE (i.e., the optimal solution), its performance and that of the proposed methods are almost indistinguishable.

1.2 Related work

Young [18] studied maximum likelihood estimators under (a variation of) the noisy orders model and two objectives: identifying the top alternative of the true ranking (which coincides with our objectives for $k = 1$), and identifying the MLE ranking. In fact, Young's paper is based on work done by the marquis de Condorcet roughly two centuries earlier [10]. Young found that when the noise level is sufficiently high, the winner according to Borda count is the MLE for the top alternative, and regardless of the noise level the Kemeny rule is an MLE for the true ranking. Our main results for Objectives 1 and 2 generalize Young's results for Borda count by extending them to a more powerful noise model and (more importantly) to dif-

[1] Subtleties with respect to tie breaking are discussed in detail in Section 3.

ferent values of k. Our result for Objective 3 connects Young's results for Borda ($k = 1$) and Kemeny ($k = m$) via a sequence of optimal voting rules for intermediate values of k, while again generalizing the noise model.

A series of relatively recent AI papers deal with voting rules as MLEs (see, e.g., [6, 8, 17, 16]). In particular, in a UAI 2005 paper, Conitzer and Sandholm [6] reverse Young's question by asking for which common voting rules there exist (constrained) noise models such that the voting rules are MLEs for the top alternative or the true ranking. One section of the paper of Xia and Conitzer [16] studies a setting where a set of alternatives must be selected, under a noise model that is different from ours, where there is a set of winners of size k but no underlying ranking. They provide a single result for this setting: an evaluation problem that is related to identifying the set of winners is $\mathcal{NP}$-hard.

Under standard noise models such as noisy orders and noisy comparisons, computing the MLE true ranking is also $\mathcal{NP}$-hard [3, 5], but there is a significant amount of work on this problem (see, e.g., [1, 2, 7, 12, 4]). For example, Braverman and Mossel [4] provide polynomial time algorithms that compute the MLE ranking with high probability. However, we see below that selecting the top k elements of the MLE ranking is not the optimal solution to our objectives (with the obvious exception of Objective 3 for $k = m$) and moreover our experiments show that this method provides poor performance with respect to our objectives in practice.

2 The Model

We denote $[k] = \{1, \ldots, k\}$. In addition, let $\arg\max^k_{s \in S} H(s)$ be the set of k-subsets of S (let $|S| = t$) with largest values under the given function H. In other words, for each order $(s_1, \ldots, s_t)$ of the elements of S such that $H(s_i) \geq H(s_{i+1})$ for all $i \in [t-1]$, $\arg\max^k_{s \in S} H(s)$ includes the set $\{s_1, \ldots, s_k\}$.

We consider a set of alternatives A; denote $|A| = m$. We will use small letters to denote specific alternatives. Let $L(A)$ be the set of permutations (which we think of as linear orders or rankings) on A, where each permutation is a bijection $\sigma : A \to \{1, 2, \ldots, m\}$. Hence, $\sigma(a)$ denotes the position of alternative a in σ, and $\sigma^{-1}(i)$ denotes the alternative at the ith position, i.e., the ith most preferred alternative when σ is viewed as a ranking over the alternatives. In particular, $\sigma(a) < \sigma(b)$ denotes that a is preferred to b under σ. We let $\sigma^{-1}([k]) = (\sigma^{-1}(1), \ldots, \sigma^{-1}(k))$ denote the ordered tuple consisting of the k-prefix of σ.

We assume that there exists a true hidden order $\sigma^* \in L(A)$ over the alternatives, which reflects their true strengths. We also make the standard assumption that σ^* is selected using a uniform prior over $L(A)$. Let $a^* = (\sigma^*)^{-1}(1)$ denote the best alternative under σ^*.

Our objective is to find a "good" set of alternatives given noisy observations. We consider two standard noise models (see, e.g., [4]).

2.1 Noisy comparisons and tournaments

In the *noisy comparisons* model, a pairwise preference $a \succ b$ denotes that alternative a is preferred to alternative b. We imagine that each pair of alternatives is presented to n voters (with possibly different sets of voters for each pair). The preferences returned by the voters are independently consistent with the true ranking σ^* with a fixed probability $1/2 < p < 1$. Hence, the dataset D is a set of comparisons where each pair of alternatives appears exactly n times, for a fixed value of n. Note that the case of $n = 1$ with relatively high value of p can also represent the aggregate opinion of many voters.

We think of the dataset D as corresponding to a slightly nonstandard *weighted tournament*. Denote by n_{ab} the number of $a \succ b$ votes. The tournament T_D is a directed graph where the vertex set is the set of alternatives, there are edges between each pair of alternatives in both directions, and the weight of the edge $e = (a, b)$ is $w_e = n_{ab}$.[2]

2.2 Noisy orders and ranked voting

In our second model, a fixed set of n voters provide rankings over all alternatives. In this *noisy orders model* (also known as the *Condorcet noise model [10]*), each ranking is generated independently by drawing pairwise preferences similarly to the noisy comparisons model, except that the process is restarted if the generated vote has a cycle (e.g. $a \succ b \succ c \succ a$). Concisely, the probability of drawing each ranking σ_i given the true order $\sigma^* = \sigma$ is proportional to $p^{\binom{m}{2} - d_K(\sigma_i, \sigma)} \cdot (1-p)^{d_K(\sigma_i, \sigma)}$. The distance $d_K(\cdot, \cdot)$ is the *Kendall tau* distance between two rankings, which counts their number of disagreements on pairs of alternatives. Probabilities are normalized using a normalization constant which can be shown to be independent of the true ranking σ^* (see, e.g., [13]). Note that this model is equivalent to the *Mallows* model [14], which is widely used in machine learning and statistics.

A *voting rule* (also known as a *social choice function*) is a function $f : L(A)^n \to A$ that accepts n rankings $(\sigma_1, \sigma_2, \cdots, \sigma_n) \in L(A)^n$ as input and outputs a selected alternative. We will informally use the same

[2] Typically tournaments have exactly one directed edge between each pair of vertices.

term to refer to functions that output a ranking of the alternative, i.e., an element of $L(A)$; such functions are also known as *social welfare functions*.

Below we consider a number of well-known voting rules; we begin with two that will play a special role. Under *Borda count* each voter i awards $m - \sigma_i(a)$ points to each alternative $a \in A$, and an alternative with most points overall is selected. The *Kemeny* rule selects a ranking $\pi \in L(A)$ that minimizes $\sum_{i=1}^{n} d_K(\pi, \sigma_i)$. Informally, the Kemeny ranking minimizes the number of disagreements with voters over pairs of alternatives.

In Section 6 we consider some additional voting rules as benchmarks. Under *Maximin*, the score of an alternative a is $\min_{a' \in A \setminus \{a\}} |\{i \in [n] : \sigma_i(a) < \sigma_i(a')\}|$. Under *plurality*, each voter i awards one point to $\sigma_i^{-1}(1)$, and under *k-approval*, one point to each of $\sigma_i^{-1}(1), \ldots, \sigma_i^{-1}(k)$.

2.3 A generalization: The noisy choice model

We next present the *noisy choice model*, a general framework that unifies both models; to the best of our knowledge this model is novel. The model is characterized by two properties. First, a notion of n_{ab} for all alternatives $a \in A$ and $b \in A \setminus \{b\}$ that denotes the degree to which a is preferred over b in the input. For a fixed n and all $a \in A$ and $b \in A \setminus \{a\}$, $n_{ab} + n_{ba} = n$.

Second, a likelihood of a dataset D given that the true order is $\sigma^* = \sigma$,

$$\Pr[D|\sigma^* = \sigma] = \frac{\gamma^{d(\sigma,D)}}{Z_\gamma}, \tag{1}$$

where the normalizing constant Z_γ is independent of σ (although it might depend on the parameters of the model), and the distance function is defined as $d(\sigma, D) = \sum_{a,b \in A:\, \sigma(a) < \sigma(b)} n_{ba}$. The distance intuitively measures the amount of disagreement between the ranking and the dataset on pairs of alternatives. Crucially, the likelihood of the dataset diminishes exponentially as its distance from the true order increases.

The noisy comparisons model and noisy orders model both fall under this more general framework. Indeed, the notion of n_{ab} is clear in both models: it is simply the number of votes that prefer a to b. It is also easy to verify that $\gamma = (1-p)/p$ for both models.

In addition to noisy comparisons and noisy orders, the noisy choice model can capture other practical models of inputs. For example, consider the model where inputs are noisy partial orders of a fixed length l generated as follows. For each voter, l alternatives are chosen uniformly at random from the set of all alternatives. Then a partial order is generated according to the Mallows Model over the chosen l alternatives. Alternatively, we can consider a model where each voter reports an unweighted tournament over the alternatives, i.e., individual preferences may be "irrational".

Note that γ is a measure of the level of noise; $\gamma \approx 0$ induces a distribution that is highly centered around the true order and $\gamma \approx 1$ induces a distribution that is close to the uniform distribution. We also remark that the distance function $d(\cdot, \cdot)$ under the noisy orders model is just the sum of Kendall tau distances of a particular ranking from the input orders.

3 Including the Top Alternative

We first consider the case where we want to select a k-subset of alternatives that is most likely to contain a^*, the top alternative of the true ranking σ^*.

Objective 1 *Given k, find a k-subset of alternatives that maximizes the probability of containing the best alternative, i.e., a subset in*

$$\arg\max_{S \subseteq A,\, |S|=k} \Pr[a^* \in S|D].$$

A crucial observation regarding Objective 1 is that

$$\Pr[a^* \in S|D] = \sum_{a \in S} \Pr[a^* = a|D] \propto \sum_{a \in S} \Pr[D|a^* = a],$$

where the last step follows from Bayes' rule and the assumption of uniform prior over rankings. The following observation is immediately implied.

Observation 3.1 *The optimal solution to Objective 1 under the noisy choice model is any subset in*

$$\arg\max^k_{a \in A} \Pr[a^* = a|D].$$

In words, we choose the k most likely alternatives according to their probabilities of coinciding with the top alternative of the true ranking. Equivalently, one could select any subset in $\arg\max^k_{a \in A} \Pr[D|a^* = a]$ since we have assumed a uniform prior over rankings. Despite Observation 3.1, finding an optimal solution to Objective 1 is computationally hard.

Theorem 3.2 *For any $k \in [m-1]$, computing an optimal solution to Objective 1 is $\mathcal{NP}$-hard under noisy orders and noisy comparisons.*

The theorem's proof appears in the full version of the paper.[3] Note that the theorem also proves $\mathcal{NP}$-hardness under the noisy choice model because noisy

[3]The full version of the paper is available from: `http://www.cs.cmu.edu/~arielpro/papers.html`.

orders and noisy comparisons are just special cases. The intuition behind the proof is as follows. Young [18] demonstrated (via an example) that when p close to 1, under a specific noise model that is very similar to the noisy comparisons model, the optimal solution with respect to Objective 1 with $k = 1$ coincides with the first element of an MLE of the true ranking σ^*. We show that this result holds under both noisy comparisons and noisy orders and also prove that computing the first element of an MLE ranking is $\mathcal{NP}$-hard by utilizing the $\mathcal{NP}$-hardness of computing the MLE ranking itself. Here, an MLE ranking is a minimum feedback ranking under noisy comparisons (see, e.g., [4]), and a Kemeny ranking under noisy orders [18], which are both $\mathcal{NP}$-hard to compute [5, 3]. Finally, we leverage the case of $k = 1$ to extend the $\mathcal{NP}$-hardness to other values of k.

Because of these computational connections, it is natural to wonder whether the optimal solution to Objective 1 is given by taking the top k elements of the MLE ranking for any k and any value of p. However, Young [18] also showed that this is not the case when p is close to 1/2 even for $k = 1$ (in fact he did not consider the case of $k > 1$). Indeed, he showed that when p is close to 1/2, in his example the MLE ranking σ is the only ranking that puts the alternative $\sigma(1)$ first and has significant probability, whereas a different alternative (the winner under Borda count) appears first in rankings that individually have smaller probability than the MLE ranking, but combined have a larger overall probability. Below we extend this result by showing that when p is sufficiently close to 1/2, the problem is indeed tractable for any value of k under our general noisy choice model, and in fact the solution coincides with intuitive methods. Although the theoretical guarantees are for the case where p is close to 1/2 (i.e., very noisy settings, $\gamma \approx 1$ in Equation (1)), the experiments in Section 6 show that the methods developed here also work well when the noise level is lower.

Our general method, which we refer to as the *extended scoring method*,[4] is well defined for input data generated according to the noisy choice model. For an alternative $a \in A$, let the score of a be

$$\mathrm{sc}(a) = \sum_{b \in A \setminus \{a\}} n_{ab}. \tag{2}$$

We choose the top k alternatives according to their score, i.e., we return a set in $\arg\max_a^k \mathrm{sc}(a)$.

Theorem 3.3 *For every n and m there exists $\gamma' < 1$ such that for all $\gamma \geq \gamma'$, the optimal solutions to Objective 1 under the noisy choice model are in $\arg\max_a^k sc(a)$.*

[4]We use the term "extended" to avoid confusion with generalized scoring rules [15].

The theorem's formulation leaves open the possibility that some sets in $\arg\max_a^k \mathrm{sc}(a)$ are far from being optimal. However, the theorem's proof in fact shows that for any $\delta > 0$ there is sufficiently large γ such that *every* $S \in \arg\max_a^k \mathrm{sc}(a)$ is optimal up to δ, i.e., for any $S' \subseteq A$ such that $|S'| = k$,

$$\Pr[a^* \in S|D] \geq \Pr[a^* \in S'|D] - \delta.$$

Proof of Theorem 3.3 Let $\gamma = 1 - \epsilon$, $\epsilon > 0$. By Observation 3.1, we know that the optimal solution is given by $\arg\max_a^k \Pr[D|a^* = a]$. In our model

$$\begin{aligned}\Pr[D|a^* = a] &= \sum_{\sigma \in L(A), \sigma^{-1}(1)=a} \Pr[D|\sigma^* = \sigma] \\ &= \sum_{\sigma \in L(A), \sigma^{-1}(1)=a} \frac{\gamma^{d(\sigma,D)}}{Z_\gamma}.\end{aligned}$$

Let $L_a(A) = \{\sigma \in L(A) | \, \sigma^{-1}(1) = a\}$. Thus $|L_a(A)| = (m-1)!$. Define an objective function $f(a) = Z_\gamma \cdot \Pr[D|a^* = a]$. Since Z_γ is a constant, the optimal solution is also given by $\arg\max_a^k f(a)$. Using $\gamma = 1-\epsilon$ and the fact that $(1-\epsilon)^t \geq 1 - t \cdot \epsilon$ for any $t \in \mathbb{N}$, we obtain the following lower bound on our objective function f:

$$f(a) \geq \hat{f}(a) = \sum_{\sigma \in L_a(A)} (1 - \epsilon \cdot d(\sigma, D)). \tag{3}$$

In addition, the gap between f and $\hat{f}$ can be upper bounded using

$$|(1-\epsilon)^t - (1 - t \cdot \epsilon)| \leq \sum_{i=2}^{t} \binom{t}{i} \cdot \epsilon^i \leq 2^t \cdot \epsilon^2$$

for $\epsilon < 1$. It follows that for every $a \in A$,

$$\begin{aligned} f(a) - \hat{f}(a) \quad &\leq \sum_{\sigma \in L_a(A)} 2^{d(\sigma,D)} \cdot \epsilon^2 \\ &\leq \epsilon^2 \cdot (m-1)! \cdot 2^{n \cdot \binom{m}{2}}. \end{aligned} \tag{4}$$

The theorem will now follow by proving two statements: $\arg\max_a^k f(a) \subseteq \arg\max_a^k \hat{f}(a)$, and $\arg\max_a^k \hat{f}(a) = \arg\max_a^k \mathrm{sc}(a)$. We use the following claim.

Claim 3.4 *For every $a \in A$,*

$$\hat{f}(a) = C_\epsilon + \epsilon \cdot (m-1)! \cdot sc(a)$$

where C_ϵ depends only on ϵ (and not on a).

Proof First, we simplify $\hat{f}$ by summing the individual terms in Equation (3).

$$\hat{f}(a) = (m-1)! - \epsilon \cdot \sum_{\sigma \in L_a(A)} d(\sigma, D). \tag{5}$$

Furthermore, note that $\sum_{\sigma \in L_a(A)} d(\sigma, D)$ equals

$$\begin{aligned}
&\sum_{\sigma \in L_a(A)} \sum_{x \in A, y \in A \setminus \{x\}} n_{yx} \cdot \mathbb{1}[\sigma(x) < \sigma(y)] \\
&= \sum_{\sigma \in L_a(A)} \sum_{x \in A, y \in A \setminus \{x\}} (n - n_{xy}) \cdot \mathbb{1}[\sigma(x) < \sigma(y)] \\
&= n \cdot \sum_{\sigma \in L_a(A)} \sum_{x \in A, y \in A \setminus \{x\}} \mathbb{1}[\sigma(x) < \sigma(y)] \\
&\quad - \sum_{x \in A, y \in A \setminus \{x\}} n_{xy} \cdot \sum_{\sigma \in L_a(A)} \mathbb{1}[\sigma(x) < \sigma(y)]
\end{aligned}$$

The symbol $\mathbb{1}$ represents the indicator function. For the first term it holds that

$$\begin{aligned}
&n \cdot \sum_{\sigma \in L_a(A)} \sum_{x \in A, y \in A \setminus \{x\}} \mathbb{1}[\sigma(x) < \sigma(y)] \\
&= n \cdot \sum_{\sigma \in L_a(A)} \binom{m}{2} = n \cdot (m-1)! \cdot \binom{m}{2}.
\end{aligned}$$

To analyze the second term we consider three cases separately: (i) $x = a$, $y \in A \setminus \{a\}$, (ii) $x \in A \setminus \{a\}$, $y = a$, and (iii) $x \in A \setminus \{a\}$, $y \in A \setminus \{a, x\}$. If $x = a$, then for every $y \in A \setminus \{a\}$ and every $\sigma \in L_a(A)$ it holds that $a \succ y$, and hence n_{ay} is multiplied by $(m-1)!$. Similarly, if $y = a$, then for every $x \in A \setminus \{a\}$, n_{xa} is multiplied by 0. If $x \in A \setminus \{a\}$ and $y \in A \setminus \{a, x\}$, then n_{xy} is multiplied by $(m-1)!/2$ because $x \succ y$ in exactly half of the rankings in the summation. Thus the second terms equals

$$\begin{aligned}
&(m-1)! \cdot \left(\sum_{y \in A \setminus \{a\}} n_{ay} + \frac{1}{2} \cdot \sum_{x \in A \setminus \{a\}, y \in A \setminus \{a,x\}} n_{xy} \right) \\
&= (m-1)! \cdot \mathrm{sc}(a) + \frac{(m-1)!}{2} \cdot n \cdot \binom{m-1}{2},
\end{aligned}$$

since $n_{xy} + n_{yx} = n$ for every $x \neq y$. Combining both terms and substituting back,

$$\begin{aligned}
&\sum_{\sigma \in L_a(A)} d(\sigma, D) \\
&= n \cdot (m-1)! \cdot \binom{m}{2} \\
&\quad - \frac{(m-1)!}{2} \cdot n \cdot \binom{m-1}{2} - (m-1)! \cdot \mathrm{sc}(a) \\
&= C'_\epsilon - (m-1)! \cdot \mathrm{sc}(a),
\end{aligned}$$

for some constant C'_ϵ independent of a. Plugging this into Equation (5) we get

$$\hat{f}(a) = C_\epsilon + \epsilon \cdot (m-1)! \cdot \mathrm{sc}(a)$$

as required. ■(Claim 3.4)

Claim 3.4 directly implies that $\arg\max_a^k \hat{f}(a) = \arg\max_a^k \mathrm{sc}(a)$. It therefore remains to prove that $\arg\max_a^k f(a) \subseteq \arg\max_a^k \hat{f}(a)$. For this purpose it is sufficient to show that for every $a, a' \in A$, $\hat{f}(a) > \hat{f}(a')$ implies $f(a) > f(a')$.

Note that $\hat{f}(a) > \hat{f}(a')$ implies $\mathrm{sc}(a) \geq \mathrm{sc}(a') + 1$ (since scores are integers) and using Claim 3.4 this implies $\hat{f}(a) \geq \hat{f}(a') + \epsilon \cdot (m-1)!$. Therefore

$$\begin{aligned}
f(a) &\geq \hat{f}(a) \geq \hat{f}(a') + \epsilon \cdot (m-1)! \\
&\geq f(a') - \epsilon^2 \cdot (m-1)! \cdot 2^{n \cdot \binom{m}{2}} + \epsilon \cdot (m-1)!.
\end{aligned}$$

The third transition follows from Equation (4). Setting $\epsilon < 2^{-n \cdot \binom{m}{2}}$, i.e., $\gamma > \gamma' = 1 - 2^{-n \cdot \binom{m}{2}}$, we have that $f(a) > f(a')$ as required. ■

The notion of score underlying the extended scoring method (Equation (2)) provides an intuitive reflection of the quality of an alternative. In the special case of the noisy comparisons model, $\mathrm{sc}(a) = \sum_{x \in A \setminus \{a\}} n_{ax}$ is just the sum of weights of the outgoing edges from a in the weighted tournament defined in Section 2. Hence, the extended scoring method reduces to picking k alternatives with highest weighted outdegrees.

In the special case of the noisy orders model,

$$\begin{aligned}
\mathrm{sc}(a) &= \sum_{x \in A \setminus \{a\}} n_{ax} = \sum_{x \in A \setminus \{a\}} \sum_{i=1}^{n} \mathbb{1}[\sigma_i(a) < \sigma_i(x)] \\
&= \sum_{i=1}^{n} \sum_{x \in A \setminus \{a\}} \mathbb{1}[\sigma_i(a) < \sigma_i(x)] = \sum_{i=1}^{n} (m - \sigma_i(a)),
\end{aligned}$$

which is exactly the Borda score of alternative a. Hence, the extended scoring method reduces to picking k alternatives with maximum Borda scores. Theorem 3.3 thus extends Young's result for Borda count [18] from the noisy orders model to the noisy choice model and from $k = 1$ to any value of k under Objective 1.

4 Identifying the Top Subset

Under Objective 1 we choose k alternatives, each of which is likely to be the top alternative a^*. However, in principle it may be the case that each of these alternatives is either the top-ranked alternative or among the bottom-ranked alternatives. In this section we seek

to identify the set of top k alternatives, but we will see that the solution in fact coincides with the solution to Objective 1.

Objective 2 *Given k, find the k-subset of alternatives that maximizes the probability of coinciding with the top k alternatives of the true hidden order, i.e., a subset in*

$$\arg\max_{S\subseteq A,|S|=k} \Pr[S = \{(\sigma^*)^{-1}(i)\}_{i\in[k]}|D].$$

It is easy to see that this objective coincides with Objective 1 for $k = 1$, and hence it is $\mathcal{NP}$-hard for $k = 1$ under noisy orders and noisy comparisons. As before, we can extend this observation to any $k \in [m-1]$ for all three models (the proof appears in the full version of the paper).

Next, we show that the extended scoring method is again optimal when $\gamma \approx 1$.

Theorem 4.1 *For every n and m there exists $\gamma' < 1$ such that for all $\gamma \geq \gamma'$, the optimal solutions to Objective 2 under the noisy choice model are in* $\arg\max_a^k sc(a)$.

Theorem 4.1 (whose proof is given in the full version of the paper) suggests that the alternatives selected by the extended scoring method are not only good candidates for the best alternative individually, but as a whole they also make a good "team", i.e, when put together they are the most likely to coincide with the top k alternatives. Theorems 4.1 and 3.3 together provide an argument in favor of the extended scoring method and, in particular, they strongly advocate Borda count when inputs are noisy orders.

5 Identifying the Top Tuple

In this section we study an objective that is even more ambitious than Objective 2: not only do we want to correctly identify the top k alternatives of σ^*, we seek to identify them *in the correct order*.

Objective 3 *Given k, find the ordered k-tuple that maximizes the probability of coinciding with the k-prefix of the true hidden order, i.e., a tuple in*

$$\arg\max_{(a_1,a_2,\ldots,a_k)\in A^k} \Pr[(\sigma^*)^{-1}([k]) = (a_1, a_2, \ldots, a_k)|D].$$

Objective 3 coincides with its predecessors when $k = 1$, and reduces to finding an MLE for the true ranking when $k = m$. In fact we are able to prove that computing the optimal solution to Objective 3 is $\mathcal{NP}$-hard for any $k \in [m]$ under noisy orders and noisy comparisons (the proof appears in the full version of the paper).

To tackle Objective 3 we propose a new method, which we call the *scored tuples* method. Similarly to the extended scoring method, it maximizes a lower bound of the stated objective function and provides optimality guarantees when $\gamma \approx 1$. We first extend the definition of the noisy choice model's distance function to compute the distance between a k-tuple $(a_1, a_2, \ldots, a_k)$ and a dataset D; this distance is defined as

$$d((a_1, a_2, \ldots, a_k), D) = \sum_{1\leq i<j\leq k} n_{a_j a_i}.$$

Next, for a k-tuple $(a_1, a_2, \ldots, a_k)$, define the score of the tuple as

$$\mathrm{sc}(a_1, a_2, \ldots, a_k) = \sum_{i=1}^{k} \mathrm{sc}(a_i) - d((a_1, a_2, \ldots, a_k), D), \tag{6}$$

where $\mathrm{sc}(a_i)$ is defined as in Equation (2). We select a k-tuple in $\arg\max_{(a_1,a_2,\ldots,a_k)\in A^k} \mathrm{sc}(a_1, a_2, \ldots, a_k)$.

It may seem that overloading the notation of $\mathrm{sc}(a)$ as we have (via Equation (2) and Equation (6) with a tuple of length 1) may create inconsistencies, but in fact the $k = 1$ case of Equation (6) reduces to Equation (2).

It turns out that the above method provides guarantees with respect to Objective 3 that are equivalent to those that we were able to obtain for previous objectives.

Theorem 5.1 *For every n and m there exists $\gamma' < 1$ such that for all $\gamma \geq \gamma'$, the optimal solutions to Objective 3 under the noisy choice model are in* $\arg\max_{(a_1,a_2,\ldots,a_k)\in A^k} sc(a_1, a_2, \ldots, a_k)$.

The proof of Theorem 5.1 is given in the full version of the paper; let us consider its implications with respect to the noisy orders model. Since maximizing $\mathrm{sc}(a_1, a_2, \ldots, a_k)$ is optimal when $\gamma \approx 1$, it must be the case (and indeed it is easy to verify) that this solution reduces to finding the Borda winner when $k = 1$ and reduces to finding the Kemeny ranking when $k = m$. Thus the optimal solution for $k = 1, \ldots, m$ induces a range of voting rules where Borda count lies on one extreme, and the Kemeny rule lies on the other. We find it intriguing (and of independent interest to social choice theory) that Borda count and Kemeny are connected via a sequence of "optimal" voting rules.

We remark that the Kemeny rule has been suggested as a method of aggregating the search results given by different search engines; in particular it can be formally argued that spam websites will appear at the bottom of the aggregate ranking [11]. However, since

users are usually only interested in the top 50 results or so, our results suggest that the scored tuples method with a relatively small k may outperform the Kemeny rule (same method with $k = m$) in this context.

Finally, an important note is that although computing $\arg\max_{(a_1,a_2,\ldots,a_k)\in A^k} \mathrm{sc}(a_1, a_2, \ldots, a_k)$ is $\mathcal{NP}$-hard in general, it can be computed in polynomial time for constant k. In some practical settings one would only need to select a constant number of alternatives (consider, e.g., the search engine example given above) and the rule can therefore be easily applied.

6 Experiments

We performed simulations under the noisy comparisons model and the noisy orders model. We experimented with various values of the accuracy parameter p (recall that $\gamma = (1-p)/p$). Although the theoretical guarantees hold only for p close to 1/2 (which corresponds to γ close to 1), we observed that for various values of p in the practical range the methods suggested in this paper significantly outperform various other known methods.

The graphs present results for particular values of p for which the probabilities are visible; the probabilities quickly go to 1 for higher values of p and go to 0 for lower values of p. The results are also verified empirically for various values of m (number of alternatives) and n (number of voters) and p (accuracy parameter) under both models. Error bars correspond to 95% confidence intervals and thus verify that the suggested methods show statistically significant improvement over other methods. In all the graphs shown below each point is computed by taking the average over 10000 iterations.

We remark that the simulations are symmetric with respect to the true order, i.e., it does not matter which true order we begin with as long as the methods do not use any information about it. If we perform simulations on a fixed true order, it becomes necessary to break ties uniformly at random, which is what we do.

For noisy orders we compared Borda count for Objectives 1 and 2, and the scored tuples method for Objective 3, against the Kemeny rule (which is the MLE ranking), k-approval, plurality, maximin, and maximizing unweighted outdegree in the tournament where there is an edge from a to b if a majority of voters rank a above b (a.k.a. *Copeland*). For noisy comparisons we compared weighted outdegree for Objectives 1 and 2, and the scored tuples method for Objective 3, against the Minimum Feedback ranking (which is the MLE ranking), unweighted outdegree, and Maximin.

For Objective 1, we were also able to estimate the actual optimal solution using Observation 3.1. For this we needed to sample rankings according to $\Pr[\sigma^* = \sigma|D]$. One obstacle is that it can be shown that even computing $\Pr[\sigma^* = \sigma|D]$ is $\mathcal{NP}$-hard. We used the fact that $\Pr[\sigma^* = \sigma|D] \propto \Pr[D|\sigma^* = \sigma] \propto \gamma^{d(\sigma,D)}$ and sampled rankings using the Metropolis-Hastings algorithm. Note though that for larger values of the parameters the optimal solution is very difficult to estimate, whereas finding a Borda winner is a trivial computational task.

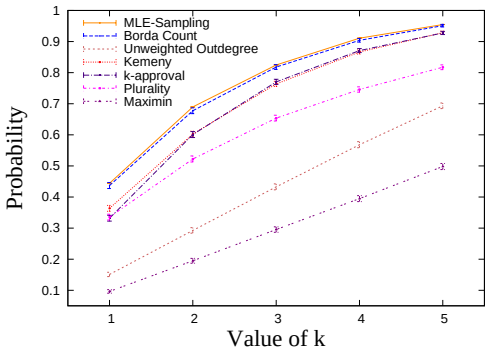

Fig. 1: Objective 1, Noisy Orders, m=10, n=10, p=0.55.

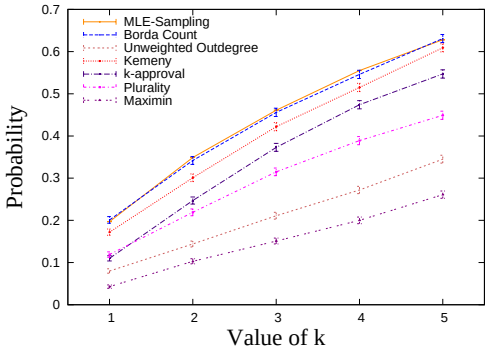

Fig. 2: Objective 1, Noisy Orders, m=20, n=100, p=0.505.

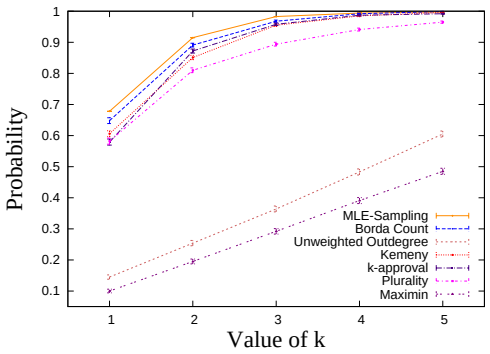

Fig. 3: Objective 1, Noisy Orders, m=10, n=10, p=0.6.

Figure 1 shows simulations for 10 alternatives, 10 voters and $p = 0.55$ under noisy orders. Clearly Borda

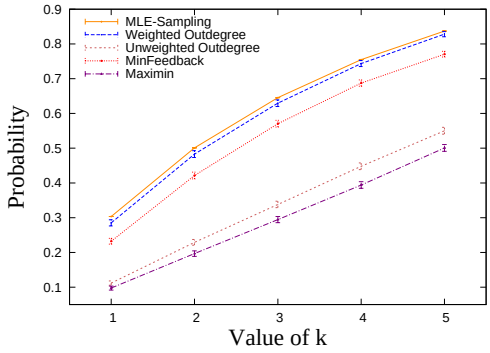

Fig. 4: Objective 1, Noisy Comparisons, m=10, n=10, p=0.55.

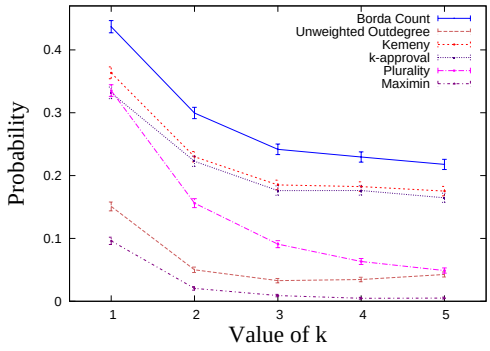

Fig. 5: Objective 2, Noisy Orders, m=10, n=10, p=0.55.

count outperforms other methods by a large margin, and in fact it is almost indistinguishable from the actual optimal solution. Extensive simulations show that similar results hold for a large number of alternatives and/or a large number of voters as well. An example with 20 alternatives, 100 voters and $p = 0.505$ under noisy orders is shown in Figure 2.

As mentioned above, the value of p is chosen such that the graphs span the probability spectrum (probabilities are not constantly 1 or 0) but similar results hold for other values of p as well. For example, Figure 4 shows that Borda count dominates other methods when $p = 0.6$. However, the margin is smaller. Indeed, for this relatively high value of p, most methods under consideration achieve excellent accuracy with only ten voters.

We also performed detailed simulations under the noisy comparisons model and observed similar results. Figure 4 shows a sample simulation for 10 alternatives, 10 voters and $p = 0.55$. In this case weighted outdegree (which is the special case of the extended scoring method) outperforms other methods by a statistically significant margin.

Under Objective 2, the extended scoring method again outperforms other methods as shown in Figure 5 (with 10 alternatives, 10 voters and $p = 0.55$ under noisy orders). As expected, under Objective 3 the scored tuples method outperforms other methods. Figure 6 shows simulations with 10 alternatives, 10 voters and $p = 0.55$ under noisy orders. We do not provide additional graphs for noisy comparisons due to lack of space, but the results are similar: the methods that are theoretically optimal for p close to $1/2$ outperform other methods for practical values of p.

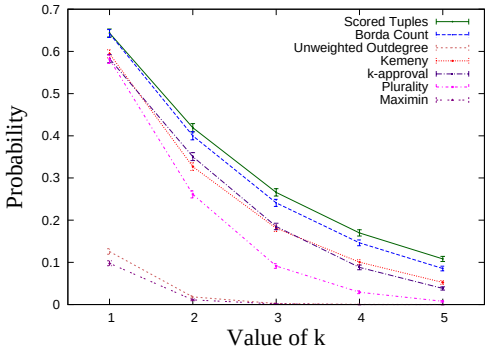

Fig. 6: Objective 3, Noisy Orders, m=10, n=10, p=0.55.

7 Discussion

We began our exposition with the human computation angle, and we would like to revisit it now that we have gained some new insights. Voting is a natural and almost ubiquitous tool in human computation systems. However, the designers of these systems usually employ simplistic voting rules such as plurality or k-approval (as EteRNA does). Our results suggest that the choice of voting rule can significantly affect performance. For example, given that we are indeed interested in singling out one great design, switching from k-approval to Borda count in EteRNA can provide significant benefits. Of course we cannot expect players to rank all the proposed designs, but we can work with partial rankings or pairwise comparisons (as described in Section 2). We find it exciting that social choice theory can help improve human computation systems. Indeed, it is difficult to apply the principles of social choice (e.g., voting rules as MLEs) to political elections, because it is almost impossible to switch voting rules. In contrast, human computation provides a perfect testbed for these principles.

Abstract

EDML is a recently proposed algorithm for learning MAP parameters in Bayesian networks. In this paper, we present a number of new advances and insights on the EDML algorithm. First, we provide the multivalued extension of EDML, originally proposed for Bayesian networks over binary variables. Next, we identify a simplified characterization of EDML that further implies a simple fixed-point algorithm for the convex optimization problem that underlies it. This characterization further reveals a connection between EDML and EM: a fixed point of EDML is a fixed point of EM, and vice versa. We thus identify also a new characterization of EM fixed points, but in the semantics of EDML. Finally, we propose a hybrid EDML/EM algorithm that takes advantage of the improved empirical convergence behavior of EDML, while maintaining the monotonic improvement property of EM.

1 INTRODUCTION

EDML is a recently proposed algorithm for learning MAP parameters of a Bayesian network from incomplete data (Choi, Refaat, & Darwiche, 2011). EDML is procedurally very similar to Expectation Maximization (EM), yet EDML was shown to have certain advantages, both theoretically and practically. Theoretically, EDML can in certain specialized cases provably converge in one iteration, whereas EM may require many iterations to solve the same learning problem. Empirically, a preliminary experimental evaluation suggested that EDML could find better parameter estimates than EM, in fewer iterations.

In this paper, we present a number of new results and insights on the EDML algorithm. First, we provide a simple extension of EDML to Bayesian networks over multivalued variables, whereas EDML was initially proposed for Bayesian networks over binary variables. We also show that the convex optimization problem that underlies the binary version of EDML, remains convex for the multivalued case.

Next, we identify a new and simplified characterization of EDML, which facilitates a number of theoretical observations about EDML. For example, this new characterization implies a simple, fixed-point iterative algorithm for solving the convex optimization problems underlying EDML. Moreover, we show that this fixed-point algorithm monotonically improves the solutions of these convex optimization problems, which correspond to an approximate factorization of the posterior over network parameters.

Armed with this new characterization of EDML, we go on to identify a surprising connection between EDML and EM (considering their theoretical and practical differences). In particular, we show that a fixed point of EDML is a fixed point of EM, and vice versa. This observation has a number of implications. First, it provides a new perspective on EM fixed points, based on the semantics of EDML, which was originally inspired by an approximate inference algorithm for Bayesian networks that subsumed the influential loopy belief propagation algorithm as a degenerate case (Pearl, 1988; Choi & Darwiche, 2006). Second, it suggests a hybrid EDML/EM algorithm that seeks to take advantage of the desirable properties from each: the improved convergence behavior of EDML, and the monotonic improvement property of EM.

2 TECHNICAL PRELIMINARIES

We use upper case letters (X) to denote variables and lower case letters (x) to denote their values. Variable sets are denoted by bold-face upper case letters ($\mathbf{X}$) and their instantiations by bold-face lower case letters ($\mathbf{x}$). Generally, we will use X to denote a variable

in a Bayesian network and $\mathbf{U}$ to denote its parents. A network parameter will therefore have the general form $\theta_{x|\mathbf{u}}$, representing the probability $Pr(X=x|\mathbf{U}=\mathbf{u})$.

Each variable X in a Bayesian network can be thought of as inducing a number of conditional random variables, denoted by $X|\mathbf{u}$, where the values of variable $X|\mathbf{u}$ are drawn based on the conditional distribution $Pr(X|\mathbf{u})$. Parameter estimation in Bayesian networks can be thought of as a process of estimating the distributions of these conditional random variables.

We will use θ to denote the set of all network parameters. Given a network structure G, our goal is to learn its parameters from an incomplete dataset, such as:

example	E	B	A	C
1	e_1	b_1	a_1	?
2	?	b_2	a_2	?
3	e_1	b_2	a_2	c_1

We use $\mathcal{D}$ to denote a dataset, and $\mathbf{d}_i$ to denote an example. The dataset above has three examples, with example $\mathbf{d}_2$ being $B = b_2$, and $A = a_2$.

2.1 LEARNING PARAMETERS

A commonly used measure for the quality of parameter estimates θ is their likelihood, defined as:

$$L(\theta|\mathcal{D}) = \prod_{i=1}^{N} Pr_\theta(\mathbf{d}_i),$$

where Pr_θ is the distribution induced by network structure G and parameters θ. In the case of complete data (each example fixes the value of each variable), the maximum likelihood (ML) parameters are unique and easily obtainable. Learning ML parameters is harder when the data is incomplete and the EM algorithm (Dempster, Laird, & Rubin, 1977; Lauritzen, 1995) is typically employed. EM starts with some initial parameters θ^0, called a *seed,* and successively improves on them via iteration. EM uses the update equation:

$$\theta^{k+1}_{x|\mathbf{u}} = \frac{\sum_{i=1}^{N} Pr_{\theta^k}(x\mathbf{u}|\mathbf{d}_i)}{\sum_{i=1}^{N} Pr_{\theta^k}(\mathbf{u}|\mathbf{d}_i)},$$

which requires inference on a Bayesian network parameterized by θ^k, in order to compute $Pr_{\theta^k}(x\mathbf{u}|\mathbf{d}_i)$ and $Pr_{\theta^k}(\mathbf{u}|\mathbf{d}_i)$. It is known that one run of the jointree algorithm on each example is sufficient to implement an iteration of EM, which is guaranteed to never decrease the likelihood of its estimates across iterations. EM also converges to every local maxima, given that it starts with an appropriate seed. It is common to run EM with multiple seeds, keeping the best local maxima it finds. See (Darwiche, 2009; Koller & Friedman, 2009) for recent treatments on parameter learning in Bayesian networks via EM and related methods.

EM can also be used to find Maximum a Posteriori (MAP) parameters given Dirichlet priors on network parameters. The Dirichlet prior for the parameters of a random variable $X|\mathbf{u}$ is specified by a set of exponents, $\psi_{x|\mathbf{u}}$, leading to a density $\propto \prod_x [\theta_{x|\mathbf{u}}]^{\psi_{x|\mathbf{u}}-1}$. It is common to assume that exponents are > 1, which guarantees a unimodal density. For MAP parameters, EM uses the update (see, e.g., Darwiche (2009)):

$$\theta^{k+1}_{x|\mathbf{u}} = \frac{\psi_{x|\mathbf{u}} - 1 + \sum_{i=1}^{N} Pr_{\theta^k}(x\mathbf{u}|\mathbf{d}_i)}{\psi_{X|\mathbf{u}} - |X| + \sum_{i=1}^{N} Pr_{\theta^k}(\mathbf{u}|\mathbf{d}_i)}, \quad (1)$$

where $\psi_{X|\mathbf{u}} = \sum_x \psi_{x|\mathbf{u}}$. When $\psi_{x|\mathbf{u}} = 1$, the equation reduces to the one for computing ML parameters. Moreover, using $\psi_{x|\mathbf{u}} = 2$ leads to ML parameters with Laplace smoothing. This is a common technique to deal with the problem of insufficient counts (i.e., instantiations that never appear in the dataset, leading to zero probabilities and division by zero). We will use Laplace smoothing in our experiments.

2.2 SOFT EVIDENCE

EDML makes heavy use of soft evidence (i.e., evidence that changes the distribution of a variable without necessarily fixing its value). In this section, we give an introduction to the semantics of soft evidence.

We follow the treatment of (Chan & Darwiche, 2005) for soft evidence, which models soft evidence as hard evidence on a virtual event η. In particular, soft evidence on some variable X with k values is quantified by a vector $\lambda_{x_1}, \ldots, \lambda_{x_k}$ with $\lambda_{x_i} \in [0, \infty)$. The semantics is that $\lambda_{x_1} : \cdots : \lambda_{x_k} = Pr(\eta|x_1) : \cdots : Pr(\eta|x_k)$. The soft evidence on variable X is then emulated by asserting the hard evidence η. That is, the new distribution on variable X after having asserted the soft evidence is modeled by $Pr(X|\eta)$. Note that $Pr(X|\eta)$ depends only on the ratios $\lambda_{x_1} : \cdots : \lambda_{x_k}$, not on their absolute values. Hard evidence of the form $X = x_j$ can be modeled using $\lambda_{x_i} = 0$ for all $i \neq j$, and $\lambda_{x_j} = 1$. Moreover, neutral evidence can be modeled using $\lambda_{x_i} = 1$ for all i. The reader is referred to (Chan & Darwiche, 2005) for more details.

3 BINARY EDML

EDML is a recent method for learning Bayesian network parameters from incomplete data (Choi et al., 2011). It is based on Bayesian learning in which one formulates estimation in terms of computing posterior distributions on network parameters. That is, given a Bayesian network, one constructs a corresponding *meta network* in which parameters are explicated as variables, and on which the given dataset $\mathcal{D}$ can be asserted as evidence; see Figure 1. One then estimates

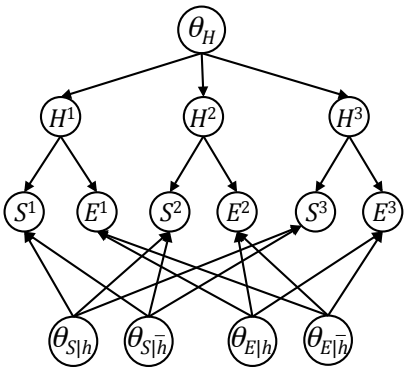

Figure 1: A meta network induced from a base network $S \longleftarrow H \longrightarrow E$. The CPTs here are based on standard semantics; see, e.g., (Darwiche, 2009, Ch. 18).

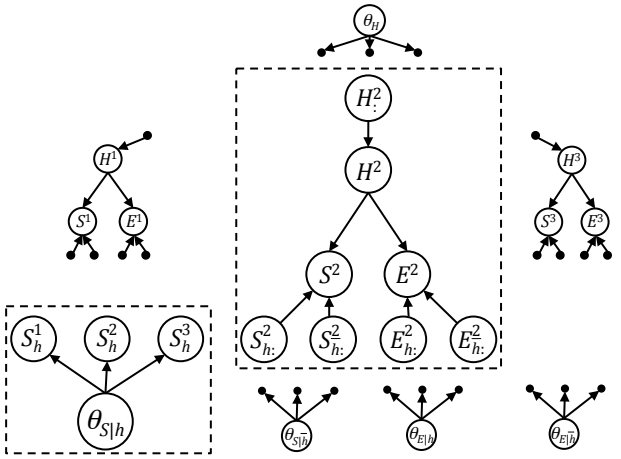

Figure 2: An edge-deleted network obtained from the meta network in Figure 1. Highlighted are the island for example $\mathbf{d}_2$ and the island for parameter set $\theta_{S|h}$.

parameters by considering the posterior distribution obtained from conditioning the meta network on the given dataset $\mathcal{D}$. Suppose for example that the meta network induces distribution $\mathcal{P}$ and let θ denote an instantiation of variables that represent parameters in the meta network. One can then obtain MAP parameter estimates by computing $\text{argmax}_\theta \mathcal{P}(\theta|\mathcal{D})$ using inference on the meta network; see (Darwiche, 2009) for an example treatment of Bayesian learning.

It is known that meta networks tend to be too complex for exact inference algorithms, especially when the dataset is large enough. The basic insight behind EDML was to adapt a specific approximate inference scheme to meta networks with the goal of computing MAP parameter estimates. In particular, the original derivation of EDML adapted the approximate inference algorithm proposed by (Choi & Darwiche, 2006), in which edges are deleted from a Bayesian network

Algorithm 1 Binary EDML

input:

G: A Bayesian network structure
$\mathcal{D}$: An incomplete dataset $\mathbf{d}_1, \ldots, \mathbf{d}_N$
θ: An initial parameterization of structure G
$\alpha_{X|\mathbf{u}}, \beta_{X|\mathbf{u}}$: Beta prior for each random variable $X|\mathbf{u}$

1: **while** not converged **do**
2: $Pr \leftarrow$ distribution induced by θ and G
3: **Compute** Bayes factors:

$$\kappa^i_{x|\mathbf{u}} \leftarrow \frac{Pr(x\mathbf{u}|\mathbf{d}_i)/Pr(x|\mathbf{u}) - Pr(\mathbf{u}|\mathbf{d}_i) + 1}{Pr(\bar{x}\mathbf{u}|\mathbf{d}_i)/Pr(\bar{x}|\mathbf{u}) - Pr(\mathbf{u}|\mathbf{d}_i) + 1}$$

for each family instantiation $x\mathbf{u}$ and example $\mathbf{d}_i$
4: **Update** parameters:

$$\theta_{x|\mathbf{u}} \leftarrow \underset{p}{\text{argmax}}\ [p]^{\alpha_{X|\mathbf{u}}-1}[1-p]^{\beta_{X|\mathbf{u}}-1} \prod_{i=1}^{N} [\kappa^i_{x|\mathbf{u}} \cdot p - p + 1]$$

5: **return** parameterization θ

to make it sparse enough for exact inference, followed by a compensation scheme that attempts to improve the quality of the approximations obtained from the edge-deleted network. The adaptation of this inference method to meta networks is shown in Figure 2. The two specific techniques employed here were to augment each edge $\theta_{X|\mathbf{u}} \longrightarrow X^i$ by an auxiliary variable $X^i_{\mathbf{u}}$, leading to $\theta_{X|\mathbf{u}} \longrightarrow X^i_{\mathbf{u}} \longrightarrow X^i$, where $X^i_{\mathbf{u}} \longrightarrow X^i$ is an equivalence edge. This is followed by deleting the equivalence edge. This technique yielded a disconnected meta network with two classes of subnetworks, called *parameter islands* and *network islands.*

Deleting edges, as proposed by (Choi & Darwiche, 2006), leads to introducing two auxiliary nodes in the Bayesian network for each deleted edge. Moreover, approximate inference by edge deletion follows the deletion process by a compensation scheme that searches for appropriate CPTs of these auxiliary nodes. As it turns out, the search for these CPTs, which is done iteratively, was amenable to a very intuitive interpretation as shown in (Choi et al., 2011).

In particular, one set of CPTs corresponded to soft evidence on network parameters, where each network island contributes one piece of soft evidence for each network parameter. The second set of CPTs corresponded to updated parameter estimates, where each parameter island contributes an estimate of its underlying parameter set. This interpretation was the basis for the form of EDML shown in Algorithm 1. This particular version of EDML, introduced in (Choi et al., 2011), assumes that all network variables are binary. Binary EDML, as we shall call it, iterates just

like EM does, producing new estimates after each iteration. However, EDML iterations can be viewed as having two phases. In the first phase, each example in the data set is used to compute a piece of soft evidence on each parameter set (Line 3 of Algorithm 1). In the second phase, the pieces of soft evidence pertaining to each parameter set are used to compute a new estimate of that set (by solving the convex optimization problem on Line 4 of Algorithm 1). The process repeats until some convergence criteria is met. Aside from this optimization task, EM and EDML have the same computational complexity.

4 MULTIVALUED EDML

One contribution of this paper is the extension of binary EDML so that it handles multivalued variables as well. In principle, the extension turns out to be straightforward and is depicted in Algorithm 3. However, two issues require further discussion. The first concerns the specification of soft evidence for multivalued variables. The second is confirming that the optimization problem corresponding to a parameter island (on Line 4 of Algorithm 3) remains strictly concave, therefore, admitting unique solutions. We will consider both issues next.

4.1 EXAMPLES AS SOFT EVIDENCE

The first key concept of EDML is to interpret a data example $\mathbf{d}_i$ in the dataset as soft evidence on a conditional random variable $X|\mathbf{u}$. As mentioned earlier, soft evidence on a variable is modeled using a vector of parameters, one for each value of the variable. We will therefore use $\lambda_{x|\mathbf{u}}$ to denote the parameter pertaining to value x of variable $X|\mathbf{u}$.

EDML uses Equation 2 in Algorithm 3 to compute soft evidence. In particular, example $\mathbf{d}_i$ is viewed as soft evidence on conditional random variable $X|\mathbf{u}$ that is quantified as follows:

$$\lambda^i_{x|\mathbf{u}} \leftarrow Pr(x\mathbf{u}|\mathbf{d}_i)/Pr(x|\mathbf{u}) - Pr(\mathbf{u}|\mathbf{d}_i) + 1$$

We will not derive this equation here as it resembles the one for binary EDML. We will, however, discuss some of its key properties in this and further sections.

Consider the case when the example $\mathbf{d}_i$ is inconsistent with the parent instantiation $\mathbf{u}$. In this case, the example should be irrelevant to variable $X|\mathbf{u}$. Equation 2 does the right thing here as it reduces to 1 for all values of x, which amounts to neutral evidence.

Another special case is when example $\mathbf{d}_i$ is complete; that is, it has no missing values. In this case, one can verify that if $\mathbf{d}_i$ is consistent with $\mathbf{u}$ (relevant), then $\lambda^i_{x|\mathbf{u}} = 0$ for all values x except the value $x^\star$ consistent with $\mathbf{d}_i$. This is equivalent to hard evidence in favor of $x^\star$. On the other hand, if $\mathbf{d}_i$ is inconsistent with $\mathbf{u}$ (irrelevant), then $\lambda^i_{x|\mathbf{u}} = 1$ for all values x, providing neutral evidence. In a nutshell, a complete example provides either hard evidence, if it is relevant; or neutral evidence, if it is irrelevant.

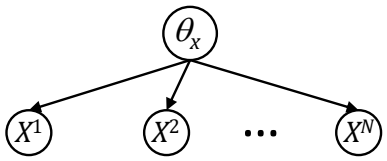

Figure 3: Learning from independent, hard observations $X^1, \ldots, X^N$. The distribution of variable X is specified by parameter set θ_X.

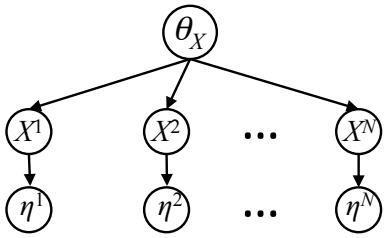

Figure 4: Learning from independent, soft observations $\eta_1, \ldots, \eta_N$. The distribution of variable X is specified by parameter set θ_X.

4.2 LEARNING FROM SOFT EVIDENCE

Consider the standard learning problem depicted in Figure 3. Here, we have a variable X that takes k values $x_1, \ldots, x_k$ and has a distribution specified by a parameter set $\theta_X : \theta_{x_1}, \ldots, \theta_{x_k}$. That is, each parameter θ_{x_i} represents the corresponding probability $Pr(X = x_i)$. Suppose further that we have a Dirichlet prior $\rho(\theta_X)$ on the parameter set with exponents ψ_{x_i} greater than one. A standard learning problem here is to compute the MAP estimates of parameter set θ_X given N independent observations on the variable X. MAP estimates are known to be unique in this case and have a corresponding closed form. In particular, it is known that the posterior $\rho(\theta_X|X^1, \ldots, X^N)$ is a unimodal Dirichlet and, hence, has a unique maximum; see for example (Darwiche, 2009).

EDML is based on a variant of this learning problem in which we are given N *soft observations* on variable X instead of hard observations. This variant is shown in Figure 4, where each observation X^i has a child η^i that is used to emulate soft evidence on X^i. That is, to represent soft evidence $\lambda^i_{x_1}, \ldots, \lambda^i_{x_k}$, we simply choose the CPT for η^i so that $Pr(\eta^i|x_1) : \cdots : Pr(\eta^i|x_k) =$

Algorithm 2 EM

input:
G: A Bayesian network structure
$\mathcal{D}$: An incomplete dataset $\mathbf{d}_1, \ldots, \mathbf{d}_N$
θ: An initial parameterization of structure G
ψ: A Dirichlet prior for each parameter set $\theta_{X|\mathbf{u}}$

1: **while** not converged **do**
2: $Pr \leftarrow$ distribution induced by θ and G
3: **Compute** probabilities:

$$Pr(x\mathbf{u}|\mathbf{d}_i) \quad \text{and} \quad Pr(\mathbf{u}|\mathbf{d}_i)$$

for each family instantiation $x\mathbf{u}$ and example $\mathbf{d}_i$
4: **Update** parameters:

$$\theta_{x|\mathbf{u}} \leftarrow \frac{\psi_{x|\mathbf{u}} - 1 + \sum_{i=1}^{N} Pr(x\mathbf{u}|\mathbf{d}_i)}{\psi_{X|\mathbf{u}} - |X| + \sum_{i=1}^{N} Pr(\mathbf{u}|\mathbf{d}_i)}$$

5: **return** parameterization θ

Algorithm 3 Multivalued EDML

input:
G: A Bayesian network structure
$\mathcal{D}$: An incomplete dataset $\mathbf{d}_1, \ldots, \mathbf{d}_N$
θ: An initial parameterization of structure G
ψ: A Dirichlet prior for each parameter set $\theta_{X|\mathbf{u}}$

1: **while** not converged **do**
2: $Pr \leftarrow$ distribution induced by θ and G
3: **Compute** soft evidence parameters:

$$\lambda^i_{x|\mathbf{u}} \leftarrow Pr(x\mathbf{u}|\mathbf{d}_i)/Pr(x|\mathbf{u}) - Pr(\mathbf{u}|\mathbf{d}_i) + 1 \qquad (2)$$

for each family instantiation $x\mathbf{u}$ and example $\mathbf{d}_i$
4: **Update** parameters:

$$\theta_{X|\mathbf{u}} \leftarrow \operatorname*{argmax}_{\hat{\theta}_{X|\mathbf{u}}} \prod_x [\hat{\theta}_{x|\mathbf{u}}]^{\psi_{x|\mathbf{u}}-1} \prod_{i=1}^{N} \sum_x \lambda^i_{x|\mathbf{u}} \hat{\theta}_{x|\mathbf{u}} \qquad (3)$$

5: **return** parameterization θ

$\lambda^i_{x_1} : \cdots : \lambda^i_{x_k}$.

Note here that the posterior density $\rho(\theta_X|\eta^1 \ldots \eta^N)$ is no longer Dirichlet, but takes the more complex form given by Equation 3 of Algorithm 3. Yet, we have the following result.

Theorem 1 *Given N soft observations η^i on a variable X, and a Dirichlet prior on its parameters θ_X, with Dirichlet exponents $\psi_x > 1$, the posterior density $\rho(\theta_X|\eta^1 \ldots \eta^N)$ is strictly log concave.*

Therefore, the posterior density, $\rho(\theta_X|\eta^1 \ldots \eta^N)$, has a unique maximum. We next provide a simple iterative method for obtaining the maximum in this case.

5 SIMPLE EDML

Multivalued EDML, as given in Algorithm 3, works as follows. We start with some initial parameter estimates, just like EM. We then iterate, while performing two steps in each iteration. In the first step, each example $\mathbf{d}_i$ in the dataset is used to compute soft evidence on each variable $X|\mathbf{u}$, as in Equation 2 of Algorithm 3. Using this soft evidence, a learning problem is set up for the parameter set $\theta_{X|\mathbf{u}}$ as given in Figure 4, which is a learning *sub*-problem in the context of Equation 3 of Algorithm 3. The solution to this learning sub-problem provides the next estimate for parameter set $\theta_{X|\mathbf{u}}$. The process repeats. In principle, any appropriate optimization algorithm could be used to solve each of these learning sub-problems.

We will next derive a simpler description of EDML that has two key components. First, we will provide a convergent update equation that iteratively solves the optimization problem in Equation 3 of Algorithm 3. Second, we will use this update equation to provide a characterization of EDML's fixed points.

First, consider the likelihood:

$$Pr(\eta^1, \ldots, \eta^N \mid \theta_X) = \prod_{i=1}^{N} Pr(\eta^i \mid \theta_X)$$
$$= \prod_{i=1}^{N} \sum_x Pr(\eta^i \mid x) Pr(x \mid \theta_X) = \prod_{i=1}^{N} \sum_x \lambda^i_x \theta_x$$

Next, we have the posterior:

$$\rho(\theta_X \mid \eta^1, \ldots, \eta^N) \propto \rho(\theta_X) Pr(\eta^1, \ldots, \eta^N \mid \theta_X)$$
$$= \rho(\theta_X) \prod_{i=1}^{N} \sum_x \lambda^i_x \theta_x$$

Assuming a Dirichlet prior over parameter set θ_X, with Dirichlet exponents ψ_x, the log of the posterior is:

$$\log \rho(\theta_X \mid \eta^1 \ldots \eta^N)$$
$$= \sum_x (\psi_x - 1) \log \theta_x + \sum_{i=1}^{N} \log \sum_x \lambda^i_x \theta_x + \gamma$$

where γ is a constant that is independent of θ_X, which we can ignore. By Theorem 1 we know that the log of the posterior is strictly concave when $\psi_x > 1$.

To get the unique maximum of the log posterior, we solve the optimization problem:

$$\begin{aligned} &\text{minimize} && -\log \rho(\theta_X \mid \eta^1, \ldots, \eta^N) \\ &\text{subject to} && \sum_x \theta_x = 1 \end{aligned}$$

In order to characterize the unique maximum of the log posterior, we start by taking the Lagrangian:

$$L(\theta_X, \nu) = -\log \rho(\theta_X \mid \eta^1, \ldots, \eta^N) + \nu \cdot (\sum_x \theta_x - 1)$$

where ν is a Lagrange multiplier. We get the following condition for the optimal parameter estimates, by setting the gradient of $L(\theta_X, \nu)$ with respect to θ_X to zero:

$$\theta_x = \frac{\psi_x - 1 + \sum_{i=1}^{N} \frac{\lambda^i_x \theta_x}{\sum_{x^*} \lambda^i_{x^*} \theta_{x^*}}}{\psi_X - |X| + N}$$

where $\psi_X = \sum_x \psi_x$, and where we used the constraint $\sum_x \theta_x = 1$ to identify that $\nu = \psi_X - |X| + N$.

The above equation leads to a much stronger result.

Theorem 2 *The following update equation monotonically increases the posterior $\rho(\theta_{X|\mathbf{u}} \mid \eta^1, \ldots, \eta^N)$:*

$$\theta^t_{x|\mathbf{u}} = \frac{\psi_{x|\mathbf{u}} - 1 + \sum_{i=1}^{N} \frac{\lambda^i_{x|\mathbf{u}} \theta^{t-1}_{x|\mathbf{u}}}{\sum_{x^*} \lambda^i_{x^*|\mathbf{u}} \theta^{t-1}_{x^*|\mathbf{u}}}}{\psi_{X|\mathbf{u}} - |X| + N} \qquad (4)$$

This theorem suggests a convergent iterative algorithm for solving the convex optimization problem of Equation 3 in Algorithm 3. First, we start with some initial parameter estimates $\theta^0_{x|\mathbf{u}}$ at iteration $t = 0$. For iteration $t > 0$, we use the above update to compute parameters $\theta^t_{x|\mathbf{u}}$ given the parameters $\theta^{t-1}_{x|\mathbf{u}}$ from the previous iteration. If at some point, the parameters of one iteration do not change in the next (in practice, up to some limit), we say that the iterations have converged to a fixed point. The above theorem, together with Theorem 1, shows that these updates are convergent to the unique maximum of the posterior.

Given Equation 4, one can think of two types of *iterations* in EDML: local and global. A *global* iteration corresponds to executing Lines 2–4 of Algorithm 3 and is similar to an EM iteration. Within each global iteration, we have *local* iterations which correspond to the evaluations of Equation 4. Note that each parameter set $\theta_{X|\mathbf{u}}$ has its own local iterations, which are meant to find the optimal values of this parameter set. Moreover, the number of local iterations for each parameter set $\theta_{X|\mathbf{u}}$ may be different, depending on the soft evidence pertaining to that set (i.e., $\lambda^i_{x|\mathbf{u}}$) and depending on how Equation 4 is seeded for that particular parameter set (i.e., $\theta^0_{x|\mathbf{u}}$).

This leads to a number of observations on the difference between EM updates (Equation 1) and EDML updates (Equation 4). From a time complexity viewpoint, an EM update implies exactly one local iteration for each parameter set since Equation 1 needs to be evaluated only once for each parameter set. As mentioned earlier, however, an EDML update requires a varying number of local iterations. We have indeed observed that some parameter sets may require several hundred local iterations, depending on the seed of Equation 4 and the convergence criteria used. Another important observation is that EDML has a secondary set of seeds, as compared to EM, which are needed to start off Equation 4 at the beginning of each global iteration of EDML. In our experiments, we seed Equation 4 using the parameter estimates obtained from the previous global iteration of EDML. We note, however, that the choice of these secondary seeds is a subject that can significantly benefit from further research.

6 EDML FIXED POINTS

One of the more well known facts about EM is that its fixed points are precisely the stationary points of the log-likelihood function (or more generally, the posterior density when Dirichlet priors are used). This property has a number of implications, one of which is that EM is capable of converging to every local maxima of the log-likelihood, assuming that the algorithm is seeded appropriately.

In this section, we show that the fixed points of EDML are precisely the fixed points of EM. We start by formally defining what a fixed point is.

Both EM and EDML can be viewed as functions $f(\theta)$ that take a network parameterization θ and returns another network parameterization $f(\theta)$. Each algorithm is seeded with initial parameters θ^0. After the first iteration, each algorithm produces the next parameters $\theta^1 = f(\theta^0)$. More generally, at iteration i, each algorithm produces the parameters $\theta^{i+1} = f(\theta^i)$. When $\theta^{i+1} = \theta^i$, we say that parameters θ^i are a fixed point for an algorithm. We also say that the algorithm has converged to θ^i. We now have the following results.

Theorem 3 *A parameterization θ is a fixed point for EDML if and only if it is a fixed point for EM.*

The proof of this theorem rests on two observations. First, using the update equation of EM given on Line 4 of Algorithm 2, one immediately gets that the EM fixed points are characterized by the following equation

$$Pr(x|\mathbf{u}) = \frac{\psi_{x|\mathbf{u}} - 1 + \sum_{i=1}^{N} Pr(x\mathbf{u}|\mathbf{d}_i)}{\psi_{X|\mathbf{u}} - |X| + \sum_{i=1}^{N} Pr(\mathbf{u}|\mathbf{d}_i)} \qquad (5)$$

That is, we can test whether a network parameterization θ is a fixed point for EM by simply checking the probability distribution Pr it induces to see if satisfies the above equation (this is actually a set of equations, one for each family instantiation $x\mathbf{u}$ in the network).

Consider now EDML updates as given by Equation 4 and suppose that we have reached a fixed point, where $\theta^t_{x|\mathbf{u}} = \theta^{t-1}_{x|\mathbf{u}} = Pr(x|\mathbf{u})$ for all $x\mathbf{u}$. If we now replace each $\lambda^i_{x|\mathbf{u}}$ by its corresponding value in Equation 2 of Algorithm 3, we obtain, after some simplification:

$$Pr(x|\mathbf{u}) = \frac{\psi_{x|\mathbf{u}} - 1 + \sum_{i=1}^{N} \frac{\lambda^i_{x|\mathbf{u}} Pr(x|\mathbf{u})}{\sum_{x^\star} \lambda^i_{x^\star|\mathbf{u}} Pr(x^\star|\mathbf{u})}}{\psi_{X|\mathbf{u}} - |X| + N}$$
$$= \frac{\psi_{x|\mathbf{u}} - 1 + \sum_{i=1}^{N} Pr(x\mathbf{u}|\mathbf{d}_i) + Pr(\neg\mathbf{u}|\mathbf{d}_i) Pr(x|\mathbf{u})}{\psi_{X|\mathbf{u}} - |X| + N} \quad (6)$$

Thus, a parameterization θ is a fixed point for EDML iff it satisfies Equation 6. After noting that $N = \sum_{i=1}^{N} Pr(\mathbf{u}|\mathbf{d}_i) + Pr(\neg\mathbf{u}|\mathbf{d}_i)$, we rearrange Equation 6 to obtain Equation 5, which is the characteristic equation for EM fixed points. Thus, a parameterization θ satisfies Equation 6 iff it is a fixed point for EM.

7 HYBRID EDML/EM

By Theorem 3, EDML and EM share the same fixed points. This result is fairly surprising, considering the theoretical and practical differences between the two algorithms. For example, certain specialized situations were identified where EDML converges to optimal parameter estimates in a single global iteration (regardless of how it is seeded), whereas EM may require many iterations to converge to the same estimates (Choi et al., 2011). On the other hand, EDML is not guaranteed to monotonically improve its estimates after each global iteration as EM does (improvement here is in terms of increasing the likelihood of estimates, or the MAP when Dirichlet priors are used).

By carefully examining EDML updates (Equation 4), one can see that the quantities it needs to perform a single local iteration are the same quantities needed to perform an EM update (Equation 1). Hence, without any additional computational effort, one can obtain EM updates as a side effect of computing EDML updates (the converse is not true since Equation 4 may require many local iterations). As both algorithms share the same fixed points, it thus makes sense to consider a hybrid algorithm that takes advantage of the improved theoretical and practical benefits of EDML (with respect to faster convergence) and the monotonic improvement property of EM.

We thus propose a very simple hybrid algorithm. At each global iteration of EDML, we also compute EM updates simultaneously. We then evaluate each update and choose the one that increases the posterior the most. As EM is guaranteed to improve the posterior, this hybrid algorithm is also trivially guaranteed to monotonically improve the posterior, therefore, inheriting the most celebrated feature of EM.

While additionally computing an EM update is not much overhead if one is computing an EDML update, evaluating both updates with respect to the posterior incurs a non-trivial cost. As we shall see in the following section, however, the improved convergence behavior of EDML enables this hybrid algorithm to realize improvements over EM, both in terms of faster convergence (i.e., number of global iterations) and in terms of time (i.e., when taking both global and local iterations under consideration).

8 EXPERIMENTAL RESULTS

In our first set of experiments, we show that simple EDML, as compared to EM, can often find better estimates in fewer global iterations. In our second set of experiments, we show that a hybrid EDML/EM algorithm can find better estimates in less time, as well as fewer global iterations. We use the following networks: alarm, andes, asia, diagnose, pigs, spect, water, and win95pts. Network spect is a naive Bayes network induced from a dataset in the UCI ML repository, with 1 class variable and 22 attributes. Network diagnose is from the UAI 2008 evaluation. The other networks are commonly used benchmarks.[1]

Using these networks, we simulated data sets of a certain size (2^{10}), then made the data incomplete by randomly selecting a certain percentage of the nodes to be hidden (10%, 25%, 35%, 50%, and 70%). For each of these cases, and for each network, we further generated 3 data sets at random. A combination of a network, a percentage of hidden nodes, and a generated data set constitutes a learning problem. Both EM and EDML are seeded with the same set of randomly generated parameters. Local EDML iterations are seeded with the estimates of the previous global iteration.

8.1 EXPERIMENTS I

First, we study the behavior of EDML compared to EM, with respect to global iterations (more on the computation time, in the next section). For every learning problem, we run both EM and EDML[2] for 1000 global iterations and identify the best MAP estimates achieved by either of them, for the purpose of evaluation. In each global iteration, EM and EDML

[1] Available at `http://www.cs.huji.ac.il/site/labs/compbio/Repository/` and `http://genie.sis.pitt.edu/networks.html`

[2] Soft evidence and parameter updates are damped in EDML, which is typical for algorithms like loopy belief propagation, which EDML is, in part, inspired by (Choi & Darwiche, 2006).

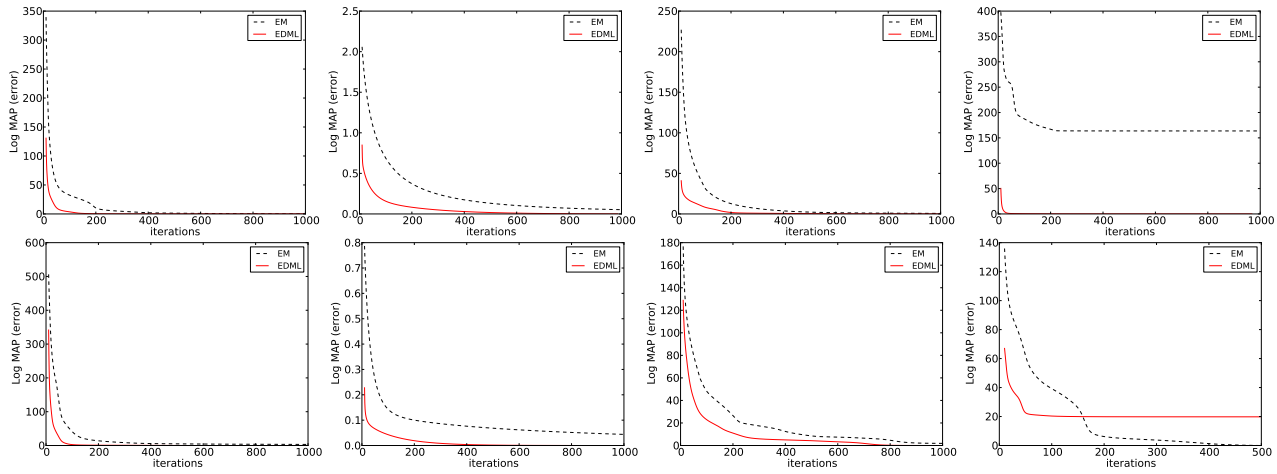

Figure 5: MAP Error of parameter estimates over iterations. Going right on the x-axis, we have increasing iterations. Going up on the y-axis, we have increasing error. EDML is depicted with a solid red line, and EM with a dashed black line. The curves are from left to right, in pairs, for the networks: andes, asia, diagnose, and alarm. Each pair of curves represents a selection of two different datasets of size 2^{10}.

each try to improve their current estimates by improving the posterior (again, EM is provably guaranteed to increase the posterior, while EDML is not). The difference between the (log) posterior of the current estimates, and the best (log) posterior found, by either algorithm, is considered to be the error. The error is measured at every global iteration of EM and EDML until it decreases below 10^{-4}. Table 1 summarizes the results by showing the percentage of global iterations in which each algorithm had less error than the other. In the global iterations where an algorithm had less error, the factor by which it decreases the error of the other algorithm, on average, is computed, and is considered the relative improvement: r and r', for EM and EDML, respectively. Table 1 shows the results for three different breakdowns: (1) by different networks, (2) by different hiding percentages, and (3) on average.

We see here that EDML can obtain better estimates than EM in much fewer global iterations. Interestingly, this is the case even though EDML is not guaranteed to improve estimates after each global iteration, as EM does. Another interesting observation is that decreasing the percentage of hidden nodes widens the gap between EDML and EM, in favor of EDML. This is not surprising though since the approximate inference scheme on which EDML is based becomes more accurate with more observations. In particular, the local optimization problems that EDML solves exactly and independently, become more independent with more observations (i.e., as the dataset becomes more complete). Figure 5 highlights a selection of error curves given by EM and EDML for different learning problems. One can see that in most cases shown, the EDML error goes to zero much faster than EM.

Table 1: Speedup results (iterations)

category	% EDML	% EM	r	r'
alarm	89.25%	10.75%	76.21%	76.44%
andes	75.89%	24.11%	88.95%	79.29%
asia	99.01%	0.99%	92.05%	76.91%
diagnose	78.99%	21.01%	77.99%	80.18%
pigs	83.34%	16.66%	83.51%	60.57%
spect	86.65%	13.35%	82.70%	79.96%
water	82.77%	17.23%	91.55%	83.78%
win95pts	78.73%	21.27%	91.75%	79.89%
hiding 10%	93.82%	6.18%	84.59%	87.13%
hiding 25%	90.95%	9.05%	83.83%	75.70%
hiding 35%	82.24%	17.76%	86.26%	75.09%
hiding 50%	77.61%	22.39%	87.8%	80.21%
hiding 70%	75.65%	24.35%	84.48%	74.21%
average	83.05%	16.95%	85.41%	76.96%

8.2 EXPERIMENTS II

Our first set of experiments showed that EDML can obtain better estimates in significantly fewer global iterations than EM. A global EDML iteration, however, is more costly than a global EM iteration as EDML performs local iterations which are needed to solve the convex optimization problem associated with each parameter set. Thus, EDML can potentially take more time to converge than EM in some cases, therefore reducing the overall benefit over EM, in terms of time (more on this later).[3] EDML can still perform favorably time-wise compared to EM, but we show here

[3]This could be alleviated, for example, by better seeding of the local EDML iterations (to speed up convergence of the local iterations), or by performing the local EDML iterations in parallel, across parameter sets.

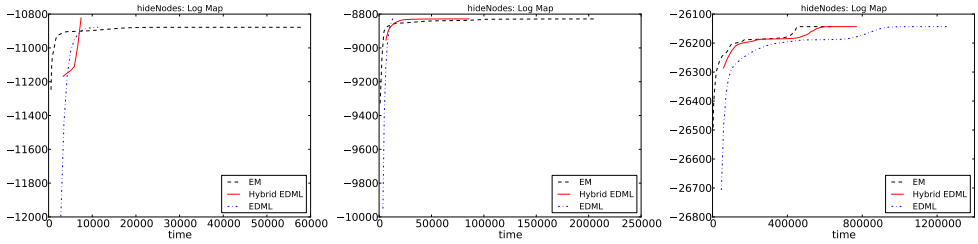

Figure 6: MAP of parameter estimates over time. Going right on the x-axis, we have increasing time (ms). Going up on the y-axis, we have increasing MAP. Hybrid EDML is depicted with a solid red line, EM with a dashed black line, and EDML with a blue dotted dashed line. The curves are from left to right for the following problems: alarm with hiding 25%, win95pts with hiding 35%, and water with hiding 50%.

Table 2: Speedup results (time)

network	% Hybrid	% EM	s	s'
alarm	46.67%	53.33%	75.80%	56.22%
andes	53.33%	46.67%	42.27%	47.08%
asia	66.67%	33.33%	70.37%	41.00%
diagnose	26.67%	73.33%	52.71%	43.14%
pigs	73.33%	26.67%	52.35%	31.32%
spect	100%	0%	98.03%	—
water	35.71%	64.29%	46.15%	43.55%
win95pts	80.00%	20.00%	66.37%	54.95%
average	60.50%	39.50%	67.45%	45.55%

that a hybrid EDML/EM can go even further.

We first run EM until convergence (or until it exceeds 1000 iterations). Second, we run our hybrid EDML/EM until it achieves the same quality of parameter estimates as EM (or until it exceeds 1000 iterations). To summarize the results, Table 2 shows the percentage of learning problems in which each algorithm was faster than the other. In the cases where the hybrid EDML/EM algorithm was faster, the average percentage by which it decreases the execution time of EM is reported as the speedup (s). The speedup for the cases in which EM was faster is given by s'.

The results suggest that hybrid EDML/EM can be used to get better estimates in less time. Specifically, on average, the hybrid method decreases the execution time by a factor of 3.07 in about 60.50% of the cases, and, in the rest of the cases, EM was faster by a factor of roughly 1.84. This is particularly interesting in light of the non-trivial overhead associated with hybrid EDML/EM, as it has to evaluate both EDML and EM estimates in order to select the better estimate. In comparison, EDML alone was on average faster than EM by a factor of 2.59 times in about 54.17% of the cases, whereas EM was faster than EDML alone by a factor of 2.38 in the remaining 45.83% of the cases.

Figure 6 shows a sample of the time curves showing two cases where EDML/EM reached better MAP estimates, faster than EM, and one case where EDML/EM finished slightly after EM. EDML alone is also plotted in Figure 6 where it is usually slower than EDML/EM except in some cases; see the center plot in Figure 6.

9 RELATED WORK

EM has played a critical role in learning probabilistic graphical models and Bayesian networks (Dempster et al., 1977; Lauritzen, 1995; Heckerman, 1998). However, learning (and Bayesian learning in particular) remains challenging in a variety of situations, particularly when there are hidden (latent) variables; see, e.g., (Elidan, Ninio, Friedman, & Shuurmans, 2002; Elidan & Friedman, 2005). More recently, there have been characterizations of EM that also have interesting connections to loopy belief propagation, and related algorithms (Liu & Ihler, 2011; Jiang, Rai, & III, 2011), although their focus is more on approximate (partial) MAP inference in probabilistic graphical models via message-passing, and less on learning.

Slow convergence of EM has also been recognized, particularly in the presence of hidden variables. In such cases, EM can be coupled with algorithms such as gradient ascent, or other more traditional algorithms for optimization; see, e.g. (Aitkin & Aitkin, 1996). A variety of other techniques for accelerating EM have been proposed in the literature; see, e.g., (Thiesson, Meek, & Heckerman, 2001).

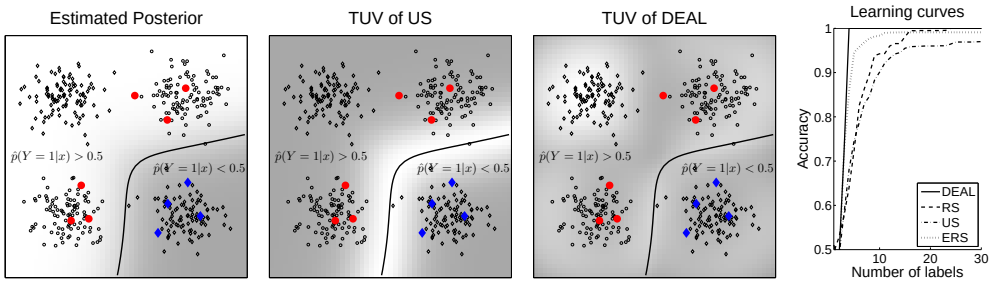
Abstract

Active Learning (AL) is increasingly important in a broad range of applications. Two main AL principles to obtain accurate classification with few labeled data are *refinement* of the current decision boundary and *exploration* of poorly sampled regions. In this paper we derive a novel AL scheme that balances these two principles in a natural way. In contrast to many AL strategies, which are based on an estimated class conditional probability $\hat{p}(y|x)$, a key component of our approach is to view this quantity as a random variable, hence explicitly considering the *uncertainty* in its estimated value. Our main contribution is a novel mathematical framework for uncertainty-based AL, and a corresponding AL scheme, where the uncertainty in $\hat{p}(y|x)$ is modeled by a second-order distribution. On the practical side, we show how to approximate such second-order distributions for kernel density classification. Finally, we find that over a large number of UCI, USPS and Caltech-4 datasets, our AL scheme achieves significantly better learning curves than popular AL methods such as uncertainty sampling and error reduction sampling, when all use the same kernel density classifier.

1 INTRODUCTION

In many applications, including computer vision and natural language processing, unlabeled data abounds while procuring labels for training is costly. Pool-based active learning (AL) schemes judiciously select those among the unlabeled points that are deemed most informative, and thought to help achieve a steeper learning curve. The prospect of reduced labeling effort has spurred intense efforts to improve AL. On the theoretical side, several works considered the sample complexity and potential benefits of AL, see (Beygelzimer et al., 2009; Balcan et al., 2010; Hanneke, 2011). On the practical side, various works suggested concrete AL schemes, recently e.g. (Huang et al., 2010; Siddiquie and Gupta, 2010), with large gains over random labeling in various applications, see (Settles, 2010) for a comprehensive review.

In this paper we focus on pool based AL. We first review a potential weakness common to many popular AL methods, and then derive a new pool-based AL scheme. In a pool-based setting, one typically starts with a small (possibly empty) set of labeled samples $\mathcal{L} = \{x_i, y_i\}_{i=1}^{\ell}$, and a large pool of unlabeled samples $\mathcal{U} = \{x_j\}_{j=\ell+1}^{n}$. Most pool-based AL schemes rely on a classifier – or more precisely, a regressor – that outputs not only a predicted class label $\hat{y}$ at a new sample x, but also an estimate $\hat{p}(y|x)$ of the conditional class probabilities $\Pr[Y = y|X = x]$ for all classes y. Then, sequential one-step looka-



(a) (b) (c) (d)

Figure 1: Active learning on the XOR problem. Small black symbols are unlabeled data, large colored symbols are the labeled ones. (a) Class-conditional probability and decision boundary estimated by kernel density classification, with labeled data in only 3 out of 4 quadrants. (b), (c) Training utility values (TUV) of uncertainty sampling and the proposed DEAL, lighter color representing a higher TUV. Uncertainty sampling prematurely concentrates on local refinement of the current decision boundary. DEAL keeps exploring before reverting to refinement. (d) Resulting learning curves.

head AL schemes compute a Training Utility Value (TUV) for any unlabeled sample, and query the label of the sample with largest TUV.

One popular and successful AL strategy is uncertainty sampling (US) which iteratively selects the sample whose current class prediction is least confident[1] (Baum, 1991; Hwang et al., 1991; Seung et al., 1992; Lewis and Gale, 1994).

Another common strategy is to query that sample whose inclusion in the training set may contribute most towards a "confident" classification. Here, confidence is measured by the entropy of the class conditional probabilities, or the expected estimated risk (MacKay, 1992; Roy and McCallum, 2001; Zhu et al., 2003): the more assertive the resulting classifier, the better, according to these algorithms. A variant in the regression context has been proposed in (Boutilier et al., 2003).

Yet another popular AL strategy is to select samples that minimize the uncertainty in the estimated parameters of a classifier, e.g. by maximally reducing the version space of a SVM (Tong and Koller, 2002) or by minimizing the variance of the parameter estimates in multinomial logistic regression (Schein and Ungar, 2007).

A common theme to all these AL schemes is their use of point estimates $\hat{p}(y|x)$, possibly combined with density estimates $\hat{p}(x)$, but without consideration of the inherent random uncertainties in these quantities. By definition, $\hat{p}(y|x)$ is estimated from the finite, and often small, currently labeled set $\mathcal{L}$.[2] Hence, at any x, $\hat{p}(y|x)$ is a random variable, which may have small bias and variance in some regions, but high uncertainty in others.

In this paper, we propose to capitalize on this seeming flaw, and to put the unavoidable uncertainty in the estimates $\hat{p}(y|x)$ at the very heart of a novel AL scheme: Distributional Estimate Active Learning (DEAL). First, in Section 2 we propose to quantify the uncertainty in the estimate $\hat{p}(y|x)$ via a *second-order distribution*, see Eq. (1). Next, in Section 3 we show how such a second-order distribution can be approximated for kernel density classification; and in Section 4 we show how such distributions can be used, in a principled mathematical framework, for uncertainty-based AL. In Section 5 we show empirically that with a baseline implementa-

[1] Note that this can be defined in many possible ways, in particular in multi-class settings.

[2] And, in the case of semi-supervised active learning, also from the unlabeled set $\mathcal{U}$.

tion using kernel density classification, DEAL performs significantly better than two highly popular AL schemes and random sampling in a thorough benchmark on more than 40 classification problems from the UCI (Frank and Asuncion, 2010) and USPS (LeCun et al., 1990) databases, and on an image classification task using the Caltech-4 dataset.

Our approach is somewhat related to the minimization of uncertainty in Gaussian process regression for space-filling experimental design (Sacks et al., 1989). In the machine learning community, several works devised efficient approximations for the intractable posterior distribution in Gaussian process classification models (Nickisch and Rasmussen, 2008). In particular, these distributions were used to compute Bayesian predictive distributions (Snelson and Ghahramani, 2005), which for classification are *point estimates* of the class conditional probabilities. Gaussian processes were also used for active learning, though there the authors suggested to label those samples whose normalized margin is smallest (Kapoor et al., 2007). Thus, even though second-order distributions were derived for logistic regression and Gaussian processes, to the best of our knowledge, these have not been used in AL for classification. In this paper we thus emphasize the importance, use, and potential benefit of second-order distributions in AL classification problems. As discussed in Section 6, second-order distributions may see potential use beyond AL.

2 CLASSIFIER UNCERTAINTY AND ACTIVE LEARNING

In statistical pattern recognition, agreement prevails that a classifier should not be forced to make a prediction unless reasonably confident about it. This principle is formalized by introducing an auxiliary "doubt" class that the classifier can always vote for, at a fixed cost (Ripley, 2008). In the generic case of a symmetric loss function, minimizing the expected risk leads to an algorithm that, given a sample x, votes for the class with highest conditional probability, $\hat{y} = \arg\max_y \hat{p}(y|x)$, provided that the expected loss of this decision is smaller than the fixed cost of the "doubt" class.

The "doubt" class captures the uncertainty of a prediction $\hat{y}$ at locations x where no class is clearly dominant. Even if the class conditional probabilities are perfectly known, this type of "first-order" uncertainty is still present wherever two classes overlap in feature space. As a direct consequence to AL, if the current labeled set makes it quite clear that two classes are equally probable at some region in feature space, it is futile to attempt reducing this first-order uncertainty by requesting more labels there!

In practice, $p(y|x)$ is unknown, and thus estimated from a finite training set. This induces a *second* kind of uncertainty: not only how confident are we in the predicted label $\hat{y}$, but also how accurate is our point estimate $\hat{p}(y|x)$. An inaccurate point estimate may result in a misleading classifier that errs and votes for the wrong class, with a class conditional probability margin that is deceptively large. Asking for the label of additional training samples in such regions can result in a decisive change in the current decision boundary. Hence, samples with highly uncertain class conditional probability estimates should be prime candidates of a good AL criterion. A point in case is the classical XOR problem, illustrated in Fig. 1. Starting with 10 labeled data in only 3 out of 4 quadrants (an event whose probability is $\sim$20% with 10 randomly selected labeled data), nearest-neighbor type classifiers give an erroneous prediction at the remaining quadrant, with a deceptively large margin. Consequently, AL schemes based on $\hat{p}(y|x)$ do not sample points in the remaining quadrant. This overconfidence of AL schemes was also noted by (Baram et al., 2004), who suggest to label at random once in a while.

Motivated by the above insights, in this paper we derive an AL scheme that incorporates this randomness in $\hat{p}(y|x)$ in a natural way. The key ingredient in our scheme is a *second-order distribution*

$$G_x(q) = \Pr[\hat{p}(y = 1|x) \leq q] \qquad (1)$$

which measures our uncertainty in the point estimate $\hat{p}(y|x)$. Before deriving the DEAL scheme, we first show how such a second-order distribution can be estimated for the kernel density classifier.

3 SECOND-ORDER DISTRIBUTIONS FOR THE KERNEL DENSITY CLASSIFIER

Kernel density classification is a prototypical non-parametric generative classifier. While with limited training data this classifier will likely have a lower accuracy compared to modern discriminative classifiers, we choose it since it is: (i) conceptually simple and easy to implement, (ii) usable in all the active learning criteria that we wish to benchmark and (iii) representative of an entire class of more advanced methods. While beyond the scope of this paper, second-order distributions can also be derived for discriminative classifiers, and then used in our AL scheme.

For simplicity, in the rest of this paper we focus on the binary classification problem, with class labels $y \in \{-1, +1\}$. To derive second-order distributions for the unknown class probabilities $p(1|x) = \Pr[Y=1|X=x]$, we use Bayes rule

$$p(1|x) = \frac{p(x|1)\pi_1}{p(x|-1)\pi_{-1} + p(x|1)\pi_1} \qquad (2)$$

with π_y the prior probability for class y. In kernel density classification, the unknown class densities $p(x|1)$ and $p(x|-1)$ are replaced by their Parzen window estimates. To derive second-order distributions, we thus need to approximate the distribution of these point estimates.

Let $\mathcal{K}$ be a normalized ($\int \mathcal{K}(u)du = 1$) isotropic kernel. Then the kernel density estimate

$$\hat{p}(x|Y=y) = \frac{1}{n_y} \sum_{x_i:y_i=y} \mathcal{K}(x - x_i) \qquad (3)$$

is a random variable. With only a single observation from class y ($n_y = 1$), the exact distribution of this random variable is given by

$$\Pr[\hat{p}(x|y) \le z] = \int \mathbf{1}\left(\mathcal{K}(u-x) \le z\right) p(u|y)du \qquad (4)$$

This distribution depends on the location of the query x, on the kernel function $\mathcal{K}$ and on the unknown density $p(x|Y=y)$. Qualitatively, for non-negative and monotonically decaying kernels $\mathcal{K}$, the resulting density must be zero for $z < 0$ and for $z > \mathcal{K}(0)$. For n_y i.i.d. observations from class y, the distribution of the class density kernel estimate is given by a n_y-fold convolution of the probability density that corresponds to Eq. (4).

Since the exact density $p(x|Y = y)$ is unknown (otherwise no learning would be necessary), we resort to an approximation of the distribution of $\hat{p}(x|y)$. Key requirements are that the approximate distribution be continuous, infinitely divisible, have no mass at $z < 0$ and its derivative should decay to zero as $z \to \infty$. A good candidate meeting these criteria is the Gamma distribution which, with its shape and location parameters k and θ, is also sufficiently rich to faithfully model a variety of situations that arise in practice. A standard estimate of mean and variance of the kernel density estimate (Härdle et al., 2004, chap. 3) allows to apply the method of moments and obtain the shape parameter $k_y = n_y\hat{p}(x|Y=y)/C_2$ and location parameter $\theta_y = C_2/n_y$, where $C_2 = \int \mathcal{K}^2(x)dx$.

When the class prior π_y is estimated by the ratio n_y/n, we obtain the following approximate distribution for the random variable $\hat{p}(x|y)$

$$\hat{p}(x|y)\hat{\pi}_y \sim \Gamma\left(\delta + \tfrac{n_y\hat{p}(x|y)}{C_2}, \tfrac{C_2}{n_y} \cdot \tfrac{n_y}{n}\right). \qquad (5)$$

Here, δ is a small positive constant added both to regularize Eq. (2) in low-density regions, and to guarantee that the shape parameter of the Gamma distribution is strictly positive, even when no labeled observations are available yet for class y.

With $\theta := C_2/n$, inserting Eq. (5) into Eq. (2) gives

$$\begin{aligned}\hat{p}(Y=1|x) &\sim \frac{\Gamma(\delta + k_1, \theta)}{\Gamma(\delta + k_{-1}, \theta) + \Gamma(\delta + k_1, \theta)} \\ &= Beta(\delta + k_1, \delta + k_{-1}) = Beta(\alpha, \beta) \qquad (6)\end{aligned}$$

In particular, for a d-dimensional isotropic Gaussian kernel with bandwidth h, we obtain

$$k_y = 2^{d/2} \sum_{x_i:y_i=y} \exp\left(-\left\|x - x_i\right\|^2 / 2h^2\right). \qquad (7)$$

4 DISTRIBUTIONAL ESTIMATE ACTIVE LEARNING (DEAL)

Our novel AL scheme requires a method (for instance the one described in the previous section, or a Gaussian process classifier) that outputs a second-order distribution $G_x(q)$, Eq. (1).

Our point of departure in deriving our AL scheme, is the following key observation (Friedman, 1997): The performance of a classifier, as measured by its misclassification error, depends only on the location of its decision boundary, and not on the precise estimates of the conditional class probabilities. In particular, inaccurate point estimates $\hat{p}(y|x)$ may still yield the optimal Bayes classifier as long as they result in the same decision boundary.

A second-order distribution can thus help assess the uncertainty in the currently estimated decision boundary. In more detail, given a second-order distribution with density $g_x(q)=\frac{d}{dq}G_x(q)$, we can extract a point estimate for the posterior probability

$$\hat{p}(1|x) = \int_0^1 q\, g_x(q) dq \tag{8}$$

and a corresponding classifier, which for a symmetric loss function is simply

$$\hat{f}(\hat{p}(1|x)) = \text{sgn}(\hat{p}(1|x) - 1/2). \tag{9}$$

The goal of classification is to build a classifier $\hat{f}$ that minimizes the overall risk

$$R = \int R[x, \hat{f}] p(x) dx \tag{10}$$

where the local risk at x is

$$R[x, \hat{f}] = \mathbb{E}_Y[L(y, \hat{f})] = \sum_{y=\pm 1} L(y, \hat{f}) p(Y = y|x). \tag{11}$$

In general, the exact local risk at x is unknown, as we do not know the exact posterior probabilities $p(y|x)$. Replacing these by their estimates gives

$$\widehat{R}[x, \hat{f}(\hat{p}(1|x))] = \sum_{y \pm 1} L(y, \hat{f}(\hat{p}(1|x)))\, \hat{p}(y|x). \tag{12}$$

Note that this formula does not take into account the inherent uncertainty in the estimate $\hat{p}(y|x)$. For example, a second-order distribution $G_x(q)$ with some spread and expectation of 1/2 implies that $p(1|x)$ *could* be much different from 1/2! In such cases, Eq. (12) is hence overly pessimistic.

A second-order distribution mitigates the overpessimism in such regions. A more balanced estimate of the risk that takes into account a second-order distribution is

$$\widehat{ER}[x] = \mathbb{E}_q[\widehat{R}[x, \hat{f}(q)]] = \int_0^1 \widehat{R}[x, \hat{f}(q)]\, g_x(q) dq \tag{13}$$

The intuition behind this estimate is as follows: if the second-order distribution has significant mass near both limits of its domain (i.e., it has a high density for values of $q = \hat{p}(y|x)$ close to 0 and 1), then it may be possible to construct a classifier with low risk at x, by querying additional labels in its neighborhood. As an extreme example, consider a second-order distribution for $\hat{p}(Y=1|x)$ given by Bernoulli(0.5), which implies that the conditional probability of class +1 is either 0 or 1. Then, $\widehat{R}[x] = 0.5$, but $\widehat{ER}[x] = 0$. This fact is taken into account by Eq. (13) but not by Eq. (12).

It is easy to prove that for any density $g_x(q)$, from which $\hat{p}(1|x)$ and $\hat{f}$ are derived via Eqs. (8) and (9), $\widehat{R}[x] \geq \widehat{ER}[x]$. Moreover, equality holds iff the entire mass of the second-order distribution lies on one side of the decision threshold, or if it is a Dirac distribution at 1/2. Interestingly, in these two cases it is of no benefit to query the label at x.

These properties suggest that the difference $\hat{R}[x] - \widehat{ER}[x]$ is a good indicator for the potential importance of acquiring a label at x, though other choices seem possible. Consequently, taking also into account that the *overall* risk is a density-weighted mean of the local risk (see Eq. (10)), we propose the following training utility value (TUV):

$$TUV(x) = \left(\widehat{R}[x] - \widehat{ER}[x]\right) \cdot \hat{p}(x) \tag{14}$$

where $\hat{p}(x)$ is some (non-parametric) estimate of the density at x. The weighting by the total density concentrates the learning effort on those regions

Table 1: One iteration of DEAL

Algorithm DEAL
Input: Labeled set $\mathcal{L}$, unlabeled set $\mathcal{U}$.
Output: Selected sample $x \in \mathcal{U}$ and its label $y(x)$
Algorithm:
1: compute density estimate $\hat{p}(x)$
2: for all $x \in \mathcal{U}$ do
- compute second-order distribution of $\hat{p}(Y=1\|x)$ by Eq. (6)
- compute $TUV(x)$ by Eq. (14)
3: query label y of $x \in \mathcal{U}$ with largest TUV

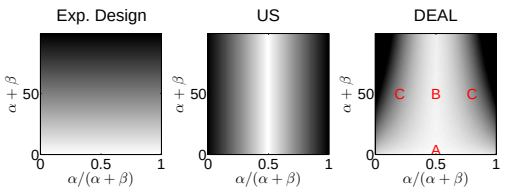


Figure 2: Training utility values, as a function of the two parameters $\alpha/(\alpha+\beta)$ and $\alpha+\beta$ in a second-order distribution of type $Beta(\alpha,\beta)$, for space-filling experimental design (Sacks et al., 1989), uncertainty sampling and DEAL. Roughly, α and β measure the local amount of evidence for either class (Eqs. (6),(7)). Not taking sample density into account, the most interesting points for DEAL are those with little evidence for either class as yet (A), followed by points with evidence for both classes (B), followed by points with strong evidence for one and little for the other class (C). In contrast, US merely takes into account the distance from the decision boundary, pretending (A)≡(B). Space-filling experimental design prefers unexplored regions, regardless of their estimated class conditional probabilities, so that (B)≡(C).

of feature space that are actually relevant. Table 1 describes the pseudo-code of a single iteration of DEAL. Of course, the density estimate $\hat{p}(x)$ need be computed only once at the start of the AL process. Fig. 2 compares the TUV of DEAL to criteria used in experimental design and for US.

5 RESULTS

We compare the empirical performance of DEAL to that of random sampling (RS), uncertainty sampling (US) (Lewis and Gale, 1994) and error reduction sampling (ERS) (Roy and McCallum, 2001). For a meaningful comparison, all methods use the same kernel density classifier, with an isotropic Gaussian kernel whose bandwidth is chosen according to the normal reference rule (Scott, 1992, chapter 6). The density $\hat{p}(x)$ in Eq. (14) is also estimated by kernel density estimation with the same kernel and bandwidth selection rule.

As is well known, non-parametric kernel density estimation with a limited number of samples may be highly inaccurate in high dimensions (Scott, 1992, chapter 7). Therefore, we first project the data to its d leading principal components, where the dimension d is chosen according to the resampling via permutation scheme of (Zhu and Ghodsi, 2006), with the minimum number of components set to two.

We always start with an empty set $\mathcal{L}$ of labeled points. In case of RS, US and ERS, the first query points are selected randomly until there is at least one label for each class. In case of DEAL, its deterministic strategy can be applied from the very beginning, with the first label requested for the point with the highest density estimate. In all our experiments, we set $\delta = 0.5$, consistent with Jeffreys' prior for the Bernoulli distribution (Jeffreys, 1946).

5.1 UCI DATA SETS BENCHMARK

We considered 32 of the most frequently used UCI data sets[3]. Each dataset was preprocessed as follows: (i) Categorical variables with more than two outcomes were replaced by #outcomes-1 indicator variables, (ii) missing values in categorical variables were treated as a separate outcome, (iii) missing values in continuous inputs were replaced by the respective mean, and (iv) the data was normalized to unit variance in each dimension. If a dataset

[3]We excluded datasets with only categorical variables, or with significant missing data. We did not exclude datasets on which our AL scheme did not perform well.

had more than two classes, the classes were joined to create binary problems such that the new classes were approximately equally abundant.

All results are obtained from 10-fold cross validation (CV), i.e., nine tenths of the data were used in active learning, with one tenth reserved for testing. To average out the randomness of the initial labeling for RS, US and ERS, all experiments are repeated 5 times for each of the 10 CV folds. Fig. 3(a) shows

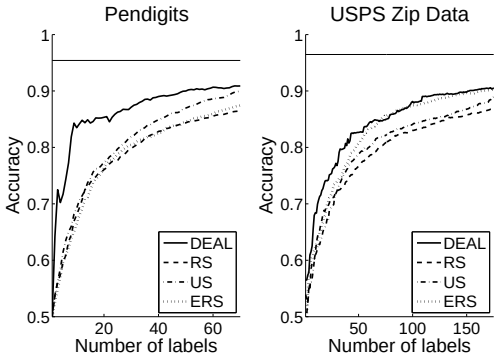

Figure 3: Learning curves for two data sets ("Pendigits" and "USPS, Grouping 10") where DEAL works well. Note that DEAL does not outperform the competing methods on every single data set, but on average across multiple data sets (see tables). The top horizontal line is the asymptotic performance of the classifier, at the end of the complete learning curve (estimated by 10-fold CV for UCI and on separate test set for the USPS data).

the learning curve for the Pendigits dataset. All others appear in the supplementary material.

To reward both initial steepness of the learning curve and early convergence to a high accuracy, we propose to measure performance by the area under the learning curve. All curves are truncated when the worst method achieves 90% of the accuracy of the classifier trained with the completely labeled training data[4], but at the latest after 200 iterations. As we compare only the relative performance

[4]Defined as the average of the 10-fold CV accuracies, each with a different set of 9/10 of the data fully labeled.

Table 2: Average accuracy of the compared AL strategies for 32 data sets from the UCI database with preprocessing as described in text, where n is the total size of the data set and d the dimension of the PCA subspace. The mean rank is computed based on ordering the performance of the AL strategies for each data set. The best and second best methods are indicated by bold font and italics, respectively. The mean rank test statistic is used for the statistical hypothesis tests described in the text.

sets are presented in Table 2.

We compare the performance of the different strategies as recommended in (Demšar, 2006). The Friedman test, which uses the mean performance ranks of Table 2, yields a p-value of $p = 2.53 \times 10^{-9}$ for the null hypothesis of equal performance of all strategies. For comparing all classifiers to each other, we use the two-tailed Nemenyi test. At a 1% significance level its threshold for differences in Mean Rank is 1.004. This means that DEAL performs significantly better than each of the other strategies. The performances of the other methods do not differ significantly from each other, even at the 10% level (corresponding to a threshold of 0.739).

5.2 USPS ZIP DATA

To obtain challenging classification tasks with convoluted decision boundaries, the digit images from the USPS corpus (LeCun et al., 1990) were grouped into two classes in various ways, see Table 3. All images were projected to the $d = 39$ leading principal components, with 7291 samples eligible for active learning and an independent set of 2007 samples held out for testing purposes.

Table 4: Average accuracy of the compared AL strategies for 3 different groupings of the Caltech-4 data set with preprocessing as described in text. The best and second best method are indicated using bold font and italics, respectively.

Grouping	RS	US	ERS	DEAL
$\{1,2\}$ vs. $\{3,4\}$	0.818	*0.846*	0.807	**0.877**
$\{1,3\}$ vs. $\{2,4\}$	0.799	*0.829*	0.803	**0.840**
$\{1,4\}$ vs. $\{2,3\}$	0.803	*0.836*	0.797	**0.872**
Mean Rank	3.333	2.000	3.667	1.000

As Table 3 shows, DEAL performed best in 9 out of the 10 groupings. Fig. 3(b) shows one learning curve, all others are in the supplementary material.

5.3 CALTECH-4

Caltech-4 is a well established standard benchmark for object categorization (Fergus et al., 2003) and has also been used in AL (Kapoor et al., 2007). This dataset consists of 4 different image groups: airplanes (category 1; 800 images), rear views of cars (2; 1155), frontal faces (3; 435) and motorbikes (4; 798). Fig. 4 shows one example from each category. We represent the images by the "Color and Edge Directivity Descriptor" (CEDD) (Chatzichristofis and Boutalis, 2008). The resulting 144-dimensional features were then projected to the 17 leading principal components. To create challenging two-class problems with convoluted decision boundaries, we grouped the 4 categories in three possible ways.

Table 4 presents the resulting performances, based on 10-fold CV with 5 repetitions (see Section 5.1). It shows that DEAL performs best for all groupings. Moreover, for this dataset, US is the second best strategy, probably because the problem is not as challenging as the Zip Data, that originally consists of 10 categories. Interestingly, ERS performs worse than random sampling in two out of three tasks.

6 DISCUSSION

In this paper we derived a new AL strategy, which considers not only the density and distance of an

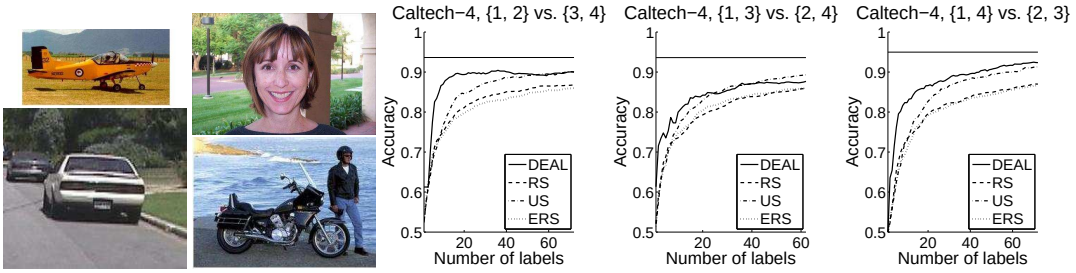

Figure 4: Left: Example images of the 4 object categories of Caltech-4 (airplane, car, face, motorbike). Right: Learning curves for three possible groupings of the 4 categories. DEAL performed best in all cases and US second best. Interestingly, ERS is not better than RS here (see also Table 4). The top horizontal line is the asymptotic accuracy of the classifier, with all training data labeled (estimated by 10-fold CV).

unlabeled sample to the decision boundary, but also the number of labeled points in its neighborhood. All this information is taken into account by requiring that the underlying classifier provide a distributional estimate at each unlabeled point, leading to a natural definition of its training utility value.

Information similar to that contained in a second-order distribution is *implicitly* used by methods that minimize the expected estimated risk (MacKay, 1992; Roy and McCallum, 2001; Zhu et al., 2003). These AL schemes indirectly measure the uncertainty of a point estimate, by perturbing the current classifier with hypothetical new labels and investing where the potential reduction in estimated risk is greatest.

In contrast, DEAL makes this dependence on the uncertainty explicit. Not only is it simple to implement, it also empirically outperformed error reduction sampling, uncertainty and random sampling schemes on a large collection of UCI, USPS and Caltech data sets. Note that one cannot expect a single strategy to perform best on all data sets. For instance, if the decision boundary is simple, strongly favoring exploitation over exploration (as in uncertainty sampling) may be the best strategy. For more challenging classification problems with complex class boundaries, balancing exploration and refinement, as DEAL does, seems a crucial ingredient for active learning.

While our AL scheme is general and applicable to any classifier that outputs second-order distributions, in this paper we focused for simplicity on its implementation with kernel density classification. As we shall describe in a future publication, second-order distributions can be derived for other classifiers, most notably random forest (Breiman, 2001). Encouragingly, with random forest as the base classifier, not only are lower classification errors achieved, but also the advantage of DEAL over the other AL strategies continues to hold.

Finally, we note that second-order distributions are not limited to AL. In the presence of few training data, they may be used to extend the "doubt" class to also include poorly explored regions with high uncertainty. While beyond the scope of this paper, second-order distributions are also useful for outlier detection, in applications such as optical inspection, where not all defects are known in advance when training the classifier. These extensions, as well as generalizing our AL scheme to multi-class problems, and deriving second-order distributions for other (discriminative) classifiers, are interesting topics for future research.

Abstract

The goal of phylodynamics, an area on the intersection of phylogenetics and population genetics, is to reconstruct population size dynamics from genetic data. Recently, a series of nonparametric Bayesian methods have been proposed for such demographic reconstructions. These methods rely on prior specifications based on Gaussian processes and proceed by approximating the posterior distribution of population size trajectories via Markov chain Monte Carlo (MCMC) methods. In this paper, we adapt an integrated nested Laplace approximation (INLA), a recently proposed approximate Bayesian inference for latent Gaussian models, to the estimation of population size trajectories. We show that when a genealogy of sampled individuals can be reliably estimated from genetic data, INLA enjoys high accuracy and can replace MCMC entirely. We demonstrate significant computational efficiency over the state-of-the-art MCMC methods. We illustrate INLA-based population size inference using simulations and genealogies of hepatitis C and human influenza viruses.

1 INTRODUCTION

Estimation of population size dynamics from molecular data is a fundamental task in ecology and public health. Since population size fluctuations affect the variability of population gene frequencies, current molecular sequence data provide information about the past population size trajectory. Such indirect inference is particularly useful in retrospective studies, where assessing past population sizes via sampling or fossil records is impossible. For example, RNA samples of hepatitis C virus (HCV) obtained in 1993 were sufficient to estimate the dynamics of HCV infections in Egypt from 1895 to 1993 (Pybus et al., 2003); and ancient and modern musk ox mitochondrial DNA samples, dated from 56,900 radiocarbon years old to contemporaneous, allowed for estimation of musk ox population dynamics throughout the late Pleistocene to the present (Campos et al., 2010).

Molecular sequence data of individuals sampled at a single time point (*isochronous* sampling) or at different points in time (*heterochronous* sampling) are related to each other via, a usually unknown, genealogical relationship. A genealogy is a rooted bifurcating tree that describes the ancestral relationships of the sampled individuals (left upper box in Figure 1). In the genealogy, each internal node indicates that the two lineages met a common ancestor. Such events are called *coalescent events*, and these events occur at *coalescent times*.

Kingman's coalescent (Kingman, 1982) is a probability model that describes a stochastic process of generating a genealogy of a random sample of molecular sequences given the effective population size (Nordborg, 2001; Hein et al., 2005). The original formulation, that considered only a constant population size, was later generalized to a variable population size (Slatkin and Hudson, 1991; Griffiths and Tavaré, 1994). Statistically, the coalescent model was an important advance, because it allowed for likelihood-based inference of population dynamics.

Many coalescent-based methods for estimation of effective population size trajectories have been developed over the last 10 years. For a recent review see (Ho and Shapiro, 2011). Some methods assume that a fixed genealogy is available (Fu, 1994; Pybus et al., 2000) and others may or may not consider the genealogical uncertainty and can produce estimates of population size trajectories from a fixed genealogy or directly from molecular data (Kuhner et al., 1995; Drummond et al., 2002, 2005; Minin et al., 2008). Felsenstein (1992) showed that likelihood-based methods that ac-

count for genealogical uncertainty are statistically the most efficient. However, all methods that incorporate genealogical uncertainty in population size dynamics reconstruction integrate over the space of genealogies using Markov chain Monte Carlo (MCMC). Such MCMC sampling of genealogies is computationally expensive. Sometimes, a single genealogy estimated from sequences that contain sufficient phylogenetic information is enough to estimate population trajectories accurately (Pybus et al., 2000; Minin et al., 2008). In this paper, we are interested in providing a fast estimation of population size trajectories from a fixed genealogy.

Some coalescent-based methods assume a simple parametric form of the population size trajectory (e.g., exponential or logistic growth), allowing the model parameters to be estimated by maximum likelihood or Bayesian methods. However, more flexible nonparametric methods are preferable for populations with poorly understood population dynamics, where it may be difficult to justify a simple parametric form of the population size trajectory. In fact, all recently developed methods rely on Bayesian nonparametric techniques to perform inference (Opgen-Rhein et al., 2005; Drummond et al., 2005; Heled and Drummond, 2008; Minin et al., 2008; Palacios and Minin, 2011). A common characteristic of most of these methods is the assumption of a piece-wise linear trajectory of effective population sizes and the possibility of the number of parameters growing with the number of samples. Bayesian skyline methods (Drummond et al., 2005; Heled and Drummond, 2008) and Opgen-Rhein et al. (2005) use multiple change point models to estimate population trajectories in a Bayesian framework. The method of Opgen-Rhein et al. (2005) is implemented only for a fixed genealogy. Recently, Bayesian nonparametric approaches that rely on Gaussian processes have been successfully implemented (Minin et al., 2008; Palacios and Minin, 2011). These methods model the effective population size as a function of a Gaussian process (GP) *a priori*, providing more flexible priors than previous Bayesian nonparametric methods.

GP-based models use MCMC methods to perform Bayesian inference. We show that when the genealogy remains fixed, these models fall into a general class of latent Gaussian models, for which integrated nested Laplace approximation (INLA) can be used to perform computationally efficient approximate Bayesian inference (Rue et al., 2009; Illian et al., 2012). Here, we adapt the INLA methodology to the estimation of population size trajectories and replace MCMC entirely. Our approximation is accurate and much faster than MCMC, while still providing the benefits of the Gaussian process-based Bayesian nonparametric approach. We illustrate the performance of our method with simulated and two real data sets.

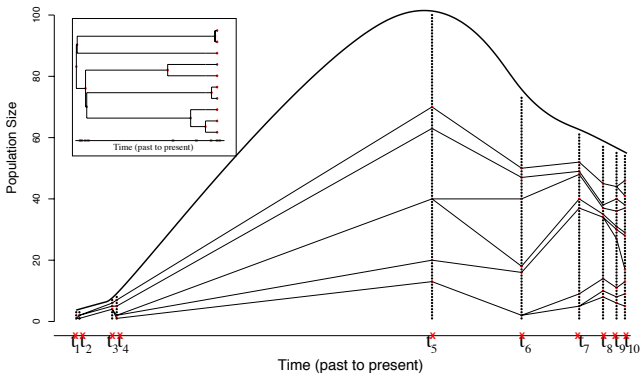

Figure 1: Example of a genealogy of 10 individuals randomly sampled at time t_{10} (red circles) from the population depicted as black circles. When we follow the ancestry of the samples back in time, two of those lineages coalesce at time t_9, the rest of the lineages continue to coalesce until the time to the most recent common ancestor of the sample at time t_1. The population size trajectory is shown as the solid black curve. When the population size is large (around t_5), for any pair of lineages that exist at time t_5 (red circles at t_5), it takes longer to meet their most recent common ancestor (t_4). The upper left box shows the genealogy reconstructed by following the ancestry of the 10 sampled individuals. The genealogy in the upper left corner is the aligned representation of the genealogy depicted in the main plot.

2 COALESCENT BACKGROUND

We assume that a genealogy with time measured in units of generations is available. Let $t_n = 0$ denote the present time when all n available sequences are sampled (*isochronous*) and let $t_n = 0 < t_{n-1} < ... < t_1$ denote the coalescent times of lineages in the genealogy. Figure 1 depicts an example of such a genealogy with time going backwards, that is, the first coalescent time occurred t_{n-1} generations ago and all the samples meet the common ancestor t_1 generations ago. Let $N_e(t)$ denote the time evolution of the effective population size as we move into the past. Then, the conditional density of the coalescent time t_{k-1}, given the previous coalescent time t_k, takes the following form:

$$P[t_{k-1}|t_k, N_e(t)] = \frac{C_k \exp\left[-\int_{t_k}^{t_{k-1}} \frac{C_k}{N_e(t)} dt\right]}{N_e(t_{k-1})}, \quad (1)$$

where $C_k = \binom{k}{2}$ is the coalescent factor that depends on the number of lineages $k = 2, ..., n$, meaning that the density for the next coalescent time is quadratic in the number of lineages and inversely proportional to the effective population size. The larger the popu-

lation size, the more genetic variability is in the population and hence, the longer it takes for two lineages to coalesce. The larger the number of lineages, the faster two of them meet their common ancestor. Figure 1 shows an example of a population that experiences growth and then a decay in population size. In this case, no pair of lineages coalesces between times t_4 and t_5, because the population is large during this time interval, while it takes little time for a pair of lineages to find their common ancestor after time t_4, when the population size becomes very small.

The *heterochronous* coalescent arises when samples of sequences are collected at different times. The conditional density of a coalescent time t_{k-1} is slightly different than Eq. 1 since it takes into account the fact that the number of lineages at each time point depends not only on the number of coalescent events (in which case, the number of lineages decreases by one each time), but also on the new samples incorporated into the analysis at any time after the last coalescent time t_k. The details of the heterochronous coalescent are omitted for brevity, however, all methods described here have been implemented to incorporate heterochronous sampling. See (Felsenstein and Rodrigo, 1999) and (Drummond et al., 2002) for a more detailed account of heterochronous sampling.

Under this coalescent-based framework, we ignore the effects of population structure, recombination and selection (Nordborg, 2001). The parameter of interest, the effective population size, can be used to approximate census population size by knowing the generation time in calendar units and the population variability in the number of offspring. The latter quantity might be difficult to know *a priori*, however, sometimes it suffices to analyze an arbitrarily rescaled population size trajectory, assuming the variability in the number of offspring remains constant.

2.1 ESTIMATION OF $N_e(t)$ USING A DISCRETE-TIME GMRF

There are two approaches to estimation of effective population size trajectories that use Gaussian processes. The first approach, developed by Minin et al. (2008), assumes *a priori* that given a genealogy, the effective population size trajectory is a piecewise constant trajectory with change points (knots) placed at coalescent times. That is,

$$N_e(t) = \sum_{k=2}^{n} \exp(\gamma_k)\, 1_{(t_k, t_{k-1}]}(t), \tag{2}$$

where

$$\boldsymbol{\gamma} = (\gamma_2, ..., \gamma_k) \sim MVN\left(0, (\tau \mathbf{Q})^{-\mathbf{1}}\right) \text{ and}$$

$$1_{(t_k, t_{k-1}]}(t) = \begin{cases} 1 & \text{if } t \in (t_k, t_{k-1}], \\ 0 & \text{otherwise.} \end{cases}$$

More specifically, *a priori* $\boldsymbol{\gamma}$ is assumed to be an intrinsic Gaussian Markov random field (GMRF) on a chain graph connecting nodes 2 through n. Minin et al. (2008) used a random walk of the first order (rw1) on an irregular grid of mid-points of inter-coalescent time intervals. For this reason, we refer to this method here as the coalescent grid Gaussian process (CGGP). The random walk construction implies that matrix $\mathbf{Q}$ is tridiagonal and positive semidefinite (hence the intrinsic GMRF). See (Rue and Held, 2005) for background on GMRFs. The precision parameter τ has a Gamma prior distribution with $\alpha = \beta = 0.001$. The authors estimate $\boldsymbol{\gamma}$ and τ by MCMC sampling from the posterior distribution of these parameters. The estimated trajectory and the corresponding uncertainty are reported in the form of pointwise posterior medians and 95% Bayesian credible intervals (BCIs) obtained from the MCMC samples.

2.2 ESTIMATION OF $N_e(t)$ USING A CONTINUOUS-TIME GP

Instead of modelling $N_e(t)$ as a piecewise continuous function *a priori*, Palacios and Minin (2011) propose a more flexible prior specification and place a transformed Gaussian process prior on $N_e(t)$. The transformation is a sigmoidal function with a lower bound. This particular transformation is required by the authors in order to perform exact posterior inference via a data augmentation scheme, which is similar to the work of Adams et al. (2009). However, a log-Gaussian transformation using a finely discretized Gaussian process, in principle, would produce similar results (Møller et al., 1998; Adams et al., 2009).

2.2.1 EXACT POSTERIOR INFERENCE WITH GP

Palacios and Minin (2011) place the following prior on $N_e(t)$:

$$N_e(t) = \left(\frac{\lambda}{1 + \exp[-\gamma(t)]}\right)^{-1}, \tag{3}$$

where

$$\gamma(t) \sim \mathcal{GP}(0, C) \tag{4}$$

and $\mathcal{GP}(0, C)$ denotes a Gaussian process with mean function 0 and covariance function C. A Gaussian process restricted to finite data is a multivariate Gaussian distribution. That is, $\gamma(t_1), ..., \gamma(t_B) \sim MVN(\mathbf{0}, \boldsymbol{\Sigma})$. *A priori*, $1/N_e(t)$ is a sigmoidal Gaussian process, a scaled logistic function of a Gaussian process which range is restricted to lie in $[0, \lambda]$; λ is a positive constant hyperparameter, inverse of which serves as a

lower bound of $N_e(t)$ (Adams et al., 2009). The likelihood function is the product of the conditional densities in Eq. 1 and involves integration of $N_e(t)$, that under the $\mathcal{GP}$ assumption, is intractable. The authors, following earlier work by Adams et al. (2009) on Poisson processes, do inference assuming an augmented data likelihood which allows to bypass intractability in the likelihood. The authors implement their method for the Brownian motion $\mathcal{GP}$ with a precision parameter τ. They place a Gamma prior distribution on the precision hyperparameter τ with $\alpha = \beta = 0.001$ and a mixture of uniform and exponential distributions on an upper bound of $1/N_e(t)$ (or equivalently, a lower bound on $N_e(t)$) as follows:

$$P(\lambda) = \epsilon \frac{1}{\hat{\lambda}} I_{\{\lambda < \hat{\lambda}\}} + (1-\epsilon)\frac{1}{\hat{\lambda}} e^{-\frac{1}{\hat{\lambda}}(\lambda - \hat{\lambda})} I_{\{\lambda \geq \hat{\lambda}\}}, \quad (5)$$

where $\epsilon > 0$ is a mixing proportion and $\hat{\lambda}$ is our best guess of the upper bound, possibly obtained from previous studies. The authors estimate τ and $N_e(t)$, or equivalently, τ, $\gamma(t)$ and λ by MCMC sampling from the posterior distribution of these parameters. The estimated trajectory and the corresponding uncertainty are reported in the form of the pointwise posterior medians and 95% BCIs evaluated at a grid of points $\{s_1, ..., s_B\}$ obtained from the MCMC samples. This grid can be made as fine as necessary after the MCMC is finished. The values of $\{\gamma(s_1), \gamma(s_2), .., .\gamma(s_B)\}$ are obtained via the $\mathcal{GP}$ predictive distribution conditioning on the values of each iteration. This method will be referred to as exact Gaussian process (EGP).

2.2.2 DISCRETIZED CONTINUOUS-TIME GP

The continuous-time version of the prior specified in Eq. 2, is

$$N_e(t) = \exp\left[\gamma(t)\right], \quad (6)$$

where $\gamma(t)$ is the Gaussian process described in Eq. 4. However, for the same reason described in section 2.2.1, the likelihood function becomes intractable. Palacios and Minin (2011) showed that estimation of the effective population size is analogous to the estimation of an inhomogeneous intensity of a point process. In this context, and under the prior described in Eq. 6, estimation of $N_e(t)$ is computationally equivalent to the estimation of the intensity function of a Log-Gaussian Cox process (Møller et al., 1998). In a Log-Gaussian Cox process, the likelihood is commonly approximated by discretization. The approximation method proceeds by constructing a fine regular grid $\{s_1, ..., s_B\}$ over the observation window and approximate

$$\int \frac{dt}{N_e(t)} = \int \exp\left[-\gamma(t)\right] dt, \quad (7)$$

by

$$\sum_{j=2}^{B} \exp\left(-\gamma_j^*\right) \Delta, \quad (8)$$

where Δ is the distance between grid points, and γ_j^* is a representative value of $\gamma(t)$ in the interval (s_{j-1}, s_j), usually $\gamma((s_j - s_{j-1})/2)$. Note that if the Gaussian process is a Brownian motion process, this approximation is similar to the CGGP method described in section 2.1. The difference is in the construction of the grid. In the CGGP method, the grid is irregular and determined by the coalescent times. For this reason, we call approximation (8) a regular grid Gaussian process (RGGP).

3 INTEGRATED NESTED LAPLACE APPROXIMATION

INLA provides fast and accurate Bayesian approximation to posterior marginals in *latent Gaussian models* (Rue et al., 2009). Latent Gaussian models are a wide class of hierarchical models in which the response variables $\mathbf{y} = (y_1, \ldots, y_n)$ are assumed to be conditionally independent given some latent parameters $\boldsymbol{\eta} = (\eta_1, \ldots, \eta_n)$ and other parameters $\boldsymbol{\theta}_1$. The second hierarchical level corresponds to specifying $\boldsymbol{\eta}$ as a function of a GMRF $\mathbf{x} = (x_1, \ldots, x_n)$ with a precision matrix $\mathbf{Q}$ and hyperparameters $\boldsymbol{\theta}_2$, and the third and last hierarchical stage corresponds to prior specifications for the hyperparameters $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$ Formally,

$$\pi(\mathbf{y}|\boldsymbol{\eta}, \boldsymbol{\theta}_1) = \prod_j \pi(y_j|\eta_j(x_j), \boldsymbol{\theta}_1), \quad (9)$$

$$\mathbf{x} \sim MVN(\mathbf{0}, \mathbf{Q}^{-1}(\boldsymbol{\theta}_2)), \quad (10)$$

and

$$\boldsymbol{\theta} \sim P(\boldsymbol{\theta}). \quad (11)$$

An interface in `R`, called `INLA`, implements a wide variety of likelihoods (Eq. 9), link functions ($\boldsymbol{\eta}$) and GMRFs (Eq. 10), including the Poisson likelihood model for each observed value of y_j (not necessarily the same for every y_j) with a logarithmic additive link function and random walk of first order as a GMRF. See `www.r-inla.org` for documentation.

The coalescent with variable population size (Eq. 1), together with the GMRF prior specification (Eq. 2) falls into the latent Gaussian model class, so INLA can be implemented for these coalescent models. In the case of the continuously specified $\mathcal{GP}$ (section 2.2), the approximate posterior method described in Section 2.2.2 (RGGP) also falls into the latent Gaussian model class.

3.1 INLA FOR PHYLODYNAMICS

Although INLA is implemented for a wide variety of latent Gaussian models, we will only describe the main steps of the approximation for posterior inference of effective population size trajectories. A typical summary of the posterior distribution of the effective population size trajectory, $N_e(t)$, is described by posterior medians and 95% BCIs evaluated pointwise on a grid of time points. These values can be obtained from the posterior marginals of the population trajectory on the grid. For the CGGP model described in section 2.1, we then wish to obtain the posterior marginals

$$\Pr(\gamma_i|\mathbf{t}) = \int_0^\infty \Pr(\gamma_i|\tau,\mathbf{t})\Pr(\tau|\mathbf{t})d\tau, i = 2,..,n \quad (12)$$

and

$$\Pr(\tau|\mathbf{t}), \quad (13)$$

where $\mathbf{t}$ denotes the vector of coalescent times. A nested procedure is used to construct approximations of $\Pr(\gamma_i|\tau,\mathbf{t})$ and $\Pr(\tau|\mathbf{t})$ first and then numerically integrate out τ to arrive at $\Pr(\gamma_i|\mathbf{t})$. The approximation of the marginal of τ is

$$\tilde{\Pr}(\tau|\mathbf{t}) \propto \left.\frac{\Pr(\boldsymbol{\gamma},\tau,\mathbf{t})}{\tilde{\Pr}_{\mathbf{G}}(\boldsymbol{\gamma}|\tau,\mathbf{t})}\right|_{\boldsymbol{\gamma}^*(\tau)}, \quad (14)$$

where $\boldsymbol{\gamma}^*(\tau)$ is the mode of the full conditional $\Pr(\boldsymbol{\gamma}|\tau,\mathbf{t})$, obtained using the Newton-Raphson algorithm, and $\tilde{\Pr}_G(\boldsymbol{\gamma}|\tau,\mathbf{t})$ is the Gaussian approximation of this full conditional constructed via a Taylor expansion around $\boldsymbol{\gamma}^*(\tau)$. The resulting $\tilde{\Pr}_G(\boldsymbol{\gamma}|\tau,\mathbf{t})$ is a Gaussian distribution with mean $\boldsymbol{\gamma}^*$ and precision matrix $\mathbf{Q}$ +diag($\mathbf{c}$), where $\mathbf{Q}$ is the prior precision matrix of the GMRF $\boldsymbol{\gamma}$ and a vector $\mathbf{c}$ consists of the second order Taylor series coefficients.

The approximation to the full conditional $\Pr(\gamma_i|\tau,\mathbf{t})$ is the following:

$$\tilde{\Pr}(\gamma_i|\tau,\mathbf{t}) \propto \left.\frac{\Pr(\boldsymbol{\gamma},\tau,\mathbf{t})}{\tilde{\Pr}_{\mathbf{G}}(\boldsymbol{\gamma}_{-i}|\tau,\mathbf{t})}\right|_{\boldsymbol{\gamma}^*_{-i}}, \quad (15)$$

where $\boldsymbol{\gamma}^*_{-i} = \mathrm{E}_G(\boldsymbol{\gamma}_{-i}|\gamma_i,\tau,\mathbf{t})$ and $\tilde{\Pr}_G(\boldsymbol{\gamma}_{-i}|\tau,\mathbf{t})$ are derived from $\tilde{\Pr}_G(\boldsymbol{\gamma}|\tau,\mathbf{t})$.

For the continuously specified GP approximation described in section 2.2.2, the INLA approximation is, in essence the same, but the GMRF is placed at the mid-points of a finer and regular grid. In this case, there are two levels of approximation, one level corresponding to the likelihood discretization and another level corresponding to the approximation of marginal posterior distributions of model parameters.

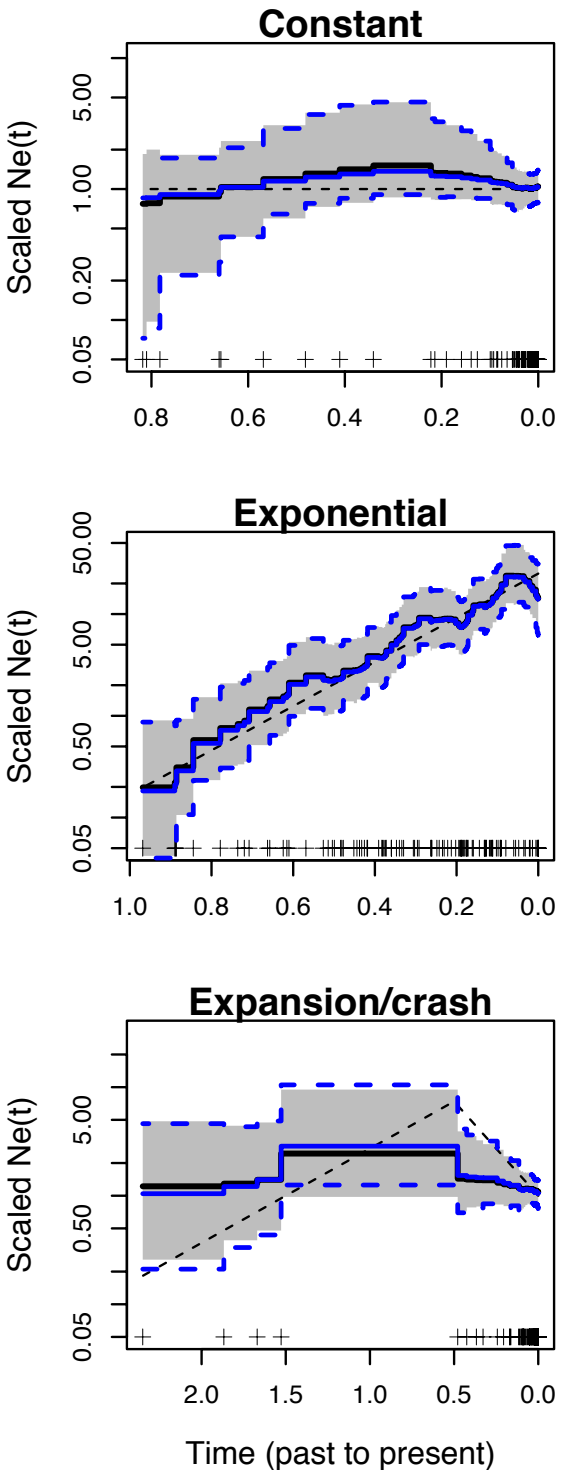

Figure 2: INLA vs MCMC for CGGP: Simulated data under the constant population size (first row), exponential growth (second row) and expansion followed by a crash (third row). The true trajectories are represented by black dashed lines. We show posterior medians estimated with MCMC sampling (solid black lines) and 95% BCIs estimated with MCMC (gray shaded areas). Posterior medians obtained using INLA are denoted by solid blue lines and INLA 95% BCIs are shown as dashed blue lines.

4 RESULTS

4.1 SIMULATED DATA

We compare INLA and MCMC approaches for the models described in sections 2.1 and 2.2. We simulate three genealogies relating $n = 100$ individuals under the following demographic scenarios:

1. Constant population size trajectory: $N_e(t) = 1$.
2. Exponential growth: $N_e(t) = 25e^{-5t}$.
3. Population expansion followed by a crash:

$$N_e(t) = \begin{cases} e^{4t} & t \in [0, 0.5], \\ e^{-2t+3} & t \in (0.5, \infty). \end{cases} \quad (16)$$

Figure 2 shows the log effective population size trajectories recovered for the three scenarios under the CGGP model using the MCMC approach (black lines and gray shaded areas) and the INLA approach (blue dark lines and blue dashed lines). In all the cases, the INLA approximation is very close to the results obtained using MCMC.

Figure 3 shows the log effective population size trajectories recovered for the same three scenarios for the continuously specified GP. In this case, the comparison is not entirely fair because we are comparing the exact MCMC method (EGP) with the doubly approximated INLA on the RGGP model. Nevertheless, both estimations look very similar for the last two cases (exponential growth and expansion followed by crash). In all cases, INLA results are very similar to the results for the CGGP model and the difference between the MCMC method and INLA methods in the constant trajectory example could be an artifact of the likelihood approximation and the convergence of the MCMC method. However, a more likely explanation is poor approximation of the marginal posterior of the Brownian motion precision, τ, by INLA. Indeed, when we examined MCMC-based and INLA-based marginal posteriors of τ, we found that the two marginals did not agree at all.

4.2 HEPATITIS C VIRUS IN EGYPT

We analyze a genealogy estimated from 63 HCV E1 sequences sampled in 1993 in Egypt. This is perhaps the most commonly used dataset for evaluating different methodologies for estimation of population size trajectories. Minin et al. (2008) compared population size trajectories recovered from a single fixed genealogy and from the sequence data directly. The authors show that there is little difference between these two

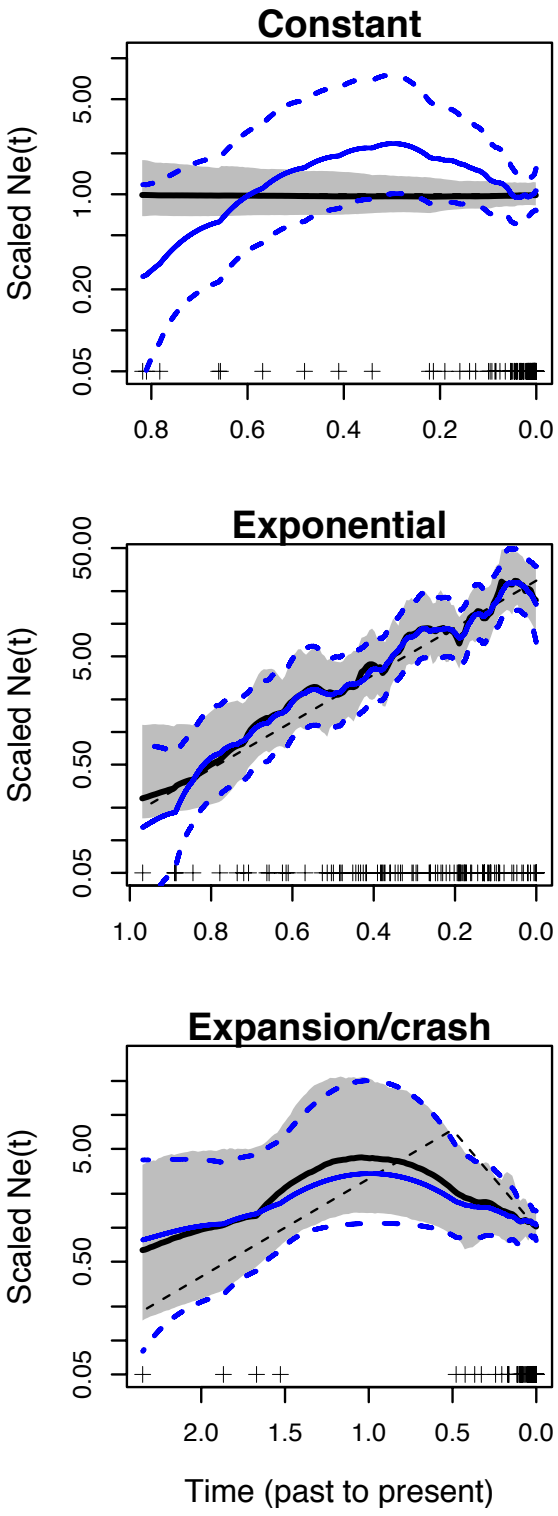

Figure 3: INLA vs MCMC for RGGP and EGP respectively: see Figure 2 for the legend.

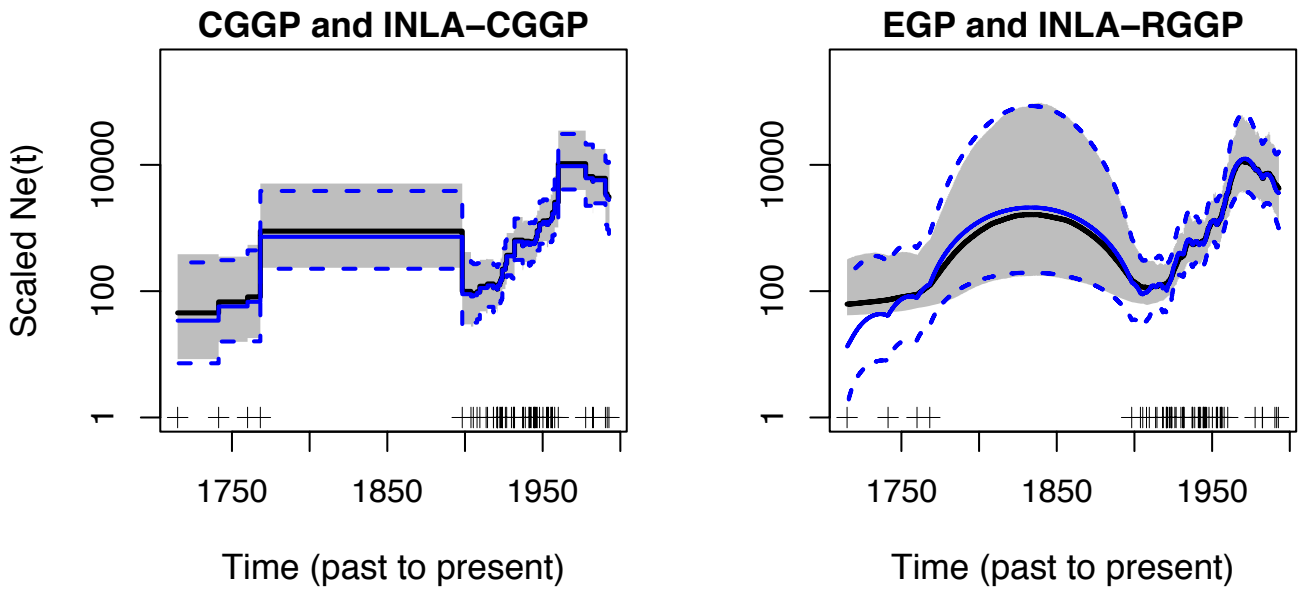

Figure 4: HCV in Egypt. Estimation of the log effective population size trajectories. In both plots, INLA approximations to posterior medians and 95% BCIs are represented by blue solid lines and blue dashed lines respectively. Approximations using MCMC sampling are represented by black solid lines and shaded areas. The left plot shows the results assuming the CGGP model and the right plot shows the result assuming the EGP for the MCMC sampling results and the RGGP model for the INLA approximation.

estimation protocols. They argue that in this case genealogical uncertainty does not play a significant role in the estimation of the Egyptian HCV population dynamics.

Figure 4 shows the recovered effective population sizes as black lines and uncertainty as gray shaded areas for the CGGP (left plot) and the EGP (right plot) using MCMC and as blue solid lines and blue dashed lines for the INLA approximation for CGGP (left plot) and RGGP (right plot). In this case, it is remarkable how similar the INLA approximations are to the MCMC results, even for the continuously specified model with the double approximation (INLA-RGGP). In all cases, the known aspects of the HCV epidemic in Egypt are recovered: an exponential growth starting around 1920s and a decline in population size after 1970s (Pybus et al., 2003).

4.3 INFLUENZA A VIRUS IN NEW YORK

We analyze a genealogy estimated from 288 H3N2 sequences sampled in New York state from January, 2001 to March, 2005 to estimate population size dynamics of human influenza A in New York. This genealogy has also been analyzed before (Palacios and Minin, 2011) and can be obtained from the authors. The key aspects of the influenza A virus epidemic in temperate regions like New York are the epidemic peaks during winters followed by strong bottlenecks at the end of the winter season. The first plot in Figure 5 shows the recovered population size trajectories assuming the CGGP model. In this case, the MCMC and the INLA approximation deviate from each other substantially, however, the expected peaks during the winter seasons in 2002, 2004 and 2005 are recovered by both methods. The MCMC approach does not recover a peak in the 2003 season, while the INLA approximation resemble more the results from the continuously specified model. INLA and MCMC results are very similar for the continuously specified model (right plot of Figure 5) with the notable differences in 95% BCIs near the time to the most recent common ancestor. This difference again may be an artifact of the double approximation involved.

4.4 RUNNING TIMES

The MCMC chains used for the CGGP model have length 1,000,000 with 100,000 of burn-in and generated using the BEAST software (Drummond and Rambaut, 2007; Minin et al., 2008) on a desktop PC. The running times range from 20 minutes to a couple of hours depending on the data. For the INLA approach, results were generated using the `R` interface `INLA` on the same computer in less than 2 seconds for all scenarios.

For the continuously specified GP model described in section 2.2, MCMC times are at best as fast as MCMC for the CGGP approach, while the results obtained

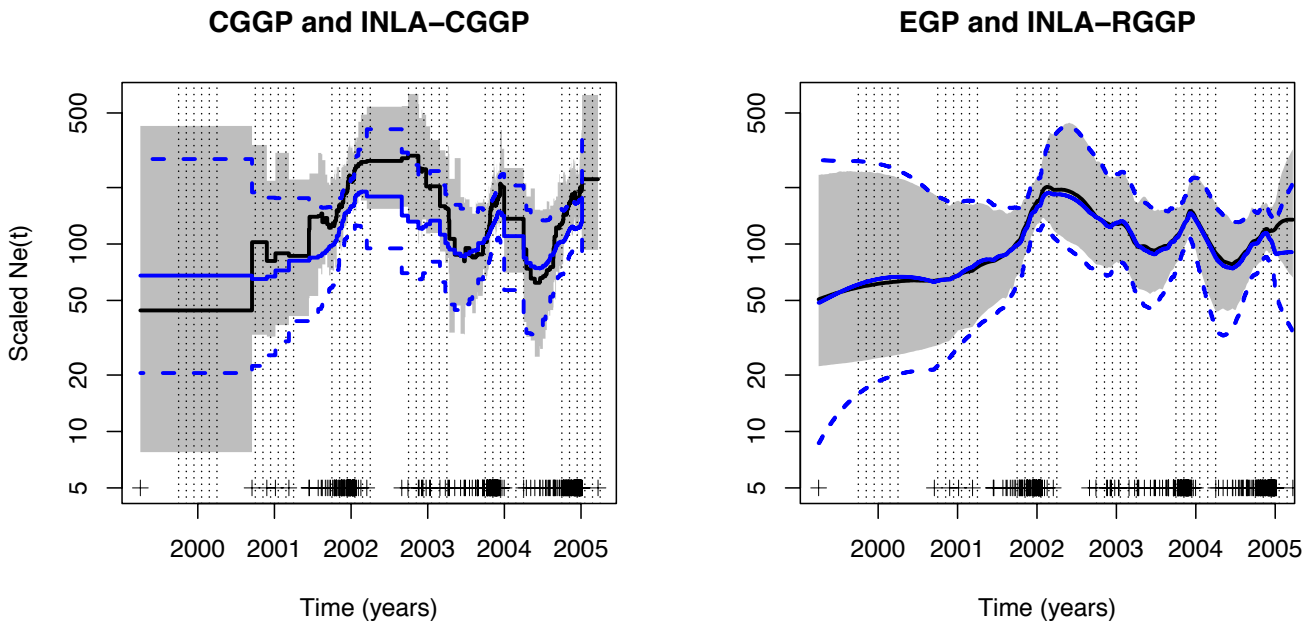

Figure 5: Influenza A in New York. Estimation of the log effective population size trajectories. In both plots, INLA approximations to posterior medians and 95% BCIs are represented by blue solid lines and blue dashed lines respectively. Approximations using MCMC sampling are represented by black solid lines and shaded areas. The left plot shows the results assuming the CGGP model and the right plot shows the result assuming the EGP for the MCMC sampling results and the RGGP model for the INLA approximation.

using `INLA`, were generated in less than 5 seconds on a grid of size 1000.

5 DISCUSSION

We show that recent Gaussian process-based Bayesian nonparametric approaches to estimation of effective population size trajectories fall into a larger class of latent Gaussian models, allowing us to perform approximate Bayesian inference using INLA. We show that it is possible to estimate population size trajectories from fixed genealogies in seconds without sacrificing any modeling advantages of recently developed Bayesian nonparametric methods.

We did observe a significant discrepancy between the INLA approximation and MCMC inference for the continuously specified GP model in the case of constant population size. We want to point out that in this case, we are not comparing apples to apples. We should be comparing INLA approximation to the MCMC for the regular grid approximation of the continuously specified GP. However, we did not have access to approximate GP-based MCMC for phylodynamics. In the absence of a better option, we are comparing INLA to the *exact* MCMC for this GP model (Palacios and Minin, 2011). Therefore, we remain uncertain whether the grid approximation or the INLA approximation is to blame for the discrepancy observed in the top plot of Figure 2. The discrepancy between the marginal posterior distributions estimated by INLA and MCMC and the fact that the precision of the RGGP likelihood discretization did not have any effect on our results suggest that INLA approximation indeed fails in this simulation scenario. This assertion is supported by another disagreement of INLA and MCMC for the CGGP model in the influenza A example, where we are comparing apples to apples.

A natural extension of the methods presented here is the incorporation of genealogical uncertainty into the model. This extension can be accomplished by introducing another level of hierarchical modeling and analyzing molecular data directly (Drummond et al., 2005; Minin et al., 2008). Even though the full posterior distribution of population trajectories from molecular sequence data no longer falls into the latent Gaussian model class, we believe that the extension is possible using Metropolis independence sampler (Rue et al., 2004). Nevertheless, the ability to obtain fast estimates of population size trajectories from a fixed genealogy (as with INLA) should be a boon for biological researchers who need to screen multiple populations of interest quickly or to provide an online analysis of epidemic outbreaks with enormous flow of molecular data in real time (Fraser et al., 2009).

There are other approaches to the estimation of effec-

tive population sizes under more complicated coalescent models that include recombination (McVean and Cardin, 2005; Li and Durbin, 2011). These methods assume a simple change point model for the effective population size trajectory. In principle, Bayesian nonparametric approaches similar to the approaches discussed here can be applied in this setting. However, presence of recombination makes such extensions potentially challenging.

Other approximate Bayesian methods could be applied to Bayesian nonparametric phylodynamics, such as variational Bayes (VB) (Bishop, 2006) and expectation propagation (EP) (Cseke and Heskes, 2010). For our particular application with a sparse GP prior, such as Brownian motion, Cseke and Heskes (2010) show that INLA should be faster than EP methods.

From imprecise probability assessments to conditional probabilities with quasi additive classes of conditioning events

Abstract

In this paper, starting from a *generalized coherent* (i.e. avoiding uniform loss) interval-valued probability assessment on a finite family of conditional events, we construct conditional probabilities with *quasi additive* classes of conditioning events which are consistent with the given initial assessment. Quasi additivity assures coherence for the obtained conditional probabilities. In order to reach our goal we define a finite sequence of conditional probabilities by exploiting some theoretical results on g-coherence. In particular, we use solutions of a finite sequence of linear systems.

1 Introduction

In many applications of Artificial Intelligence we need to reason with uncertain information under vague or partial knowledge. A possible approach to uncertain reasoning can be based on imprecise probabilistic assessments on a family of conditional events which has no particular algebraic structure. In such a case a general framework is obtained by using suitable generalizations of the coherence principle of de Finetti (de Finetti [1974]), or similar principles adopted for lower and upper probabilities. A further advantage of using these approaches is given by the possibility of looking at the conditional probability $P(E|H)$ as a primitive concept, with no need of assuming that the probability of the conditioning event H be positive. In the past, the coherence-based approach to probabilistic reasoning has covered several natural semantics for conditionals, included the ones used in default reasoning such as System P (see, e.g., Gilio [2002], Biazzo et al. [2005], Gilio and Sanfilippo [2011]). In this paper we adopt a notion of generalized coherence called *g-coherence* given in Biazzo and Gilio [2000] (see also Coletti [1994], Gilio [1995b], Biazzo et al. [2005]). The notion of g-coherence is weaker than the notion of coherence given for lower and upper probabilities (see Walley [1991], Williams [2007]) and is equivalent (Biazzo and Gilio [2002]) to the property of "avoiding uniform loss" given in Walley [1991, 1997]. Using some algorithms, a g-coherent probability assessment can be corrected obtaining a coherent assessment. We recall that, given a coherent (precise) assessment $\mathcal{P}$ on an arbitrary family $\mathcal{F}$ of conditional events, there always exists a coherent extension of $\mathcal{P}$ which is a conditional probability (Regazzini [1985]), see also Holzer [1985], Rigo [1988]). Conversely, given a conditional probability P on $\mathcal{E} \times \mathcal{X}$, where $\mathcal{E}$ is an algebra and $\mathcal{X}$ is a nonempty subset of $\mathcal{E} \setminus \{\emptyset\}$, in Rigo [1988] is shown that a suitable condition given in Császár [1955] (called Csàszàr's condition) is necessary and sufficient for coherence of P. If no restrictions are supposed regarding the class of conditioning events $\mathcal{X}$ the function P could be not coherent (Gilio and Spezzaferri [1992], Gilio [1995a], Coletti and Scozzafava [2002]). Moreover, if $\mathcal{X}$ has a particular structure, for instance $\mathcal{X}$ is additive (Holzer [1985], Coletti and Scozzafava [2002]) or quasi-additive (Gilio [1989]), then P is coherent. As quasi-additivity property is weaker than additivity it is of some interest to check if a given coherent assessment $\mathcal{P}$ could be extended as a conditional probability with the class of conditioning events quasi-additive. We remark that the such conditional probabilities may be useful because in many applications in order to take a decision we need to choose a precise and (possibly complete) probability assessment. Hence, the kind of problems studied in this paper can help the decision maker to 'integrate knowledge' by computing a probability distribution consistent with the 'incomplete or vague' initial information quantified by the imprecise assessment.

In what follows, starting from a g-coherent interval-valued probability assessment $\mathcal{A}$ on a finite family $\mathcal{F}$ of conditional events we first determine the associated interval-valued assessment $\mathcal{A}^*$ on $\mathcal{F}$ coherent in the

sense of Walley. Then, after recalling the notion of finitely additive conditional probability and for the set of conditioning events the property of quasi additivity, we construct a sequence of conditional probabilities with quasi additive classes of conditioning events. We extend the conditional probabilities of this sequence using the same (quasi additive) classes of conditioning events. Thus, we are able to define a conditional probability $P_{01\ldots k}$ on $\mathcal{E} \times \mathcal{X}$, where $\mathcal{E}$ is the algebra generated by $\mathcal{F}$ and $\mathcal{X}$ is a quasi additive class which coincides with the union of the previous classes of conditioning events. Moreover, $\mathcal{X}$ contains the initial set of conditioning events of $\mathcal{F}$. Finally, we observe that $P_{01\ldots k}$ is a coherent conditional probability on $\mathcal{F}$ consistent with $\mathcal{A}$. By this procedure one can obtain a large (potentially infinite) number of coherent conditional probabilities. The paper is organized as follows. In Section 2 we first give some preliminary notions and results on generalized coherence. Then, we recall the concepts of conditional probability and quasi additive class of events. Finally we recall a sufficient condition for coherence of conditional probability. In Section 3 we show how a g-coherence assessment, using some algorithms, can be corrected obtaining a coherent assessment. In Section 4 given a g-coherent interval-valued assessment $\mathcal{A}$ on $\mathcal{F}$ we construct a finite sequence $P_0, P_1, \ldots, P_k$ of conditional probabilities with quasi additive families of conditioning events. In Section 5 we introduce a new sequence of conditional probabilities $P_0^0, P_1^0, \ldots, P_k^0$ with quasi additive families of conditioning events such that, for each i, the probability P_i^0 is a particular extension of P_i. We also show that P_i^0 is coherent. In Section 6 we define a conditional probability $P_{01\ldots k}$ with a quasi additive class of conditioning events which contains all conditioning events on $\mathcal{F}$. We show that $P_{01\ldots k}$ is coherent and its restriction on $\mathcal{F}$ is a coherent assessment which is consistent with $\mathcal{A}$. In Section 7 we give a characterization theorem of coherent precise assessments and a relevant way of introducing quasi additive classes. Finally, we give some conclusions.

2 Preliminary notions and results

In this section we set up notation and terminology. We also recall some basic concepts and results, related with the checking of g-coherence and propagation of conditional probability bounds. Next, we recall the definition of conditional probabilities. Finally, we recall the notion of quasi-additive class of events and a sufficient condition for coherence which will be used in the next sections.

2.1 Notations

For each integer n we set $J_n = \{1, 2, \ldots, n\}$. Moreover, we denote respectively by Ω the sure event, by $\emptyset$ the impossible event and the empty set, by E^c the negation of the event E, by $E \vee H$ the disjunction of E and H and by $E \wedge H$ (or simply by EH) the conjunction of E and H. The logical implication from E to H, namely *if E is true, then also H is true*, is denoted by $E \subseteq H$.

2.2 Constituents

Given any pair of events E and H, with $H \neq \emptyset$, we look at the conditional event $E|H$ as a three-valued logical entity which is true, or false, or void, according to whether EH is true, or E^cH is true, or H^c is true. In the setting of coherence, agreeing to the betting metaphor, if you assess $P(E|H) = p$, then you agree to pay an amount p, by receiving 1, or 0, or p, according to whether $E|H$ is true, or $E|H$ is false, or $E|H$ is void (bet called off). Given a family of conditional events $\mathcal{F}_{J_n} = \{E_i|H_i, i \in J_n\}$, we set $\mathcal{H}_{J_n} = \bigvee_{j \in J_n} H_j$. For each $r \in \{0, 1, \ldots 3^n - 1\}$, we denote by $(r_n r_{n-1} \cdots r_2 r_1)$ its ternary representation, such as $r = r_1 3^0 + r_2 3^1 + \cdots + r_n 3^{r_n - 1}$, and by R_r the event defined as $R_r = R_1^{r_1} R_2^{r_2} \cdots R_n^{r_n}$, where

$$R_i^{r_i} = \begin{cases} E_i H_i, & \text{if } r_i = 1, \\ E_i^c H_i, & \text{if } r_i = 0, \\ H_i^c, & \text{if } r_i = 2. \end{cases}$$

Then, we introduce the set

$$\mathcal{C}_{J_n} = \{R_r \neq \emptyset, r \in \{0, 1, 2, \ldots, 3^n - 1\}\}$$

containing every R_r that is not impossible. As some conjunction R_r may be impossible, the cardinality of $\mathcal{C}_{J_n}$ is less than or equal to 3^n. We call *constituents* or *possible worlds* associated with $\mathcal{F}_{J_n}$ the elements of $\mathcal{C}_{J_n}$. Obviously $\mathcal{C}_{J_n}$ is a partition of Ω, that is
1. $\bigvee_{C \in \mathcal{C}_{J_n}} C = \Omega$,
2. $C' \wedge C'' = \emptyset$ for each $C', C'' \in \mathcal{C}_{J_n}$ with $C' \neq C''$.
With each event E we associate the following subset of $\mathcal{C}_{J_n}$ $C_{J_n}(E) = \{C \in \mathcal{C}_{J_n} : C \subseteq E\}$. Notice that for each pair of events E_iH_i,H_i, since $E_iH_i \subseteq H_i \subseteq \mathcal{H}_{J_n}$, it follows that $C_{J_n}(E_iH_i) \subseteq C_{J_n}(H_i) \subseteq C_{J_n}(\mathcal{H}_{J_n})$.

Example 1. Let $\mathcal{F}_{J_3} = \{E_1|H_1, E_2|H_2, E_3|H_3\} = \{ABC|D, B|AC, C|AB\}$ be a family of three conditional events. The set $\mathcal{C}_{J_3}$ of the constituents associated with $\mathcal{F}_{J_3}$ is

$$\mathcal{C}_{J_3} = \{R_6, R_8, R_{13}, R_{14}, R_{18}, R_{20}, R_{24}, R_{26}\} = \\ = \{C_1, C_2, C_3, C_4, C_5, C_6, C_7, C_8\},$$

where

$$C_1 = ABC^cD,\ C_2 = ABC^cD^c,\ C_3 = ABCD, \\ C_4 = ABCD^c,\ C_5 = AB^cCD,\ C_6 = AB^cCD^c, \\ C_7 = (A^c \vee B^cC^c)D,\ C_8 = (A^c \vee B^cC^c)D^c\,.$$

Moreover, we have that $\mathcal{H}_{J_3} = \{D \vee AC \vee AB\}$ and

$$\mathcal{C}_{J_3}(\mathcal{H}_{J_3}) = \mathcal{C}_{J_3} \setminus \{C_8\} = \{C_1, C_2, \ldots, C_7\}. \quad (1)$$

2.3 Coherence and g-coherence

Given an arbitrary family of conditional events $\mathcal{F}$ and a real function $\mathcal{P}$ on $\mathcal{F}$, for every $n \in \mathbb{N}$, let $\mathcal{F}_{J_n} = \{E_i|H_i, i \in J_n\}$ be a subfamily of $\mathcal{F}$ and $\mathcal{P}_{J_n}$ the vector $(p_i, i \in J_n)$, where $p_i = \mathcal{P}(E_i|H_i)$. We use the same symbols for events and their indicator. Then, considering the random gain

$$G_{J_n} = \sum_{i \in J_n} s_i H_i (E_i - p_i),$$

with $s_i, i \in J_n$, arbitrary real numbers, we denote by $G_{J_n}|\mathcal{H}_{J_n}$ the restriction of G_{J_n} to $\mathcal{H}_{J_n}$. Then, based on the betting scheme, we have

Definition 1. The function $\mathcal{P}$ is said coherent iff

$$\max G_{J_n}|\mathcal{H}_{J_n} \geq 0,\ \forall n \geq 1, \forall \mathcal{F}_{J_n} \subseteq \mathcal{F}, \forall s_i \in \mathbb{R}, i \in J_n.$$

Given an interval-valued probability assessment $\mathcal{A}_{J_n} = ([a_1, b_1], \ldots, [a_n, b_n])$ on a family $\mathcal{F}_{J_n} = \{E_i|H_i, i \in J_n\}$ we adopt the following condition of generalized coherence (*g-coherence*) given in Biazzo and Gilio [2000].

Definition 2. The interval-valued probability assessment $\mathcal{A}_{J_n}$ on $\mathcal{F}_{J_n}$ is said g-coherent if and only if there exists a precise coherent assessment $\mathcal{P}_{J_n} = (p_i,\ i \in J_n)$ on $\mathcal{F}_{J_n}$, with $p_i = P(E_i|H_i)$, which is consistent with $\mathcal{A}_{J_n}$, that is such that $a_i \leq p_i \leq b_i$ for each $i \in J_n$.

Given an interval-valued probability assessment $\mathcal{A}_{J_n}$ on $\mathcal{F}_{J_n}$, we denote by $(\mathcal{S}_{J_n})$ the following system, associated with the pair $(\mathcal{F}_{J_n}, \mathcal{A}_{J_n})$, with nonnegative unknown $\underline{\lambda} = (\lambda_C,\ C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n}))$:

$$(\mathcal{S}_{J_n}) \begin{cases} \sum_{C \in \mathcal{C}_{J_n}(E_i H_i)} \lambda_C \leq b_i \cdot \sum_{C \in \mathcal{C}_{J_n}(H_i)} \lambda_C\,, \forall i \in J_n \\ \sum_{C \in \mathcal{C}_{J_n}(E_i H_i)} \lambda_C \geq a_i \cdot \sum_{C \in \mathcal{C}_{J_n}(H_i)} \lambda_C\,, \forall i \in J_n \\ \sum_{C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n})} \lambda_C = 1\,,\ \ \lambda_C \geq 0, \forall C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n}). \end{cases}$$

In an analogous way, given a subset J of J_n, we denote by $(\mathcal{F}_J, \mathcal{A}_J)$ the pair corresponding to J, by $(\mathcal{S}_J)$ the system associated with $(\mathcal{F}_J, \mathcal{A}_J)$ and by $\mathcal{C}_J$ the set of constituents associated with $\mathcal{F}_J$.
We recall a result given in Gilio [1995a], where the notion of g-coherence (see Biazzo and Gilio [2000]) was simply named coherence.

Theorem 1. *The interval-valued probability assessment $\mathcal{A}_{J_n}$ on $\mathcal{F}_{J_n}$ is g-coherent if and only if, for every $J \subseteq J_n$, the system $(\mathcal{S}_J)$ is solvable.*

2.4 Conditional probabilities

Given an algebra of events $\mathcal{E}$ and a non empty subfamily $\mathcal{X}$ of $\mathcal{E}$, with $\emptyset \notin \mathcal{X}$, a (finitely-additive) *conditional probability* on $\mathcal{A} \times \mathcal{X}$ is a real-valued function P defined on $\mathcal{E} \times \mathcal{X}$ satisfying the following properties (Dubins [1975], see also Rényi [1955], Császár [1955], Regazzini [1985], Coletti [1994], Coletti and Scozzafava [2002]):

- (i) $P(\cdot|H)$ is a finitely additive probability on $\mathcal{E}$, for each $H \in \mathcal{X}$;
- (ii) $P(H|H)$=1, for each $H \in \mathcal{X}$;
- (iii) $P(E_1E_2|H) = P(E_2|E_1H)P(E_1|H)$, for every E_1, E_2, H, with $E_1 \in \mathcal{E}$, $E_2 \in \mathcal{E}$, $H \in \mathcal{X}$ and $E_1H \in \mathcal{X}$.

As in Rényi [1955] we do not suppose any restrictions regarding the class of conditioning events $\mathcal{X}$ of the conditional probability P. In Dubins [1975], in order to define a finitely-additive conditional probability, it is required that $\mathcal{X} \cup \{\emptyset\}$ must be a subalgebra of $\mathcal{E}$.

2.5 Quasi additivity and coherence

Let P be a conditional probability on $\mathcal{E} \times \mathcal{X}$, the family $\mathcal{X}$ of conditioning events is said a *$P-$quasi-additive* class (or quasi additive w.r.t. P) if, for every $H_1 \in \mathcal{X}, H_2 \in \mathcal{X}$, there exists $K \in \mathcal{X}$ such that (Császár [1955])

$$\begin{array}{l} (i)\ \ H_1 \vee H_2 \subseteq K, \\ (ii)\ \ P(H_1|K) + P(H_2|K) > 0. \end{array} \quad (2)$$

We observe that, given any conditional probability P on $\mathcal{E} \times \mathcal{X}$, if $\mathcal{X}$ is additive or $\mathcal{X} \cup \{\emptyset\}$ is a subalgebra of $\mathcal{E}$, then $\mathcal{X}$ is $P-$quasi additive. Some sufficient conditions for coherence of a conditional probability are given in Gilio [1989] from which we recall the following result

Theorem 2. *If P is a conditional probability on $\mathcal{E} \times \mathcal{X}$, with $\mathcal{E}$ algebra and $\mathcal{X}$ quasi additive class w.r.t. P, then P is coherent.*

3 From g-coherent to coherent lower/upper probabilities

Let $\mathcal{A}_{J_n} = ([a_i, b_i],\ i \in J_n)$ be a g-coherent interval-valued probability assessment on $\mathcal{F}_{J_n} = \{E_i|H_i,\ i \in J_n\}$. Of course, we can assume that, if $E_i|H_i \in \mathcal{F}_{J_n}$, then $E_i^c|H_i \notin \mathcal{F}_{J_n}$. Moreover, if we replace each upper bound $P(E_i|H_i) \leq b_i$ by the equivalent lower bound $P(E_i^c|H_i) \geq 1 - b_i$, the assessment $\mathcal{A}_{J_n}$ on $\mathcal{F}_{J_n}$ can be seen as a lower probability $(a_i, 1 - b_i,\ i \in J_n)$ on the family $\{E_i|H_i, E_i^c|H_i,\ i \in J_n\}$. Then, using a suitable alternative theorem, it can be shown that g-coherence

and avoiding uniform loss (AUL) property of lower and upper probabilities (Walley [1991]) are equivalent (see Biazzo and Gilio [2002], Theorem 10).
Given a further conditional event $E_{n+1}|H_{n+1}$, as it can be verified (Biazzo and Gilio [2000]), there exists a suitable interval $[p_\circ, p^\circ]$ such that

Theorem 3. *The interval-valued assessment* $\mathcal{A}_{J_{n+1}} = ([a_i, b_i],\ i \in J_{n+1})$ *with* $a_{n+1} = b_{n+1} = p_{n+1}$ *on the family* $\mathcal{F}_{J_{n+1}} = \{E_i|H_i,\ i \in J_{n+1}\}$, *is g-coherent if and only if* $p_{n+1} \in [p_\circ, p^\circ]$.

Then, it immediately follows

Theorem 4. *Given a g-coherent interval-valued assessment* $\mathcal{A}_{J_n} = ([a_i, b_i],\ i \in J_n)$ *on the family* $\mathcal{F}_{J_n} = \{E_i|H_i,\ i \in J_n\}$, *the extension* $[a_{n+1}, b_{n+1}]$ *of* $\mathcal{A}_{J_n}$ *to a further conditional event* $E_{n+1}|H_{n+1}$ *is g-coherent if and only if* $[a_{n+1}, b_{n+1}] \cap [p_\circ, p^\circ] \neq \emptyset$.

The values $p_\circ, p^\circ$ can be determined by exploiting a suitable algorithm given in Biazzo and Gilio [2000]. By the same algorithm, starting with a g-coherent assessment $\mathcal{A}_{J_n}$ on $\mathcal{F}_{J_n}$, we can make the "least-committal" correction (see Pelessoni and Vicig [1998]) of $\mathcal{A}_{J_n}$.
In this way, we obtain the coherent (lower and upper) probability $\mathcal{A}^*_{J_n}$ on $\mathcal{F}_{J_n}$ which would be produced by applying the natural extension principle proposed in Walley [1991].
To determine $\mathcal{A}^*_{J_n}$, we just need to apply n times such algorithm, by replacing each time $E_{n+1}|H_{n+1}$ by $E_j|H_j$, $j \in J_n$, using as probabilistic constraints on the conditional events of $\mathcal{F}_{J_n}$ the g-coherent assessment $\mathcal{A}_{J_n}$.
Example 1 (continued)
Let $\mathcal{A}_{J_3} = ([\frac{1}{2}, 1], [0, \frac{1}{2}], [\frac{1}{3}, \frac{2}{3}])$ be an imprecise probability assessment on $\mathcal{F}_{J_3} = \{ABC|D, B|AC, C|AB\}$. By applying the algorithm for checking g-coherence given in Biazzo and Gilio [2000] it can be proved that $\mathcal{A}_{J_3}$ is g-coherent. Moreover, $\mathcal{A}_{J_3}$ is coherent [1] and then $\mathcal{A}_{J_3} = \mathcal{A}^*_{J_3}$.

4 Construction of classes of conditional probabilities with quasi additive families of conditioning events

In this section, starting with a finite interval-valued probability assessment, we will construct classes of conditional probabilities with quasi additive families of conditioning events. Quasi additivity will assure coherence for the obtained conditional probabilities.

Remark 1. We observe that $\mathcal{C}_{J_n} = \mathcal{C}_{J_n}(\mathcal{H}_{J_n}) \cup \{\mathcal{H}^c_{J_n}\}$. In particular, $\mathcal{C}_{J_n} = \mathcal{C}_{J_n}(\mathcal{H}_{J_n})$, if $\mathcal{H}_{J_n} = \Omega$. Moreover,

[1] Coherence can also be checked by the CkC-package (Baioletti et al.) available at
`http://www.dmi.unipg.it/~upkd/paid/software.html`

the system $(\mathcal{S}_{J_n})$ is solvable if and only if the following system is solvable

$$(\mathcal{S}^*_{J_n}) \begin{cases} \sum_{C \in \mathcal{C}_{J_n}(E_i H_i)} \lambda_C \leq b_i \cdot \sum_{C \in \mathcal{C}_{J_n}(H_i)} \lambda_C, \forall\, i \in J_n \\ \sum_{C \in \mathcal{C}_{J_n}(E_i H_i)} \lambda_C \geq a_i \cdot \sum_{C \in \mathcal{C}_{J_n}(H_i)} \lambda_C, \forall\, i \in J_n \\ \sum_{C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n})} \lambda_C > 0\,, \quad \lambda_C \geq 0 \ \ \forall\, C \in \mathcal{C}_{J_n}. \end{cases}$$

In fact, given a solution $\underline{\lambda}^* = (\lambda^*_C, C \in \mathcal{C}_{J_n})$ of $(\mathcal{S}^*_{J_n})$, the vector $\underline{\lambda}' = (\lambda'_C, C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n}))$, defined by

$$\lambda'_C = \frac{\lambda^*_C}{\sum_{C \subseteq \mathcal{H}_{J_n}} \lambda^*_C}\,,\ \forall\, C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n})\,,$$

is a solution of $(\mathcal{S}_{J_n})$. Conversely, given a solution $\underline{\lambda}' = (\lambda'_C, C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n}))$ of $(\mathcal{S}_{J_n})$, any vector $\underline{\lambda}^* = (\lambda^*_C, C \in \mathcal{C}_{J_n})$, with

$$\lambda^*_C = \alpha \lambda'_C\,,\ \forall C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n})\,,\ \ \alpha > 0\,,\ \ \lambda^*_{\mathcal{H}^c_{J_n}} \geq 0\,,$$

is a solution of $(\mathcal{S}^*_{J_n})$. Of course, the variable $\lambda_{\mathcal{H}^c_{J_n}}$ in $(\mathcal{S}^*_{J_n})$ disappears when $\mathcal{H}^c_{J_n} = \emptyset$.
In what follows, we will use system $(\mathcal{S}^*_{J_n})$ in the equivalent formulation given below

$$(\mathcal{S}^*_{J_n}) \begin{cases} \sum_{C \in \mathcal{C}_{J_n}(E_i H_i)} \lambda_C \leq b_i \cdot \sum_{C \in \mathcal{C}_{J_n}(H_i)} \lambda_C, \forall i \in J_n \\ \sum_{C \in \mathcal{C}_{J_n}(E_i H_i)} \lambda_C \geq a_i \cdot \sum_{C \in \mathcal{C}_{J_n}(H_i)} \lambda_C, \forall i \in J_n \\ \sum_{C \in \mathcal{C}_{J_n}} \lambda_C = \sum_{C \in \mathcal{C}_{J_n}(\mathcal{H}_{J_n})} \lambda_C = 1\,, \\ \lambda_C \geq 0\ \ , \forall C \in \mathcal{C}_{J_n}. \end{cases}$$

Remark 2. We denote by Π the set of coherent precise assessments $\mathcal{P} = (p_{E|H},\ \ E|H \in \mathcal{F}_{J_n})$ on $\mathcal{F}_{J_n}$ which are consistent with $\mathcal{A}_{J_n}$. Let $\mathcal{A}^*_{J_n} = ([a^*_i, b^*_i], i \in J_n)$ be the coherent assessment associated with $\mathcal{A}_{J_n}$, computed by the procedure cited in the previous section. We recall that coherence of $\mathcal{A}^*_{J_n}$ amounts to the existence, for any given $j \in J_n$ and any $x_j \in [a^*_j, b^*_j]$, of a coherent precise probability assessment $(p_{E_i|H_i},\ \ i \in J_n)$ on $\mathcal{F}_{J_n}$, which is consistent with $\mathcal{A}^*_{J_n}$ and is such that $p_{E_j|H_j} = x_j$. We observe that, denoting by Π^* the set of coherent precise assessments $\mathcal{P} = (p_{E|H},\ \ E|H \in \mathcal{F}_{J_n})$ on $\mathcal{F}_{J_n}$ which are consistent with $\mathcal{A}^*_{J_n}$, it holds that $\Pi = \Pi^*$.

To construct the classes of conditional probabilities associated with a given pair $(\mathcal{F}_{J_n}, \mathcal{A}_{J_n})$, we will use a suitable finite sequence $(\mathcal{F}_0, \mathcal{A}_0)$, $(\mathcal{F}_1, \mathcal{A}_1), \ldots, (\mathcal{F}_k, \mathcal{A}_k)$, with $(\mathcal{F}_0, \mathcal{A}_0) = (\mathcal{F}_{J_n}, \mathcal{A}_{J_n})$ and $\mathcal{F}_0 \supset \mathcal{F}_1 \supset \cdots \supset \mathcal{F}_k$, where $\mathcal{A}_j$ is the sub-assessment associated with $\mathcal{F}_j$.
Rather than discuss this in full generality, let us look at

$(\mathcal{F}_0, \mathcal{A}_0)$. Let $\mathcal{C}_0$ be the set of constituents associated with $\mathcal{F}_0$ and Π_0 the set of coherent precise assessments $\mathcal{P}$ on $\mathcal{F}_0$ which are consistent with $\mathcal{A}_0$. Then, given a precise coherent assessment $\mathcal{P}_0 = (p^{(0)}_{E|H}, \quad E|H \in \mathcal{F}_0) \in \Pi_0$ on $\mathcal{F}_0$ we consider the following system $(\mathcal{S}_0)$ in the unknowns $\underline{\lambda} = (\lambda_C, C \in \mathcal{C}_0)$ associated with $(\mathcal{P}_0, \mathcal{F}_0)$

$$(\mathcal{S}_0) \begin{cases} \sum\limits_{C \in \mathcal{C}_0(EH)} \lambda_C = p_{E|H} \cdot \sum\limits_{C \in \mathcal{C}_0(H)} \lambda_C, \ \forall E|H \in \mathcal{F}_0 \\ \sum\limits_{C \in \mathcal{C}_0} \lambda_C = \sum\limits_{C \in \mathcal{C}_0(\mathcal{H}_0)} \lambda_C = 1\,, \ \ \lambda_C \geq 0 \ \ \forall C \in \mathcal{C}_0, \end{cases}$$

where $\mathcal{H}_0 = \bigvee_{E|H \in \mathcal{F}_0} H$.
We observe that $\mathcal{P}_0$ is a particular interval-valued probability assessment on $\mathcal{F}_0$ where each upper bound coincides with the respective lower bound. Therefore, based on Theorem 1 and Remark 1, the system $(\mathcal{S}_0)$ is solvable. Denoting by $\mathcal{E}_0$ the algebra generated by the elements of $\mathcal{C}_0$, we introduce the following real function of the pair $(E, \underline{\lambda})$, with E in $\mathcal{E}_0$ and $\underline{\lambda} = (\lambda_C, C \in \mathcal{C}_0)$ a vector of non-negative numbers,

$$\phi_0(E, \underline{\lambda}) = \begin{cases} \sum_{C \in \mathcal{C}_0(E)} \lambda_C, & \text{if } C_0(E) \neq \emptyset \\ 0, & \text{otherwise.} \end{cases} \tag{3}$$

Next, let $\underline{\lambda}^\star = (\lambda^\star_C : C \in \mathcal{C}_0)$ be a solution of the system $(\mathcal{S}_0)$ and $D_0 = \{H : E|H \in \mathcal{F}_0\}$ be the set of conditioning events of $\mathcal{F}_0$, we consider the following partition of D_0

$$D_0^z = \{H \in D_0 \ : \phi_0(H, \underline{\lambda}^\star) = 0\}, \tag{4}$$

$$D_0^+ = D_0 \setminus D_0^z = \{H \in D_0 \ : \phi_0(H, \underline{\lambda}^\star) > 0 \ \}. \tag{5}$$

Remark 3. Note that the subset D_0^+ cannot be empty (that is $D_0^z \subset D_0$). In fact, as $\underline{\lambda}^\star$ is a solution of (S_0) we have

$$\sum_{H \in D_0} \phi_0(H, \underline{\lambda}^\star) \geq \sum_{C \in \mathcal{C}_0(\mathcal{H}_0)} \lambda^\star_C = \sum_{C \in \mathcal{C}_0} \lambda^\star_C = 1.$$

Hence, there exists an event $H \in D_0$ such that $\phi(H, \underline{\lambda}^\star) > 0$, that is $D_0^+ \neq \emptyset$.

Let $\mathcal{X}_0 = D_0^+ \cup \{\mathcal{H}_0\}$ be a family of conditioning events and $\underline{\lambda}^\star$ be a solution of (S_0), we set

$$P_0(E|H) = \frac{\phi_0(EH, \underline{\lambda}^\star)}{\phi_0(H, \underline{\lambda}^\star)}, \forall E|H, \text{ with } E \in \mathcal{E}_0, \ H \in \mathcal{X}_0. \tag{6}$$

Then, we have

Theorem 5. *The real function P_0 is a conditional probability on $\mathcal{E}_0 \times \mathcal{X}_0$, with $\mathcal{X}_0$ quasi-additive w.r.t. P_0.*

Proof. In order to prove that P_0 is a conditional probability on $\mathcal{E}_0 \times \mathcal{X}_0$ we need to show that P_0 satisfies properties $(i), (ii), (iii)$. Then, such a proof will be divided into three steps.

1) Let H be a conditioning event in $\mathcal{X}_0$. We obviously have
$$P_0(\Omega|H) = \frac{\phi_0(H, \underline{\lambda}^\star)}{\phi_0(H, \underline{\lambda}^\star)} = 1.$$
Moreover, for every $E \in \mathcal{E}_0$ one has $P_0(E|H) \geq 0$. Finally, for every couple of incompatible events E_1, E_2 in $\mathcal{E}_0$, we have
$$P_0(E_1 \vee E_2|H) = \tfrac{\phi_0(E_1H \vee E_2H, \underline{\lambda}^\star)}{\phi_0(H, \underline{\lambda}^\star)} = \tfrac{\phi_0(E_1H, \underline{\lambda}^\star)}{\phi_0(H, \underline{\lambda}^\star)} + \tfrac{\phi_0(E_2H, \underline{\lambda}^\star)}{\phi_0(H, \underline{\lambda}^\star)} = P_0(E_1|H) + P_0(E_2|H).$$
Therefore, for each $H \in \mathcal{X}_0$, $P_0(\cdot|H)$ is a finitely additive probability on $\mathcal{E}_0$; that is P_0 satisfies property (i).

2) For each conditioning event $H \in \mathcal{X}_0$ we trivially have $P_0(H|H) = 1$. Then, P_0 satisfies property (ii).

3) Let E_1, E_2, H be three events in $\mathcal{E}_0$ such that H and E_1H are in $\mathcal{X}_0$. Then, one has $\phi_0(H, \underline{\lambda}^\star) > 0$ and $\phi_0(E_1H, \underline{\lambda}^\star) > 0$. Therefore, we obtain
$$\begin{aligned} P_0(E_1E_2|H) &= \tfrac{\phi_0(E_1E_2H, \underline{\lambda}^\star)}{\phi_0(H, \underline{\lambda}^\star)}, \\ P_0(E_2|E_1H) &= \tfrac{\phi_0(E_1E_2H, \underline{\lambda}^\star)}{\phi_0(E_1H, \underline{\lambda}^\star)}, \\ P_0(E_1|H) &= \tfrac{\phi_0(E_1H, \underline{\lambda}^\star)}{\phi_0(H, \underline{\lambda}^\star)}. \end{aligned}$$
Hence, it is easily seen that $P_0(E_1E_2|H) = P_0(E_2|E_1H)P_0(E_1|H)$, so that P_0 satisfies property (iii).

Therefore, P_0 is a conditional probability on $\mathcal{E}_0 \times \mathcal{X}_0$. Next, we prove that $\mathcal{X}_0$ is a P_0-quasi additive class. Given two conditioning events $H_1, H_2 \in \mathcal{X}_0$ we have $H_1 \vee H_2 \subseteq \mathcal{H}_0$. In addition, as $\phi_0(H_1, \underline{\lambda}^\star) > 0$ and $\phi_0(H_2, \underline{\lambda}^\star) > 0$, it follows that $P_0(H_1|\mathcal{H}_0) > 0$ and $P_0(H_2|\mathcal{H}_0) > 0$. Hence, conditions (i) and (ii) in (2) hold with $K = \mathcal{H}_0$. Hence, $\mathcal{X}_0$ is a P_0-quasi additive class. □

From Theorem 5 and Theorem 2, it immediately follows

Corollary 1. *The conditional probability P_0 on $\mathcal{E}_0 \times \mathcal{X}_0$ is coherent.*

We define the following partition of $\mathcal{F}_0$

$$\mathcal{F}_0^z = \{E|H \in \mathcal{F}_0 : H \in D_0^z\}$$
$$\mathcal{F}_0^+ = \{E|H \in \mathcal{F}_0 : H \in D_0^+\}.$$

Remark 4. Note that as $\underline{\lambda}^\star$ is a solution of system $(\mathcal{S}_0)$ one has

$$P_0(E|H) = p^{(0)}_{E|H}, \ \forall E|H \in \mathcal{F}_0^+ \,. \tag{7}$$

If $\mathcal{F}_0^z \neq \emptyset$, setting $\mathcal{F}_1 = \mathcal{F}_0^z$, we consider the pair $(\mathcal{F}_1, \mathcal{A}_1)$. Note that, since D_0^+ cannot be empty it follows that $\mathcal{F}_1$ is a strict subset of $\mathcal{F}_0$. Then, repeating what has already been done to construct P_0, replacing index 0 by 1, we are able to define a real function P_1 on $\mathcal{E}_1 \times \mathcal{X}_1$ which is a coherent conditional probability on $\mathcal{E}_1 \times \mathcal{X}_1$, with $\mathcal{X}_1$ quasi additive w.r.t. P_1.
Consequently, if $\mathcal{F}_1^z \neq \emptyset$, we set $\mathcal{F}_2 = \mathcal{F}_1^z$ and so on. We continue in this way until we obtain $\mathcal{F}_k^z = \emptyset$ for some integer k. Therefore, we construct a strictly decreasing sequence $(\mathcal{F}_0, \mathcal{A}_0), (\mathcal{F}_1, \mathcal{A}_1), \dots (\mathcal{F}_k, \mathcal{A}_k)$. Incidentally, we also have a sequence $\{\mathcal{F}_0^+, \mathcal{F}_1^+, \dots, \mathcal{F}_k^+\}$ which is a partition of $\mathcal{F}_{J_n}$. In this way we are able to construct a finite sequence $P_0, P_1, \dots, P_k$ such that, for each $i = 0, 1, \dots, k$, P_i is a conditional probability on $\mathcal{E}_i \times \mathcal{X}_i$, with $\mathcal{X}_i$ quasi additive w.r.t. P_i. Moreover, each P_i is also coherent. Based on a reasoning as in Remark 4, for each $i = 0, 1, \dots, k$, we have

$$P_i(E|H) = p_{E|H}^{(i)} \quad , \forall E|H \in \mathcal{F}_i^+ \, . \tag{8}$$

Finally, we note that the finite sequence $\{\mathcal{E}_0, \mathcal{E}_1, \dots, \mathcal{E}_k\}$ is not increasing and given two sets $\mathcal{X}_i, \mathcal{X}_j$ in $\{\mathcal{X}_0, \mathcal{X}_1, \dots, \mathcal{X}_k\}$, with $i \neq j$, one has

$$\mathcal{X}_i \cap \mathcal{X}_j = \emptyset. \tag{9}$$

Example 1 (continued)
We set $(\mathcal{F}_0, \mathcal{A}_0) = (\mathcal{F}_{J_3}, \mathcal{A}_{J_3})$. The set $\mathcal{C}_0(\mathcal{H}_0)$ of the constituents associated with $\mathcal{F}_0$ and contained in $\mathcal{H}_0 = \{D \vee AC \vee AB\}$ is given in (1). By setting $\mathcal{P}_0 = (\frac{1}{2}, 0, \frac{1}{3})$ as a precise assessment on $\mathcal{F}_0$, it can be proved that $\mathcal{P}_0 \in \Pi_0$; moreover the system $(\mathcal{S}_0)$ associated with $(\mathcal{F}_0, \mathcal{P}_0)$ is

$$(\mathcal{S}_0) \begin{cases} \lambda_3 = \frac{1}{2}(\lambda_1 + \lambda_3 + \lambda_5 + \lambda_7) \\ \lambda_3 + \lambda_4 = 0(\lambda_3 + \lambda_4 + \lambda_5 + \lambda_6) \\ \lambda_3 + \lambda_4 = \frac{1}{3}(\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4) \\ \lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 + \lambda_5 + \lambda_6 + \lambda_7 = 1 \\ \lambda_h \geq 0, \ h = 1, 2, \dots, 7 \, . \end{cases}$$

Coherence of $\mathcal{P}_0$ requires that system $(\mathcal{S}_0)$ is solvable. The vector $\underline{\lambda}^* = (\lambda_h^*, h = 1, \dots, 7)$ with $\lambda_6^* = 1$ and $\lambda_h^* = 0$, if $h \neq 6$, is a solution of $(\mathcal{S}_0)$. Moreover, we have $\phi_0(D, \underline{\lambda}^*) = \lambda_1^* + \lambda_3^* + \lambda_5^* + \lambda_7^* = 0$, $\phi_0(AC, \underline{\lambda}^*) = \lambda_3^* + \lambda_4^* + \lambda_5^* + \lambda_6^* = 1$ and $\phi_0(AB, \underline{\lambda}^*) = \lambda_1^* + \lambda_2^* + \lambda_3^* + \lambda_4^* = 0$. Thus, $D_0^z = \{D, AB\}$ and $D_0^+ = \{AC\}$. Then, we set $P_0 : \mathcal{E}_0 \times \mathcal{X}_0$ as in (6), where $\mathcal{E}_0$ is the algebra generated by the constituents given in (1) and $\mathcal{X}_0 = \{AC, D \vee AC \vee AB\}$ is trivially a quasi additive class w.r.t. P_0. In particular, the value

$$P_0(E_2|H_2) = P_0(B|AC) = \frac{\lambda_3^* + \lambda_4^*}{\lambda_3^* + \lambda_4^* + \lambda_5^* + \lambda_6^*} = 0$$

is consistent with $\mathcal{A}_{J_3}$. Now, since $\mathcal{F}_0^+ = \{B|AC\}$, we set $\mathcal{F}_1 = \mathcal{F}_0 \setminus \{B|AC\}$ and we consider the pair $(\mathcal{F}_1, \mathcal{A}_1) = (\{ABC|D, C|AB\}, ([\frac{1}{2}, 1], [\frac{1}{3}, \frac{2}{3}]))$. The set $\mathcal{C}_1$ of the constituents associated with the family $\mathcal{F}_1$ is

$$\mathcal{C}_1 = \{R_0, R_2, R_4, R_5, R_6, R_7\} = \{C_1, \dots, C_6\},$$

where $C_1 = ABC^cD$, $C_2 = ABC^cD^c$, $C_3 = ABCD$, $C_4 = ABCD^c$, $C_5 = (A^c \vee B^c)D$, $C_6 = (A^c \vee B^c)D^c$. Moreover $\mathcal{H}_1 = \{D \vee AB\}$ and $C_1(\mathcal{H}_1) = \mathcal{C}_1 \setminus \{C_6\}$. We choose the sub-assessment $(\frac{1}{2}, \frac{1}{3})$ of $\mathcal{P}_0$ on $\mathcal{F}_1$ as the precise coherent assessment $\mathcal{P}_1$ on $\mathcal{F}_1$ consistent with $\mathcal{A}_1$ (we could have chosen any other coherent assessment $\mathcal{P}_1$ on $\mathcal{F}_1$ consistent with $\mathcal{A}_1$). The system $(\mathcal{S}_1)$ associated with the pair $(\mathcal{F}_1, \mathcal{P}_1)$, where $\mathcal{P}_1 = (\frac{1}{2}, \frac{1}{3})$, is

$$(\mathcal{S}_1) \begin{cases} \lambda_3 = \frac{1}{2}(\lambda_1 + \lambda_3 + \lambda_5) \\ \lambda_3 + \lambda_4 = \frac{1}{3}(\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4) \\ \lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 + \lambda_5 = 1 \\ \lambda_h \geq 0, \ h = 1, 2, \dots, 5 \, . \end{cases}$$

Since coherence of $\mathcal{P}_0$ requires coherence of each subvector, we have that the assessment $\mathcal{P}_1$ on $\mathcal{F}_1$ is coherent. Then, system $(\mathcal{S}_1)$ is solvable and a solution is given by $\underline{\lambda}^* = (\lambda_h^*, h = 1, \dots, 5)$ with $\lambda_1^* = \lambda_2^* = \lambda_3^* = \frac{1}{3}$ and $\lambda_4^* = \lambda_5^* = 0$. We have $\phi_1(D, \underline{\lambda}^*) = \lambda_1^* + \lambda_3^* + \lambda_5^* = \frac{2}{3}$ and $\phi_0(AB, \underline{\lambda}^*) = \lambda_1^* + \lambda_2^* + \lambda_3^* + \lambda_4^* = 1$. Thus, $D_1^z = \emptyset$ and $D_1^+ = \{D, AB\}$. Then, we set $P_1 : \mathcal{E}_1 \times \mathcal{X}_1$ as in (6) where index 0 is replaced by index 1, $\mathcal{E}_1$ is the algebra generated by the constituents $C_1, \dots, C_5$ and $\mathcal{X}_1$ is the class of conditional events $\{D, AB, D \vee AB\}$. In particular, the values

$$P_1(ABC|D) = \frac{\lambda_3^*}{\lambda_1^* + \lambda_3^* + \lambda_5^*} = \frac{\frac{1}{3}}{\frac{2}{3}} = \frac{1}{2},$$
$$P_1(C|AB) = \frac{\lambda_3^* + \lambda_4^*}{\lambda_1^* + \lambda_2^* + \lambda_3^* + \lambda_4^*} = \frac{\frac{1}{3}}{1} = \frac{1}{3}$$

are consistent with $\mathcal{A}_{J_3}$. Moreover, $\mathcal{X}_1$ is quasi additive w.r.t. P_1 ($\mathcal{X}_1$ is also additive); in particular $P_1(D|\mathcal{H}_1) + P_1(AB|\mathcal{H}_1) > 0$.

5 Extension of the probability P_i on $\mathcal{E}_i \times \mathcal{X}_i$ to P_i^0 on $\mathcal{E}_0 \times \mathcal{X}_i$

In this section, for each $i = 1, \dots, k$ (supposing $k \geq 1$), we introduce a conditional probability P_i^0 on $\mathcal{E}_0 \times \mathcal{X}_i$, with $\mathcal{X}_i$ quasi additive w.r.t. P_i^0, such that its restriction on $\mathcal{E}_i \times \mathcal{X}_i$ is the probability P_i defined above. Rather than discuss this in full generality, let us look at $i = 1$. Based on definition (6), where we have replaced index 0 by 1, for every $E|H$ with $E \in \mathcal{E}_1$, $H \in \mathcal{X}_1$ the probability P_1 is defined as follows

$$P_1(E|H) = \frac{\phi_1(EH, \underline{\delta}^\star)}{\phi_1(H, \underline{\delta}^\star)}, \tag{10}$$

where $\underline{\delta}^\star$ is a solution of the following system $(\mathcal{S}_1)$ in the unknown $\underline{\delta} = (\delta_B,\ B \in \mathcal{C}_1)$

$$(\mathcal{S}_1)\begin{cases} \sum_{B\in\mathcal{C}_1(EH)} \delta_B = p_{E|H}\cdot \sum_{B\in\mathcal{C}_1(H)} \delta_B\,, \forall E|H \in \mathcal{F}_1 \\ \sum_{B\in\mathcal{C}_1} \delta_B = \sum_{B\in\mathcal{C}_1(\mathcal{H}_1)} \delta_B = 1\,,\ \ \delta_B \geq 0\ \ \forall B \in \mathcal{C}_1. \end{cases}$$

Since $\mathcal{E}_0 \supseteq \mathcal{E}_1$, each constituent $B \in \mathcal{C}_1$ can be written as the disjunction of the constituents contained in $\mathcal{C}_0(B)$, such as

$$B = \bigvee_{C\in\mathcal{C}_0(B)} C. \tag{11}$$

We note that, as $\mathcal{C}_0$ is a partition of Ω, each set $\mathcal{C}_0(B)$ is non empty. Moreover, given two constituents B' and B'' belonging to $\mathcal{C}_1$, as $B'B'' = \emptyset$, we have

$$\mathcal{C}_0(B') \cap \mathcal{C}_0(B'') = \emptyset. \tag{12}$$

Next, adding, for each component δ_B of $\underline{\delta}$, the following constraints

$$\delta_B = \sum_{C\in\mathcal{C}_0(B)} \lambda_C,\ \ \lambda_C \geq 0,\ \ \forall C \in \mathcal{C}_1(B) \tag{13}$$

to system $(\mathcal{S}_1)$, we obtain the following system (S_1^0) in the unknown $\underline{\lambda} = (\lambda_C,\ C \in \mathcal{C}_0)$ associated with (S_1)

$$\begin{cases} \sum_{B\in\mathcal{C}_1(EH)} (\sum_{C\in\mathcal{C}_0(B)} \lambda_C) = p_{E|H}\cdot \sum_{B\in\mathcal{C}_1(H)} (\sum_{C\in\mathcal{C}_0(B)} \lambda_C), \\ \qquad\qquad \forall E|H \in \mathcal{F}_1, \\ \sum_{B\in\mathcal{C}_1} (\sum_{C\in\mathcal{C}_0(B)} \lambda_C) = \sum_{B\in\mathcal{C}_1(\mathcal{H}_1)} (\sum_{C\in\mathcal{C}_0(B)} \lambda_C) = 1, \\ \delta_B = \sum_{C\in\mathcal{C}_0(B)} \lambda_C,\ \forall B \in \mathcal{C}_1, \\ \lambda_C \geq 0, \quad \forall\, C \in \mathcal{C}_0(B)\,,\ \forall\, B \in \mathcal{C}_1. \end{cases}$$

Then, from (11) and (12) we deduce that for each solution of (S_1) there exists at least a solution (in general infinite solutions) of (S_1^0). In particular, indicating by $r_0(\cdot)$ the cardinality of $\mathcal{C}_0(\cdot)$, a solution of (S_1) could be $\underline{\lambda}^* = (\lambda_C^*,\ C \in \mathcal{C}_0)$ with

$$\lambda_C^* = \frac{\delta_C^\star}{r_0(B)}\,,\ \ \forall C \in \mathcal{C}_0(B)\,,\ \ B \in \mathcal{C}_1\,. \tag{14}$$

Therefore, choosing a solution $\underline{\lambda}^*$ of $\mathcal{S}_1^0$ we set

$$P_1^0(E|H) = \frac{\phi_0(EH,\underline{\lambda}^*)}{\phi_0(H,\underline{\lambda}^*)}, \forall E|H,\ \text{with}\ E \in \mathcal{E}_0,\ H \in \mathcal{X}_1. \tag{15}$$

Then, we have

Proposition 1. *The restriction to $\mathcal{E}_1\times\mathcal{X}_1$ of the function P_1^0 defined on $\mathcal{E}_0 \times \mathcal{X}_1$ is P_1.*

Proof. It is sufficient to prove that for every event $E \in \mathcal{E}_1$ it must be $\phi_1(E,\underline{\delta}^\star) = \phi_0(E,\underline{\lambda}^*)$. From (11) and (12) we have $C_0(E) = \bigvee_{B\in\mathcal{C}_1(E)} \left(\bigvee_{C\in\mathcal{C}_0(B)} C\right)$. Then, we obtain

$$\phi_1(E,\underline{\delta}^\star) = \sum_{B\in\mathcal{C}_1(E)} \delta_B^\star = \sum_{B\in\mathcal{C}_1(E)} \sum_{C\in\mathcal{C}_0(B)} \lambda_C^* = \sum_{C\in\mathcal{C}_0(E)} \lambda_C^* = \phi_0(E,\underline{\lambda}^*).$$

□

Finally, we have

Theorem 6. *The real function P_1^0 is a conditional probability on $\mathcal{E}_0\times\mathcal{X}_1$. Moreover, the class $\mathcal{X}_1$ is quasi-additive w.r.t. P_1^0.*

Proof. By repeating the reasoning done in the first part of the proof of Theorem 5, it can be shown that P_1^0 is a conditional probability on $\mathcal{E}_0\times\mathcal{X}_1$. In addition, we observe that quasi additive property involves only conditioning events in $\mathcal{X}_1 \subseteq \mathcal{E}_1$, where $\mathcal{X}_1$ is P_1-quasi additive. Then, from Proposition 1 it follows that $\mathcal{X}_1$ is a quasi additive class w.r.t. P_1^0. □

By repeating the reasoning above for $i = 2\ldots k$ and by setting $P_0^0 = P_0$ we are able to construct a sequence of conditional probabilities P_i^0 defined on $\mathcal{E}_0 \times \mathcal{X}_i$, $i = 0,\ldots k$, such that, for each i, $\mathcal{X}_i$ is quasi additive w.r.t. P_i^0. Furthermore, by Theorem 2, each P_i^0 is a coherent conditional probability on $\mathcal{E}_0 \times \mathcal{X}_i$.

6 A quasi additive class with all conditioning events of $\mathcal{F}$.

In this section we will construct a conditional probability $P_{01\ldots k}$ on $\mathcal{E}\times\mathcal{X}$, where $\mathcal{E} = \mathcal{E}_0$ and $\mathcal{X}$ is the union of the classes $\mathcal{X}_0, \mathcal{X}_1, \ldots, \mathcal{X}_k$. Therefore, each conditioning event of $\mathcal{F}$ will belong to $\mathcal{X}$. Next, we will show that $\mathcal{X}$ is a quasi additive class respect to this probability. Finally, we will see that $P_{01\ldots k}$ coincides with $\mathcal{P}$ on $\mathcal{F}$.
Let $\{P_i^0,\ i = 0,\ldots,k\}$ be the sequence of conditional probabilities introduced in the previous section, with P_i^0 defined on $\mathcal{E}_0 \times \mathcal{X}_i$. For every $E|H$ with $E \in \mathcal{E}_0$ and $H \in \mathcal{X}$, where $\mathcal{X} = \mathcal{X}_0 \cup \mathcal{X}_1 \cup \ldots \cup \mathcal{X}_k$, we set

$$P_{01\ldots k}(E|H) = P_i^0(E|H),\ \ \text{with } i \text{ such that } H \in \mathcal{X}_i \tag{16}$$

Remark 5. The previous definition of $P_{01\ldots k}$ is not ambiguous. In fact, given an event $H \in \mathcal{X}$, by relation (9) there exists a unique $\mathcal{X}_i$ in $\{\mathcal{X}_0, \mathcal{X}_1, \ldots, \mathcal{X}_k\}$ such that $H \in \mathcal{X}_i$.

Then, we have

Theorem 7. *The real function $P_{01\ldots k}$ is a conditional probability on $\mathcal{E}_0 \times \mathcal{X}$. Moreover, the class $\mathcal{X}$ is quasi-additive w.r.t. $P_{01\ldots k}$.*

Proof. In order to prove that $P_{01\ldots k}$ is a conditional probability on $\mathcal{E}_0 \times \mathcal{X}$ we have to show that $P_{01\ldots k}$ satisfies properties $(i), (ii), (iii)$. Let H be a conditioning event in $\mathcal{X}$, we have that $H \in \mathcal{X}_r$ for some $r = \{0, 1, \ldots, k\}$. Since both properties (i) and (ii) are known to hold for P_r^0, from definition (15) it follows that they also hold for $P_{01\ldots k}$. Next, given three events E_1, E_2 and H, with $E_1, E_2 \in \mathcal{E}_0$ and $H, E_1H \in \mathcal{X}$, the proof that $P_{01\ldots k}$ satisfies property (iii) falls naturally into two cases.
a) If $H \in \mathcal{X}_r$ and $E_1H \in \mathcal{X}_r$ for some $r \in \{0, 1, \ldots, k\}$, then property (iii) holds for $P_{01\ldots k}$ since it holds for P_r^0.
b) If $H \in \mathcal{X}_r$ and $E_1H \in \mathcal{X}_s$, for some $r, s \in \{0, 1, \ldots, k\}$ with $r < s$, then it follows that $E_1H \notin \mathcal{X}_r$. Therefore, we have $P_r^0(E_1H|\mathcal{H}_r) = 0$. Moreover, as $E_1E_2H \subseteq E_1H$ one has $P_r^0(E_1E_2H|\mathcal{H}_r) = 0$. Thus, we obtain

$$P_{01\ldots k}(E_1E_2|H) = \frac{P_r^0(E_1E_2H|\mathcal{H}_r)}{P_r^0(H|\mathcal{H}_r)} = 0$$

and

$$P_{01\ldots k}(E_1|H) = \frac{P_r^0(E_1H|\mathcal{H}_r)}{P_r^0(H|\mathcal{H}_r)} = 0.$$

Then, property (iii), that is $P_{01\ldots k}(E_1E_2|H) = P_{01\ldots k}(E_2|E_1H)P_{01\ldots k}(E_1|H)$, is satisfied by $0 = 0$.
To prove that $\mathcal{X}$ is a quasi additive class w.r.t.$P_{01\ldots k}$ we have to show that, the conditions (i) and (ii) in (2) are satisfied by $P_{01\ldots k}$. Let H_1 and H_2 be two conditioning events in $\mathcal{X}$, we distinguish two cases:
a) $H_1, H_2 \in \mathcal{X}_r$, for some $r \in \{0, 1, \ldots, k\}$. Quasi additivity conditions (i) and (ii) in (2) hold for $P_{01\ldots k}$ since they hold for P_r^0;
b) $H_1 \in \mathcal{X}_r$ and $H_2 \in \mathcal{X}_s$ for some $r, s \in \{0, 1, \ldots, k\}$. In this case, we consider $\mathcal{H}_m$, where $m = \min\{r, s\}$. Since $\mathcal{H}_m$ is the disjunction of the conditioning events contained in D_m, it follows that $\mathcal{H}_m \in \mathcal{X}_m$. Moreover, we have

$$H_1 \vee H_2 \subseteq \bigvee_{H \in D_m} H = \mathcal{H}_m,$$

then condition (i) in (2) is satisfied by $K = \mathcal{H}_m$. Next, we have

$$P_{01\ldots k}(H_1|\mathcal{H}_m) + P_{01\ldots k}(H_2|\mathcal{H}_m) > 0.$$

In fact, if $m = r$, then $P_{01\ldots k}(H_1|\mathcal{H}_m) = P_r^0(H_1|\mathcal{H}_r) > 0$, otherwise if $m = s$, then $P_{01\ldots k}(H_2|\mathcal{H}_m) = P_s^0(H_2|\mathcal{H}_s) > 0$. We can conclude that condition (ii) in (2) is satisfied by $K = \mathcal{H}_m$. □

Remark 6. We observe that in the first part of the previous proof the further case $H \in \mathcal{X}_r$ and $E_1H \in \mathcal{X}_s$, with $r > s$, cannot be possible. In fact, if it were true, as $H \notin \mathcal{X}_s$, there would be $P_s(H|\mathcal{H}_s) = 0$. Therefore, as $E_1H \subseteq H$ we would have

$$0 = P_s^0(H|\mathcal{H}_s) \geq P_s^0(E_1H|\mathcal{H}_s) > 0,$$

which is absurd.

Finally, based on Theorem 7 and Theorem 2 we can conclude that $P_{01\ldots k}$ is a coherent probability on $\mathcal{E}_0 \times \mathcal{X}$. Moreover, given a conditional event $E|H \in \mathcal{F}_{J_n}$ as $(\mathcal{F}_0^+, \mathcal{F}_1^+, \ldots, F_k^+)$ is a partition of $\mathcal{F}_{J_n}$ there exist $i \in \{0, 1, \ldots, k\}$ such that $E|H \in \mathcal{F}_i^+$. Then, from (15) and (8), for each $i = 0, 1, \ldots, k$ it follows that

$$P_{01\ldots k}(E|H) = p_{E|H}^{(i)},\ \forall E|H \in \mathcal{F}_i^+ .$$

Therefore $P_{01\ldots k}$ is consistent with $\mathcal{A}_{J_n}$.

Remark 7. Since any restriction of a coherent conditional probability is coherent too, then the restriction of $P_{01\ldots k}$ on $\mathcal{F}_{J_n}$ is coherent. We observe that $P_{01\ldots k}$ is, in general, not unique, although we start from the same precise coherent assessment. Moreover, two obtained conditional probabilities $P_{01\ldots k}$ and $P'_{01\ldots k}$ could be defined on different sets of conditioning events.

Example 1 (continued)
We set $P_0^0 = P_0$ and, by applying (15), we extend the conditional probabilities $P_1 : \mathcal{E}_1 \times \mathcal{X}_1$ to P_1^0 on $\mathcal{E}_0 \times \mathcal{X}_1$. Then, the function $P_{01} : \mathcal{E}_0 \times \mathcal{X}$ defined as

$$P_{01}(E|H) = \begin{cases} P_0^0(E|H), \text{ if } H \in \{AC, D \vee AC \vee AB\} \\ P_1^0(E|H), \text{ if } H \in \{D, AB, D \vee AB\}, \end{cases}$$

where $\mathcal{X} = \{AC, D \vee AC \vee AB, D, AB, D \vee AB\}$, is a coherent conditional probability on $\mathcal{E}_0 \times \mathcal{X} \supseteq \mathcal{F}$ Moreover, we have that: (a) P_{01} is consistent with $\mathcal{A}_{J_3}$; (b) $P_{01}(E|H) = p_{E|H}$ for every $E|H \in \mathcal{F}_{J_3}$, that is

$$P_{01}(ABC|D) = \tfrac{1}{2},\ P_{01}(B|AC) = 0, P_{01}(C|AB) = \tfrac{1}{3}\ ;$$

(c) $\mathcal{X}$ is P_{01}-quasi additive. We observe that the class $\mathcal{X}$ is not additive (for instance $D \vee AC \notin \mathcal{X}$).

7 Further results

In this section we will give a characterization theorem of coherent precise assessment on a finite family of conditional events and a relevant way of introducing quasi additive classes.
Let $\mathcal{P}$ be a precise coherent assessment on a finite family $\mathcal{F}_{J_n}$ of conditional events. We recall that $\mathcal{P}$ is a particular interval-valued probability assessment on $\mathcal{F}_{J_n}$ where each upper bound coincides with the respective lower bound, then by setting $\mathcal{A}_{J_n} = \mathcal{P}$ and based on the results obtained in previous we are able

to construct (in a direct way) a coherent conditional probability $P_{01\ldots k}$ on $\mathcal{E}_0 \times \mathcal{X} \supseteq \mathcal{F}_{J_n}$, with $\mathcal{X}$ quasi additive w.r.t. $P_{01\ldots k}$, such that the restriction of $P_{01\ldots k}$ on $\mathcal{F}_{J_n}$ coincides with $\mathcal{P}$. Moreover, as any restriction of a coherent conditional probability is coherent too, we have

Theorem 8. *A real-valued function $\mathcal{P}$ on a finite family of conditional events $\mathcal{F}_{J_n}$ is coherent if and only if $\mathcal{P}$ can be extended as a conditional probability $P_{01\ldots k}$ on $\mathcal{E}_0 \times \mathcal{X} \supseteq \mathcal{F}_{J_n}$, with $\mathcal{X}$ quasi additive w.r.t. $P_{01\ldots k}$.*

A similar result, which also has been proved when the family of conditional events is infinite, has been given in Coletti and Scozzafava [2002] (see also Coletti and Scozzafava [1999]) by assuming $\mathcal{X}$ additive. Moreover, given a precise coherent assessment $\mathcal{P}$ on a finite family of conditional events $\mathcal{F}_{J_n}$, let $\mathcal{D}$ be the associated set of conditioning events. By the results of the previous section we can show that the cardinality of the quasi additive set $\mathcal{X} \supseteq \mathcal{D}$ w.r.t. any coherent extension $P_{01\ldots k}$ is always at most $2n$, where n denotes the cardinality of $\mathcal{D}$. We observe that for an additive set $\mathcal{X}' \supseteq \mathcal{D}$ the cardinality could be at most $2^n - 1$.

Remark 8. The problem of giving an algorithm that characterizes the whole set of conditional probabilities consistent with the initial imprecise assessment seems not easy and we do not consider it in this paper. However, we illustrate a procedure for constructing relevant cases of conditional probabilities by considering the algorithm for checking g-coherence of imprecise assessments given in Biazzo and Gilio [2000]. Based on (3), denoting by Λ_0 the set of solutions of system S_0, we introduce the following sets of conditional events

$$I_0 = \{H \in D_0 : \phi_0(H, \underline{\lambda}) = 0,\ \forall \underline{\lambda} \in \Lambda_0\}\,,$$
$$\Gamma_0 = D_0 \setminus I_0\,.$$

We observe that I_0 is equivalent to the set, denoted by the same symbol, used in the algorithm for checking g-coherence given in Biazzo and Gilio [2000]. As for any given $H \in I_0$ there exists a solution $\underline{\lambda}_H$ such that $\phi_0(H, \underline{\lambda}_H) > 0$, then (by a convex linear combination of the vectors $\underline{\lambda}_H$'s, with coefficients all positive) there exists a solution $\underline{\lambda}$ such that $\phi_0(H, \underline{\lambda}) > 0$ for all $H \in I_0$. Therefore, by recalling (5), Γ_0 is the set D_0^+ associated with the solution $\underline{\lambda}$, while in general the sets D_0^+, D_0^z associated with any other solution $\underline{\lambda}^* \neq \underline{\lambda}$ are such that $\Gamma_0 \supseteq D_0^+$ and $I_0 \subseteq D_0^z$. Then, for each $I \subseteq \Gamma_0$ and for each J such that $I \subseteq J \subseteq D_0$, the class $I \cup \{\mathcal{H}_J\}$, where $\mathcal{H}_J = \bigvee_{H \in J} H$, is a quasi additive class which can be introduced at the first step of the procedure. Similar quasi additive classes can be introduced in the other steps of the procedure; at the end, based on the union of these quasi additive classes, we obtain a conditional probability consistent with the initial imprecise assessment.

We can apply the procedure above to any subset Λ_0' of the set of solutions Λ_0 of the system S_0; in this way we can determine other quasi additive classes of conditioning events and the associated conditional probabilities consistent with the initial assessment.
Concerning the computational complexity, we observe that the procedure to construct the coherent probability $P_{01\ldots k}$ is related to the problem of the global checking of coherence of the initial assessment, which tends to become intractable when the cardinality of the starting family of conditional events increases (for an analysis of complexity on this kind of problems see e.g. Biazzo et al. [2005]). Local methods for reducing the computational difficulties have been developed in some papers (see e.g. Biazzo et al. [2003], Capotorti and Vantaggi [2002], Capotorti et al. [2003]).

Example 2. Let be given an algebra of event $\mathcal{E}_0$ and a probability P_0 on $\mathcal{E}_0$. Of course, P_0 is coherent. Moreover, let $\mathcal{X} = \{H_1, H_2, \ldots, H_n, \Omega\}$ be any subset of $\mathcal{E}_0 \setminus \{\emptyset\}$, with $P_0(H_i) > 0$, $i = 1, \ldots, n$. The probability P_0 can be extended to a conditional probability P on $\mathcal{E}_0 \times \mathcal{X}$ defined as

$$P(E|H_i) = \frac{P_0(EH_i)}{P_0(H_i)},\ \forall E \in \mathcal{E}, H_i \in \mathcal{X},$$

with $P(E|\Omega) = P_0(E)$, for every $\mathcal{E}$. We remark that: (i) $H_i \vee H_j \subseteq \Omega$ for every subset $\{i, j\}$ of $\{1, 2, \ldots, n\}$; (ii) $P(H_i|\Omega) + P(H_j|\Omega) > 0$; thus, $\mathcal{X}$ is P-quasi additive and, of course, the conditional probability P is coherent. As we can see, the property of quasi additivity is implicitly exploited in all the cases in which we construct a (coherent) conditional probability by means of ratios of unconditional probabilities.

8 Conclusions

In this paper starting from a g-coherent interval-valued probability assessment $\mathcal{A}_{J_n}$ on a finite family $\mathcal{F}_{J_n}$ we first have constructed a sequence of conditional probabilities with quasi additive classes of conditioning events. Then we have extended each probability in this sequence to obtain a new sequence of conditional probabilities with quasi additive classes of conditioning events. Moreover, we have defined a conditional probability $P_{01\ldots k}$ on $\mathcal{E} \times \mathcal{X}$, where $\mathcal{E}$ is the algebra generated by the constituents associated with $\mathcal{F}_{J_n}$ and $\mathcal{X}$ is a quasi additive class of conditioning events which contains all conditioning events of $\mathcal{F}_{J_n}$. We have shown that $P_{01\ldots k}$ is coherent and consistent with the imprecise assessment $\mathcal{A}_{J_n}$ on $\mathcal{F}_{J_n}$. Finally, we have given a characterization theorem of coherent precise assessments and a relevant way of introducing quasi additive classes.

Abstract

We consider the linear programming relaxation of an energy minimization problem for Markov Random Fields. The dual objective of this problem can be treated as a concave and unconstrained, but non-smooth function. The idea of smoothing the objective prior to optimization was recently proposed in a series of papers. Some of them suggested the idea to decrease the amount of smoothing (so called temperature) while getting closer to the optimum. However, no theoretical substantiation was provided.

We propose an adaptive smoothing diminishing algorithm based on the duality gap between relaxed primal and dual objectives and demonstrate the efficiency of our approach with a smoothed version of Sequential Tree-Reweighted Message Passing (TRW-S) algorithm. The strategy is applicable to other algorithms as well, avoids adhoc tuning of the smoothing during iterations, and provably guarantees convergence to the optimum.

1 INTRODUCTION

We consider the problem of computing the most likely configuration x for a given graphical model, i.e. a distribution $p_{\mathcal{G}}(x;\theta) \propto \exp(-E_{\mathcal{G}}(\theta,x))$. The problem to compute the most likely labeling x (*MAP labeling problem*) amounts to minimizing the energy function[1]

$$\min_{x\in\mathcal{X}} E_{\mathcal{G}}(\theta,x) = \min_{x\in\mathcal{X}} \left\{ \sum_{v\in\mathcal{V}} \theta_{v,x_v} + \sum_{uv\in\mathcal{E}} \theta_{uv,x_{uv}} \right\}. \quad (1)$$

While problem (1) is known to be NP-hard, we will concentrate mainly on the linear programming (LP) relaxation of the problem, originally proposed by Schlesinger [16] – see [24] for a recent review.

A popular approach for solving the relaxed problem is based on maximization of its dual objective, which constitutes a lower bound for the initial objective (1). It is well-known that the dual can be treated as a concave but non-smooth unconstrained problem (see e.g. [17]). There are a number of algorithmic schemes targeting it in its original non-smooth form, e.g. [16, 24, 8, 17, 9, 4]. Some of them, namely sub-gradient algorithms [17, 9] are guaranteed to reach its solution, but are extremely slow, others – message passing (e.g. [8, 4, 11]) – typically perform faster, but may get stuck in non-optimal points, since they can be considered as (block-)coordinate ascent.

Slow convergence of sub-gradient methods and stalling of message-passing ones are caused by the non-smoothness of the objective. Hence the idea of applying smoothing was proposed in a series of recent papers [6, 25, 7, 15]. However to reach a good approximate solution of the initial non-smooth objective the smoothing degree should be selected properly. There are two approaches how this can be done:
(i) **Precision oriented smoothing** approach [7, 15], following the fundamental paper [12]. The smoothing degree depends on the precision to be achieved and is selected and held fixed (or it changes only slightly) during the algorithm iterations.
(ii) Iterative or **diminishing smoothing** approach follows the idea to decrease the smoothing degree as the current iterate gets closer to the optimum. So far we are not aware of any algorithm employing this scenario for the problem (1), although the basic idea is mentioned in several papers, cf. [6, 25].

The idea of the diminishing smoothing corresponds to the following intuition: as long the iterate is far from the optimum one can use a coarse (very smooth) approximation of the objective, since it allows for faster optimization. The closer the iterate is to the optimum, the finer (and thus less smooth and computationally more costly) the approximation is required to guarantee a certain solution accuracy.

[1]We describe our notation in Section 2.

Both, precision oriented and diminishing smoothing approaches operate with the *smoothing gap* i.e. the largest difference between an objective function and its smooth approximation. The smoothing gap however can be controlled only indirectly via some *smoothing parameter*. In its turn the smoothing parameter can be set based on a **worst-case** analysis describing its influence on the smoothing gap. Alternatively this influence can be estimated **adaptively**, as discussed in [15].

For our diminishing smoothing approach some method for estimating the upper bound for the LP relaxation of the energy minimization problem is required. There are several recent papers addressing this issue [26, 18, 15] and we found that the method proposed in [15] fits our needs best. Our algorithm itself was inspired by [13], but in contrast we consider a purely dual optimization instead of the primal-dual one (to avoid massive memory allocation for the primal problem). Furthermore we focus on efficiency of the algorithm on average rather than in the worst-case by exploiting the specific structure of our problem.

We demonstrate the efficiency of our approach with a smooth version of the Sequential Tree-Reweighted Message Passing (S-TRWS) algorithm evaluated on the Middlebury database [20] and a series of computer generated examples. This algorithm, proposed for fixed smoothing in [11] and partially analyzed in [25] estimates the tree-reweighted free energy and can be considered as a smooth version of TRW-S [8]. Contrary to the fixed smoothing we consider a diminishing sequence of the smoothing parameter and show that this solves the LP relaxation of the energy minimization problem (1) up to a given precision. We compare our approach to the S-TRWS algorithm with a final precision oriented smoothing and a Nesterov first-order smoothing based optimization scheme proposed in [7] and [15] and show that it significantly outperforms all of them.

Without loss of generality, we concentrate on the common special case of grid-structured models here (as the benchmark [20] deals with this setting), but our results apply to non-grid-structured graphs as well.

Contribution. The contribution of this paper is four-fold:

1. We describe a diminishing smoothing algorithm for the LP relaxation of the problem (1), based on the duality gap of the relaxed problem.

2. We analyze the method of adaptive selection of the smoothing parameter proposed in [15] and show that in general it does not guarantee attainment of the prescribed precision (as implicitly stated in [15]). We propose a modification of the method, which eliminates this disadvantage, while preserves its efficiency.

3. Additionally, we propose a method for obtaining the sound stopping criterion for algorithms which maximize the *tree-reweighted free energy* [22] via minimizing its dual [5, 3, 11]. To this end we provide a method for computing a primal bound from a current dual iterate. This bound approaches the optimum of the *tree-reweighted free energy* together with the dual iterates.

4. We evaluate the S-TRWS algorithm with different smoothing selection strategies as a method for solving the LP relaxation of the MRF energy minimization problem (1).

Paper Organization. Section 2 briefly describes basic notions. Section 3 is devoted to estimation of upper (primal) bounds for the dual objective and its smooth approximation. Section 4 describes possible strategies of smoothing selection. And finally Sections 5 and 6 contain results of experimental evaluation and conclusions respectively.

2 PRELIMINARIES

We denote by $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ the undirected graph with nodes $\mathcal{V}$ and edges $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$. Associated with the nodes $v \in \mathcal{V}$ are finite *sets of labels* $\mathcal{X}_v$. The Cartesian product set $\mathcal{X} = \otimes_{v\in\mathcal{V}}\mathcal{X}_v$ is the space of possible *labelings* $x \in \mathcal{X}$, i.e. a labeling is a collection $(x_v\colon v \in \mathcal{V})$ of labels. We use the short-hand notation x_{uv} for a pair of labels (x_u, x_v), and $\mathcal{X}_{uv}$ for the corresponding space $\mathcal{X}_u \times \mathcal{X}_v$. The cost functions $\theta_v : \mathcal{X}_v \to \mathbb{R},\ v \in \mathcal{V}$, and $\theta_{uv} : \mathcal{X}_{uv} \to \mathbb{R},\ uv \in \mathcal{E}$, are referred to as *unary* and *pairwise potentials*, respectively, with the complete set of potentials associated with the graph denoted as θ.

As mentioned in the introduction, our objective function is the dual of a linear programming relaxation of the energy minimization problem (1). As is widely known (see e.g. [24]), the linear programming relaxation of the problem (1) reads

$$\min_{\mu} \sum_{v\in\mathcal{V}} \sum_{x_v\in\mathcal{X}_v} \theta_{v,x_v}\mu_{v,x_v} + \sum_{uv\in\mathcal{E}} \sum_{x_{uv}\in\mathcal{X}_{uv}} \theta_{uv,x_{uv}}\mu_{uv,x_{uv}}$$
$$\text{s.t.} \begin{cases} \sum_{x_v\in\mathcal{V}} \mu_{v,x_v} = 1,\ v \in \mathcal{V}\,, \\ \sum_{x_v\in\mathcal{V}} \mu_{uv,x_{uv}} = \mu_{u,x_u},\ x_u \in \mathcal{X}_u,\ uv \in \mathcal{E}\,, \\ \sum_{x_u\in\mathcal{V}} \mu_{uv,x_{uv}} = \mu_{v,x_v},\ x_v \in \mathcal{X}_v,\ uv \in \mathcal{E}\,, \\ \mu_{uv,x_{uv}} \geq 0,\ x_{uv} \in \mathcal{X}_{uv},\ uv \in \mathcal{E}\,. \end{cases} \tag{2}$$

Such a formulation in terms of relaxed indicator vectors μ is commonly referred to as the overcomplete representation of a discrete graphical model, in which the *local polytope* $\mathcal{L}(\mathcal{G})$, as defined by the constraints of (2), represents a simpler outer bound to the marginal polytope, i.e. the convex hull of all indicator vectors of allowable labelings, cf. [23]. The linear program (2) can be written in short as $\min_{\mu\in\mathcal{L}(\mathcal{G})} \langle\theta, \mu\rangle$. Abusing notation we will denote $\langle\theta, \mu\rangle$ by $E(\mu)$.

It turns out that a dual problem for (2) has a simpler structure and less variables, hence its optimization is easier than

the direct optimization of (2). There are several ways how the dual problem can be derived and represented. We will follow *a dual decomposition approach* [21, 9], since it allows for efficient optimization of real-sized problems (see a comparison in [19]). For the sake of simplicity we consider a special case typical for grid graphs.

Let $\mathcal{G}^i = (\mathcal{V}^i, \mathcal{E}^i),\ i \in \{1, 2\}$, be two *acyclic* subgraphs of the *master graph* $\mathcal{G}$. Let $\mathcal{V}^1 = \mathcal{V}^2 = \mathcal{V}$, $\mathcal{E}^1 \bigcup \mathcal{E}^2 = \mathcal{E}$ and $\mathcal{E}^1 \bigcap \mathcal{E}^2 = \emptyset$ (e.g. if $\mathcal{G}$ is a grid graph, $\mathcal{E}^1$ may contain all horizontal edges of $\mathcal{G}$ and $\mathcal{E}^2$ all vertical ones). Then the overall energy becomes the sum of the energies corresponding to these subgraphs,

$$\begin{aligned} E_{\mathcal{G}}(\theta, x) &= \sum_{i=1}^{2} \sum_{v \in \mathcal{V}^i} \theta^i_{v,x_v} + \sum_{uv \in \mathcal{E}^i} \theta^i_{uv,x_{uv}} \\ &= E_{\mathcal{G}^1}(\theta^1, x) + E_{\mathcal{G}^2}(\theta^2, x), \end{aligned} \tag{3}$$

provided $\theta^i_{uv} = \theta_{uv},\ uv \in \mathcal{E}^i,\ i = 1, 2$ and $\theta^1_{v,x_v} + \theta^2_{v,x_v} = \theta_{v,x_v},\ \forall v \in \mathcal{V}, x_v \in \mathcal{X}_v$. The latter condition can be represented in a parametric way as $\theta^1_{v,x_v} = \frac{\theta_{v,x_v}}{2} + \lambda_{v,x_v}$ and $\theta^2_{v,x_v} = \frac{\theta_{v,x_v}}{2} - \lambda_{v,x_v}, v \in \mathcal{V},\ x_v \in \mathcal{X}_v$, where $\lambda_{v,x_v} \in \mathbb{R}$. The dual space $\{\lambda_{v,x_v} \in \mathbb{R} | v \in \mathcal{V},\ x_v \in \mathcal{X}_v\}$ will be denoted as Λ. Thus we consider θ^i as a function of λ and obviously have

$$\min_{x \in \mathcal{X}} E_{\mathcal{G}}(\theta, x) \geq \max_{\lambda \in \Lambda} \sum_{i=1}^{2} \min_{x \in \mathcal{X}} E_{\mathcal{G}^i}(\theta^i(\lambda), x). \tag{4}$$

It has been shown [10] that all decompositions into acyclic subgraphs which cover the original graph yield the same lower bound as the one in (4). Furthermore, it is established that this bound equals the solution of the linear programming problem (2).

Hence, in order to solve the relaxed problem (2) we will maximize its dual, the concave but non-smooth function U defined by the maximand of (4), i.e.

$$U(\lambda) = \sum_{i=1}^{2} \min_{x \in \mathcal{X}} E_{\mathcal{G}^i}(\theta^i(\lambda), x)\,. \tag{5}$$

We note that the function $U(\lambda)$ can be easily evaluated by dynamic programming for any acyclic graph $\mathcal{G}^i$.

Smoothed Dual Objective and its Primal Counterpart. There is a number of approaches to maximize (5). Along with [6, 25, 7, 15] we propose to use a smoothing technique [12] to obtain a smooth approximation of $U(\lambda)$. This would allow both to utilize powerful smooth optimization algorithms (e.g. [15]) and to obtain guarantees for convergence to the optimum of the smooth (and as we will see strictly convex) function for efficient (block-)coordinate descent methods similar to TRW-S [8].

The way we construct the smooth approximation is dictated by the need to preserve the efficiency of the decomposition. The smooth function should be easily computable over subgraphs $\mathcal{G}^i$, like its non-smooth counterpart U.

Each summand in (5) may be written as the inner product of the potential vector θ^i and a suitable binary indicator vector $\phi(x)$, i.e.

$$U^i(\lambda) := \min_{x \in \mathcal{X}} E_{\mathcal{G}^i}(\theta^i(\lambda), x) = \min_{x \in \mathcal{X}} \left\langle \theta^i(\lambda), \phi(x) \right\rangle. \tag{6}$$

As this minimum is non-smooth in λ, the same holds for the objective function (5). To obtain a smooth approximation, we replace $\min$ (or rather $-\max$) by the well-known log-sum-exp (or soft-max) function (cf. [12]), yielding

$$\tilde{U}^i_\rho(\lambda) = -\rho \log \sum_{x \in \mathcal{X}} \exp \left\langle -\theta^i(\lambda)/\rho, \phi(x) \right\rangle \tag{7}$$

with *smoothing parameter* ρ. The resulting function $\tilde{U}^i_\rho$ uniformly approximates U^i, that is

$$\tilde{U}^i_\rho(\lambda) + \rho \log |\mathcal{X}| \geq U^i(\lambda) \geq \tilde{U}^i_\rho(\lambda). \tag{8}$$

This directly implies

$$\tilde{U}_\rho(\lambda) + 2\rho \log |\mathcal{X}| \geq U(\lambda) \geq \tilde{U}_\rho(\lambda) \tag{9}$$

for $\tilde{U}_\rho := \sum_{i=1}^{2} \tilde{U}^i_\rho$.

Please note that for acyclic graphs $\mathcal{G}^i$ evaluating $\tilde{U}^i_\rho$ (and thus $\tilde{U}_\rho$) is as easy as U^i, and can be done by dynamic programming.

Inequality (9) provides a possibility to exchange optimization of the non-smooth function U with the optimization of its smooth approximation $\tilde{U}_\rho$. Selecting the smoothing parameter ρ small enough (see Section 4.1) or properly decreasing it during optimization (Section 4.2), one can guarantee attainment of the optimum of U with a given precision.

Additionally for $\rho = 1$ the function $\tilde{U}_\rho$ has another important meaning: it is a dual function for *the tree-reweighted free energy* [22] and can be used to estimate approximate marginals [5, 3, 11].

Let us denote by N_{uv} the number of subgraphs containing the edge $uv \in \mathcal{E}$ and by N_v the number of subgraphs containing the node $v \in \mathcal{V}$. In our special case $N_{uv} = 1$ and $N_v = 2$.

Theorem 1 ([22, 25]) *The tree-reweighted free energy*

$$\begin{aligned} \tilde{E}_\rho(\mu) := \langle \theta, \mu \rangle - \rho \Big(& \sum_{v \in \mathcal{V}} \sum_{x_v \in \mathcal{X}_v} N_v \mu_{v,x_v} \log \mu_{v,x_v} \\ & + \sum_{uv \in \mathcal{E}} \sum_{x_{uv} \in \mathcal{X}_{uv}} N_{uv} \mu_{uv,x_{uv}} \log \frac{\mu_{uv,x_{uv}}}{\mu_{v,x_v} \mu_{u,x_u}} \Big) \end{aligned} \tag{10}$$

defined over $\mathcal{L}(\mathcal{G})$ is a Lagrange dual for $\tilde{U}_\rho(\lambda)$. And since strict duality holds $\min_{\mu \in \mathcal{L}(\mathcal{G})} \tilde{E}_\rho(\mu) = \max_{\lambda \in \Lambda} \tilde{U}_\rho(\lambda)$.

S-TRWS Algorithm There are a number of approaches to optimize $\tilde{U}_\rho$ (see e.g. [11, 15, 5]). In this paper we evaluate the S-TRWS algorithm originally devoted to computation of the function $\tilde{U}_\rho$ with a fixed value $\rho = 1$ [11]. Contrary to this we will operate ρ in a way to obtain a good (up to a given precision) approximation for the maximum of the non-smooth function U. We selected this algorithm because its original, non-smoothed analogue [8] is one of the most efficient schemes for optimizing U. The second advantage of S-TRWS is that it is guaranteed to converge to the optimum of $\tilde{U}_\rho$ for any fixed ρ contrary to TRW-S, which does not converge to the optimum of U in general.

We introduce vector of "marginals" $\nu^i_\rho(\lambda) \in \mathbb{R}^{\sum_{w\in\mathcal{V}\cup\mathcal{E}}|\mathcal{X}_w|},\ i \in \{1,2\}$ by

$$\nu^i_\rho(\lambda)_{w,x_w} := \frac{\sum\limits_{x'\in\mathcal{X},x'_w=x_w} \exp\left\langle -\theta^i(\lambda)/\rho, \phi(x')\right\rangle}{\exp(-\tilde{U}^i_\rho(\lambda)/\rho)}\,. \quad (11)$$

It is well-known (see e.g. [15, Lemma 1]), that the coordinates of the gradient $\nabla\tilde{U}_\rho \in \mathbb{R}^{\sum_{v\in\mathcal{V}}|\mathcal{X}_v|}$ are equal to

$$\nabla\tilde{U}_\rho(\lambda)_{v,x_v} = \nu^1_\rho(\lambda)_{v,x_v} - \nu^2_\rho(\lambda)_{v,x_v}\,. \quad (12)$$

The S-TRWS algorithm is a specially organized coordinate descent procedure applied to the smoothed function $\tilde{U}_\rho$. It sequentially updates variables λ according to the rule

$$\lambda_{v,x_v} := \lambda_{v,x_v} + (\log\nu^1_\rho(\lambda)_{v,x_v} - \log\nu^2_\rho(\lambda)_{v,x_v})/2\,. \quad (13)$$

Applying this rule corresponds to a coordinate ascent step w.r.t. variable λ_{v,x_v}. The power of this algorithm stems from an extremely efficient way of processing updates (13). Namely, updates are done sequentially, but the computational cost to perform all these $\sum_{v\in\mathcal{V}}|\mathcal{X}_v|$ updates is basically the same as just computing gradient coordinates $\nu^i_\rho(\lambda)$ (see [8] for details), which makes it superior to any general-purpose gradient based algorithm. Due to (12), it is easy to see that an optimum of $\tilde{U}_\rho$ is a fix-point of this algorithm. We refer to [11] for a proof of convergence. We also note that the implementation of this algorithm is far from trivial because of the necessity to exponentiate very large numbers, corresponding to small values of ρ in (11). We coped with this difficulty efficiently based on the idea provided in [12, p.140].

3 UPPER BOUNDS ESTIMATION

There are at least two reasons why it is important to be able to reconstruct a sequence of primal feasible points $\mu^t \in \mathcal{L}(\mathcal{G})$ converging to a solution of the problem (2) or (10), from a sequence λ^t converging to the maximum of the corresponding dual objective. The first reason is the values μ^t themselves: for $\rho = 1$ they can be considered as approximate marginal probabilities [27, 22]. The second reason is an upper bound $E(\mu^t)$ or $\tilde{E}_\rho(\mu^t)$, which can be used for sound stopping criteria [15]. We will use the upper bound to construct a diminishing sequence of smoothing parameters ρ to get an ε-approximation for a maximum of the non-smooth function U via optimization of its smooth approximation $\tilde{U}_\rho$, see Section 4.2.

Primal LP Objective Estimation The simplest (and thus quite popular) way of computing upper bounds for maximum of (5) is rounding schemes [14]. It allows to estimate an integer solution $x \in \mathcal{X}$, from a dual iterate λ. However, the energy $E(\theta, x)$ corresponding to the integer solution x may not achieve the minimal value of objective (2) even in case the labeling was estimated based on the optimal value λ^* delivering the maximum of the dual objective U.

Alternatively we use the primal LP-bound construction introduced in [15]. We denote by $\mathbb{R}_+(\mathcal{G}) = \mathbb{R}_+^{\sum_{v\in\mathcal{V}}|\mathcal{X}_v|+\sum_{uv\in\mathcal{E}}|\mathcal{X}_{uv}|}$ a nonnegative linear half-space containing the local polytope $\mathcal{L}(\mathcal{G})$. Additionally we use the notation $\mathcal{L}_{uv}(\mu_u,\mu_v) \subset \mathbb{R}_+^{|\mathcal{X}_{uv}|}$ for the domain of pairwise marginals $\mu_{uv},\ uv \in \mathcal{X}_{uv}$ satisfying the constraints of (2) for given unary marginals μ_u, μ_v. We use the following reformulation of [15, Thm. 2]:

Theorem 2 *Let $\hat{\mu}_\rho(\lambda) \in \mathbb{R}_+(\mathcal{G})$ be computed as*

$$\hat{\mu}_\rho(\lambda)_{v,x_v} = \frac{\nu^1_\rho(\lambda)_{v,x_v} + \nu^2_\rho(\lambda)_{v,x_v}}{2}\,, \quad (14)$$

$$\hat{\mu}_\rho(\lambda)_{uv,x_{uv}} = \operatorname*{arg\,min}_{\mu_{uv,x_{uv}}\in\mathcal{L}_{uv}(\hat{\mu}_\rho(\lambda)_u,\hat{\mu}_\rho(\lambda)_v)} \langle\theta_{uv},\mu_{uv}\rangle\,. \quad (15)$$

Then for $\tilde{\lambda} = \arg\max_{\lambda\in\Lambda}\tilde{U}_\rho(\lambda)$ holds

$$U(\tilde{\lambda}) + 2\rho\log|\mathcal{X}| \geq E(\hat{\mu}_\rho(\tilde{\lambda})) \geq U(\lambda),\ \lambda\in\Lambda\,. \quad (16)$$

The inequality (16) basically states that the bound $E(\hat{\mu}_\rho(\tilde{\lambda}))$ becomes exact as ρ vanishes.

As noted in [15], evaluating (15) constitutes a *transportation problem* – a well-studied class in linear programing. Since the size of each individual problem is small, these can be easily solved by any appropriate method of linear programming. We found a specialization of the simplex method [1] to be quite efficient in our case.

Tree-Reweighted Free Energy Estimation. The upper bound for the minimum of the tree-reweighted energy (10) can be estimated in the same manner as in Theorem 2.

Theorem 3 *Let $\tilde{\mu}_\rho(\lambda) \in \mathbb{R}_+(\mathcal{G})$ be computed as*

$$\tilde{\mu}_\rho(\lambda)_{v,x_v} = \frac{\nu^1_\rho(\lambda)_{v,x_v} + \nu^2_\rho(\lambda)_{v,x_v}}{2}\,,$$

$$\tilde{\mu}_\rho(\lambda)_{uv,x_{uv}} = \operatorname*{arg\,min}_{\mu_{uv,x_{uv}}\in\mathcal{L}_{uv}(\tilde{\mu}_\rho(\lambda)_u,\tilde{\mu}_\rho(\lambda)_v)} \langle\theta_{uv},\mu_{uv}\rangle - \rho\sum_{x_{uv}\in\mathcal{X}_{uv}} N_{uv}\mu_{uv,x_{uv}}\log\frac{\mu_{uv,x_{uv}}}{\mu_{v,x_v}\mu_{u,x_u}}\,. \quad (17)$$

Then $\tilde{E}_\rho(\tilde{\mu}_\rho(\lambda)) \geq U(\lambda')$ *for any* $\lambda, \lambda' \in \Lambda$ *and for* $\tilde{\lambda} = \arg\max_{\lambda \in \Lambda} \tilde{U}_\rho(\lambda)$ *holds* $U(\tilde{\lambda}) = \tilde{E}_\rho(\tilde{\mu}_\rho(\tilde{\lambda}))$.

Please note that evaluating (17) constitutes a small-sized convex problem (an entropy maximization kind problem) with linear constraints. It can be efficiently solved e.g. by interior point methods.

As we already mentioned, Theorem 3 defines a method for estimating an upper bound for the optimal value of the tree-reweighted energy (10), which can be utilized to constructing a sound stopping criterion based on the duality gap for algorithms maximizing $\tilde{U}_\rho$.

4 SMOOTHING SCHEDULING

In this section we will discuss how to estimate an optimum of U via optimization of its smooth approximation $\tilde{U}_\rho$, i.e. how the smoothing parameter ρ can be selected or/and updated to guarantee the achievement of an ε-approximate solution of U.

We consider two approaches of controlling the smoothing gap $\Delta = \max_{\lambda \in \Lambda} U(\lambda) - \tilde{U}_\rho(\lambda)$: precision oriented and diminishing smoothing. Each of them will be considered in connection to both worst-case and adaptive estimation of the smoothing parameter ρ for a given value of Δ.

4.1 PRECISION-ORIENTED SMOOTHING

Precision-Oriented Worst-Case Smoothing Parameter Selection. The simplest way to select the parameter ρ is to fix it small enough. Let λ^* and $\tilde{\lambda}$ denote optimal points of U and $\tilde{U}_\rho$ respectively. By applying the inequality (9) to $\tilde{\lambda}$ and λ^* and taking into account that $\tilde{U}_\rho(\tilde{\lambda}) \geq \tilde{U}_\rho(\lambda^*)$ and $U(\lambda^*) \geq U(\tilde{\lambda})$ we obtain

$$\tilde{U}_\rho(\tilde{\lambda}) + \underbrace{2\rho \log |\mathcal{X}|}_{=:\Delta(\rho)} \geq U(\lambda^*) \geq \tilde{U}_\rho(\tilde{\lambda})\,. \tag{18}$$

Hence if the inequality

$$\Delta(\rho) < \varepsilon \tag{19}$$

holds, the optimal value $U(\lambda^*)$ can be estimated with precision ε by optimizing $\tilde{U}_\rho$. Inequality (19) can be transformed into a range of allowed values for the smoothing parameter: $0 \leq \rho < \frac{\varepsilon}{2 \log |\mathcal{X}|}$. However selecting an optimal value ρ from this range is not straightforward and depends on the algorithm used for the optimization of $\tilde{U}_\rho$. Lemma 3 in [15] claims that if the convergence rate of the optimization algorithm reads $O(\frac{1}{\rho})$ as a function of ρ, then the optimal value of ρ equals to a half of the upper bound of the range, i.e.

$$\rho = \frac{\varepsilon}{4 \log |\mathcal{X}|}\,. \tag{20}$$

However since little is known about the convergence rate of the considered S-TRWS algorithm, we employ this lemma as a hypothesis.

Precision-Oriented Adaptive Smoothing Parameter Selection. Indeed, as mentioned in [15], the estimation $2\rho \log |\mathcal{X}|$ for the smoothing gap is typically loose. Hence it was proposed by the authors to perform a local estimation the smoothing gap as

$$\hat{\Delta}^t(\rho) := \max_t U(\lambda^t) - \tilde{U}_\rho(\lambda^t) \tag{21}$$

for iterates λ^t of the optimization algorithm. The value ρ has to be selected such that $\hat{\Delta}^t(\rho) < \varepsilon$, even more, using Lemma 3 in [15] it was proposed to select ρ to satisfy

$$\hat{\Delta}^t(\rho) < \frac{\varepsilon}{2}\,. \tag{22}$$

Since this simple (and seemingly quite natural!) approach guarantees fulfillment of (19) only locally with respect to the sequence $\{\lambda^t\}$, it does not guarantee attainment of

(i) precision ε in general. Latter can be demonstrated by an example, when the difference $U(\tilde{\lambda}) - \tilde{U}_\rho(\tilde{\lambda})$ in an optimum $\tilde{\lambda}$ of the smoothed function $\tilde{U}_\rho$ is smaller than the one $U(\lambda^*) - \tilde{U}_\rho(\lambda^*)$ in the optimum λ^* of the non-smooth one, U, and $U(\lambda^*) - \tilde{U}_\rho(\tilde{\lambda}) > \varepsilon$. Starting an algorithm optimizing $\tilde{U}_\rho$ in the point $\tilde{\lambda}$ with

$$\hat{\Delta}^t(\rho) = U(\tilde{\lambda}) - \tilde{U}_\rho(\tilde{\lambda}) < \frac{\varepsilon}{2} \tag{23}$$

makes it stall in the starting point, since (a) the point $\tilde{\lambda}$ is already an optimum of $\tilde{U}_\rho$ and the algorithm can not get better with respect to $\tilde{U}_\rho$; (b) changing of the smoothing ρ is not performed since (22) holds.

(ii) the stopping condition $E(\mu_\rho(\lambda^t)) - U(\lambda^t) \leq \varepsilon$ even if (22) holds together with

$$U(\lambda^*) - \tilde{U}_\rho(\tilde{\lambda}) \leq \frac{\varepsilon}{2}\,. \tag{24}$$

Condition (24) guarantees only the attainment of the accuracy ε for the dual objective U, but not for the duality gap.

Even though we did not encounter such unfortunate cases in practice, there is a general cure for these. Due to Theorem 3 we can estimate the Lagrange dual function $\tilde{E}_\rho$ for $\tilde{U}_\rho$ and decrease ρ by a factor $\eta > 1$ together with restarting the algorithm from the current point as soon as

$$\tilde{E}_\rho(\tilde{\mu}_\rho(\lambda^t)) - \tilde{U}_\rho(\lambda^t) > \frac{\varepsilon}{2} \tag{25}$$

is not satisfied. In other words, one has to select the smoothing parameter ρ such that both conditions (22) and (25) hold. We prove this in the supplementary material because of the space limitations.

Algorithm 1 Generic diminishing smoothing algorithm.

- Given: target solution accuracy ε
- Initialize: $\lambda^0 \in \Lambda$, $\rho^0 > 0$, $E^0_{\min} = E(\hat{\mu}_{\rho^0}(\lambda^0))$.
- Iterate (for $t \geq 0$):
  1. **If** $E^t_{\min} - U(\lambda^t) < \varepsilon$ **Exit and return** λ^t.
  2. $\rho^{t+1} := \min\left\{\rho^t, F(E^t_{\min}, \tilde{U}_{\rho^t}(\lambda^t))\right\}$.
  3. $\lambda^{t+1} := \psi[\tilde{U}_{\rho^{t+1}}](\lambda^t)$.
  4. $E^{t+1}_{\min} := \min\{E^t_{\min}, E(\hat{\mu}_{\rho^{t+1}}(\lambda^{t+1}))\}$.
  5. $t := t + 1$. **Goto** 1.

4.2 DIMINISHING SMOOTHING

Instead of using a fixed value of ρ satisfying (19) or keeping it rarely changed when estimation $\hat{\Delta}(\rho)$ of the smoothing gap does not satisfy (22), we will construct a diminishing ρ-sequence depending on the duality gap. This idea is based on the assumption that maximization of $\tilde{U}_\rho$ is more efficient for larger values of ρ.

Let us consider a generic algorithm - Algorithm 1 - for the diminishing smoothing. Step 1 checks the stopping condition based on the duality gap. Minimization in steps 2 and 4 is required to ensure monotone decreasing of ρ and to keep the best upper bound $E^t_{\min}$ so far. A (for the moment) unknown mapping $F\colon \mathbb{R} \times \mathbb{R} \to \mathbb{R}_+$ determines how the smoothing parameter ρ should be updated. The mapping $\psi[\tilde{U}_\rho]$ corresponds to one or more iterates of the S-TRWS algorithm (see (11) and (13)) applied to the function $\tilde{U}_\rho$.

Our goal is to determine such mappings F, which at least guarantee convergence of Algorithm 1 iterates to the optimum of the non-smooth function U.

Definition 1 *A mapping $\psi[\tilde{U}_\cdot]\colon \mathbb{R}_+ \times \Lambda \to \Lambda$ is called* an optimizing mapping *if*
(i) for any $\rho > 0$ and any $\lambda^0 \in \Lambda$ the iterative process $\lambda^{t+1} = \psi[\tilde{U}_\rho](\lambda^t)$ converges to the set $\Lambda^*(\tilde{U}_\rho)$ of optimal solutions of $\tilde{U}_\rho$;
(ii) $\tilde{U}_\rho(\psi[\tilde{U}_\rho](\lambda)) \geq \tilde{U}_\rho(\lambda)$, moreover for $\lambda \notin \Lambda^*(\tilde{U}_\rho)$ holds $\tilde{U}_\rho(\psi[\tilde{U}_\rho](\lambda)) > \tilde{U}_\rho(\lambda)$,
(iii) $\psi[\tilde{U}_\rho](\lambda)$ is continuous w.r.t. ρ for any $\lambda \in \Lambda$.

Due to continuity of $\exp, \sum$ and $\log$, the iterates of the S-TRWS algorithm depend continuously on ρ. Theorem 6 in [25] proves that every iteration of the algorithm strictly increases the value of $\tilde{U}_\rho$ for a fixed ρ; the convergence of the S-TRWS algorithm to the optimum of the function $\tilde{U}_\rho$ for any fixed ρ is proved in [11]. Hence one or more iterations of the algorithm satisfy the conditions of Def. 1. We explain the practical importance of using more than a single iteration of the algorithm at the end of this paragraph.

Theorem 4 *Let $\psi[\tilde{U}_\cdot]\colon \mathbb{R}_+ \times \Lambda \to \Lambda$ be an optimizing mapping and let the mapping $F\colon \mathbb{R} \times \mathbb{R} \to \mathbb{R}_+$ satisfy the condition*

$$\Delta\left(F(E^t_{\min}, \tilde{U}_{\rho^t}(\lambda^t))\right) \leq \frac{E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t)}{2} \qquad (26)$$

where equality holds only when $E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t) = 0$. Then iterates λ^t of Algorithm 1 converge to the optimum of the function U.

Proof. From the first property of an optimizing mapping (see Def. 1) follows that it suffices to prove that $\rho^t \xrightarrow{t\to\infty} 0$ and $\rho^t > 0$, $\forall t$. Since $E(\mu) > \tilde{U}_\rho(\lambda)$ for any $\mu, \lambda \notin \Lambda^*(U)$ and $\rho \geq 0$, from step 2 follows that $\rho^t > 0$, $\forall t$. Sequence ρ^t is monotone and bounded by 0 from below, thus it converges to some $\rho^* \geq 0$. We will prove that $\rho^* = 0$. Let $\rho^* \neq 0$. From (26), which is strict while $E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t) \neq 0$, follows that $\tilde{U}_{\rho^t}(\lambda^t) + \Delta(\rho^{t+1}) < E(\hat{\mu}_\rho(\lambda^t)) - \Delta(\rho^{t+1})$. Taking the limit as t tends to infinity, denoting $\tilde{\lambda} = \arg\min_{\lambda\in\Lambda} \tilde{U}_{\rho^*}(\lambda)$ and using continuity in ρ and λ of $U(\lambda)$, $\tilde{U}_\rho(\lambda)$, $E(\hat{\mu}_\rho(\lambda))$ and ψ we obtain $\tilde{U}_{\rho^*}(\tilde{\lambda}) + \Delta(\rho^*) < E(\hat{\mu}_{\rho^*}(\tilde{\lambda})) - \Delta(\rho^*)$. Since $\Delta(\rho) = 2\log|\mathcal{X}|$, from (16) follows $E(\hat{\mu}_{\rho^*}(\tilde{\lambda})) - \Delta(\rho^*) \leq U(\tilde{\lambda})$ and thus $\tilde{U}_{\rho^*}(\tilde{\lambda}) + \Delta(\rho^*) < U(\tilde{\lambda})$. From (9) follows the contradiction, which implies $\rho^* = 0$. □

As follows from the proof nothing prevents to improve the upper bound $E^t_{\min}$ by using any available method of its estimation align with the one provided by Theorem 2. In our experiments we use rounding schemes [14], which sometimes allows to get better estimation of $E^t_{\min}$ and hence speed-up Algorithm 1.

Number of cycles of the S-TRWS algorithm, used for computing the optimizing mapping ψ, should be carefully selected because of the fact, that performing 1 cycle of the S-TRWS without prior change of the smoothing parameter is computationally 2 times cheaper than performing it with the change. This is caused by peculiarities of the S-TRWS algorithm. Namely, to compute values $\nu^i_\rho(\lambda)_{v,x_v}$ (see (11)) it has to perform both so-called *forward* and *backward* moves of a dynamic programming algorithm. And if after a given run no changes where made to smoothing, the result of the forward (backward) move do not need to be recomputed. It means, that computing n cycles of the S-TRWS algorithm with a *constant* smoothing costs only $n + 1$ oracle calls (additional one oracle call for the initial forward move) instead of $2n$.

Diminishing Worst-Case Smoothing Parameter Selection. Theorem 4 implies that for some $\gamma > 1$

$$F(E^t_{\min}, \tilde{U}_{\rho^t}(\lambda^t)) = \Delta^{-1}\left(\frac{E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t)}{2\gamma}\right), \qquad (27)$$

at the step 2 of Algorithm 1. Here γ is some constant (which indeed can differ from iteration to iteration)

and $\Delta^{-1}(\cdot)$ denotes the inverse mapping to $\Delta(\cdot)$. Since $\Delta(\rho) = 2\rho \log |\mathcal{X}|$ it reads $\Delta^{-1}(A) = \frac{A}{2 \log |\mathcal{X}|}$. Hence

$$F(E^t_{\min}, \tilde{U}_{\rho^t}(\lambda^t)) = \frac{E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t)}{4\gamma \log |\mathcal{X}|}\,,\ \gamma > 1\,, \quad (28)$$

and Algorithm 1 is defined up to a parameter γ. We refer to Section 5 for experimental evaluation of this parameter.

Diminishing Adaptive Smoothing Parameter Selection. As we already mentioned the estimate $2\rho \log |\mathcal{X}|$ for the smoothing gap is often too loose in practice, which can potentially slow down optimization algorithms. In this section we show how the adaptive estimate (21) can be used together with an appropriate approximation of the inverse mapping Δ^{-1} to speed up the algorithm. Additionally we will use a procedure similar to the one presented in (25) to prevent the algorithm from stalling.

The method is based on a local approximation of $\hat{\Delta}^t(\rho)$ near the current point λ with an affine function $\hat{\Delta}^t(\rho) := \delta \cdot \rho + \alpha$, where $\delta = \frac{\partial \hat{\Delta}^t}{\partial \rho} = \frac{\partial (U - \tilde{U}_\rho)}{\partial \rho} = -\frac{\partial \tilde{U}_\rho}{\partial \rho}$ and assigning $\hat{\Delta}^{-1}(d) := (d - \alpha)/\delta$. Hence step 2 of Algorithm 1 takes the form

$$\delta^t := -\frac{\partial \tilde{U}_{\rho^t}}{\partial \rho}(\lambda^t), \quad \alpha^t := \hat{\Delta}^t - \delta^t \rho^t, \quad (29)$$

$$\rho^{t+1} := \min\left\{\rho^t, \left(\frac{E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t)}{2\delta^t \gamma} - \frac{\alpha^t}{\delta^t}\right)\right\}. \quad (30)$$

Parameter α^t of this approximation depends on the estimate $\hat{\Delta}^t$ defined by (21).

To avoid stalling of the algorithm one should decrease ρ as soon as

$$\tilde{E}_\rho(\mu_\rho(\lambda^t)) - \tilde{U}_\rho(\lambda^t) \le \frac{E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t)}{2\gamma}\,. \quad (31)$$

The proof for that is based on comparing (23) and (25) to (27) and (31). Note that they become equivalent when $\varepsilon = (E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t))/\gamma$.

We sum up the above considerations in Algorithm 2. This algorithm additionally depends on the parameter η defining how much the smoothing parameter ρ should be decreased. In our experiments we use $\eta = 2$, but we observed the inequality (31) being fulfilled only for γ close to 1 (which we found to be non-optimal) and thus the value η does not influence results of our experiments.

It remains only to note that the derivative $\frac{\partial \tilde{U}_{\rho^t}(\lambda^t)}{\partial \rho}$ can be computed efficiently, since it is given by a ready-to-apply formula in the following proposition.

Proposition 1 *Let* $\nu^i_\rho(\lambda) \in \mathbb{R}^{\sum_{w \in \mathcal{V} \cup \mathcal{E}} |\mathcal{X}_w|}$ *be defined by (11). Then*

$$\frac{\partial \tilde{U}_\rho(\lambda)}{\partial \rho} = \frac{\tilde{U}_\rho(\lambda)}{\rho} - \frac{1}{\rho} \sum_{i=1}^{2} \sum_{w \in \mathcal{V}^i \cup \mathcal{E}^i} \sum_{x_w \in \mathcal{X}_w} \theta^i(\lambda)_{w,x_w} \nu^i_\rho(\lambda)_{w,x_w}\,.$$

Algorithm 2 Adaptive diminishing smoothing (ADS*al*)

- Given: a prescribed solution accuracy ε.
- Initialize: $\lambda^0 \in \Lambda$, $\rho^0 > 0$, $\gamma > 1$, $\eta > 1$, $E^0_{\min} = E(\hat{\mu}_{\rho^0}(\lambda^0))$.
- Iterate (for $t \ge 0$):
  1. **If** $E^t_{\min} - U(\lambda^t) < \varepsilon$ **Exit and return** λ^t.
  2. $\delta^t := -\frac{\partial \tilde{U}_{\rho^t}}{\partial \rho}(\lambda^t)$, $\alpha^t := \hat{\Delta}^t - \delta^t \rho^t$.
  3. $\rho^{t+1} := \min\left\{\rho^t, \left(\frac{E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t)}{2\delta^t \gamma} - \frac{\alpha^t}{\delta^t}\right)\right\}$.
  4. **If** $\tilde{E}_\rho(\tilde{\mu}_\rho(\lambda^t)) - \tilde{U}_\rho(\lambda^t) \le \frac{E^t_{\min} - \tilde{U}_{\rho^t}(\lambda^t)}{2\gamma}$ **then** $\rho^{t+1} := \frac{\rho^{t+1}}{\eta}$.
  5. $\lambda^{t+1} := \psi[\tilde{U}_{\rho^{t+1}}](\lambda^t)$.
  6. $E^{t+1}_{\min} := \min\{E^t_{\min}, E(\hat{\mu}_{\rho^{t+1}} \lambda^{t+1})\}$.
  7. $t := t + 1$. **Goto** 1.

5 EXPERIMENTAL EVALUATION

For an experimental evaluation we used datasets from the Middlebury MRF benchmark [20] (datasets *tsukuba, venus, family*) and a computer generated grid model of size 256×256 with 4 labels. The unary and pairwise factors of this model were randomly selected uniformly in the interval $[0, 1]$. This dataset will be denoted as *artificial*. Complete results of all our experiments are present in the supplementary material. In the main body of the paper we present only subset of plots and a summary Table 5 to save space.

We consider the following four smoothing-based algorithms described in the paper: (i) adaptive diminishing smoothing algorithm (**A-DSal**) – Algorithm 2; (ii) diminishing worst-case smoothing (**WC-DSal**) is defined by Algorithm 1, where the mapping F is specified by (28); (iii) precision oriented adaptive smoothing (**A-STRWS**), where the smoothing degree is controlled by (21), (22) and (25); (iv) precision oriented worst-case smoothing (**WC-STRWS**), where the smoothing degree is fixed and given by (20). In all cases we use the S-TRWS algorithm as an optimizing mapping.

We compare our approaches also to the original **TRW-S** code [8] and to the accelerated first-order Nesterov optimization scheme [15] (**NEST**), for which an implementation was kindly provided by the authors.

Additionally to the upper $\Delta(\rho)$-bound computed due to

Table 1: Results of algorithms evaluation. *Req. OC 0.1%* and *Req. OC 1* – number of oracle calls required to achieve the relative precision 0.1% and the absolute precision 1 respectively; *primal/dual bound*–the best upper/lower bounds achieved during the iterations: about 8000-10000 oracle calls for NEST, TRW-S and other methods. In case the best primal bound is an integer one we print it without decimal point. Please note that A-DSal turned out to be the most efficient solver for all datasets except *family* We did not mark "dual bounds winner" for *tsukuba* dataset, because in this case all algorithms except TRW-S were terminated as soon as the duality gap dropped below 1.

	Algorithm	A-DSal	WC-DSal	A-STRWS	WC-STRWS	NEST	TRWS

Theorem 2 we also estimate a so-called *integer* upper bound, which corresponds to integer values of variables μ in (2). The latter bound turns to be often better at the beginning of the optimization process, but contrary to the non-integer one it does not posses a crucial property of convergence to the optimum of the relaxed problem (2).

Since the performance of the precision-oriented smoothing algorithms (A-STRWS, WC-STRWS and NEST) depends on the target precision we run each algorithm on each dataset twice: with target *relative* precision 0.1% and with target *absolute* precision 1. Since potentials of all considered problem from the Middlebury benchmark are integers, getting an integer upper bound within the latter precision would mean solving the corresponding problem exactly in its original, non-relaxed formulation (1). Indeed it has happen for the *tsukuba* dataset – see below.

We use the notion of *oracle calls* for measuring the speed of the algorithms to eliminate the influence of different implementations. One oracle call corresponds to a single (either forward or backward) move of the S-TRWS algorithm. It requires approximately 1.5 seconds for the *tsukuba* dataset, 3.5 s for *venus*, 4.5 s for the *family* and less than 0.5 s for the *artificial* dataset, on a 2.5GHz machine. Such an oracle call approximately corresponds to the oracle call used in NEST, it is 5 times slower than a single (either forward or backward) move of the original non-smooth TRWS algorithm in our implementation and 10 times slower than the original implementation by Kolmogorov [8] for general-form pairwise potentials. The non-smooth TRWS is faster because of the evaluation of the exp-operation needed for smoothing. Preliminary experiments show that simply switching to GPU would already reduce this operation's cost to that of a simple multiplication operation. Hence we ignore the mentioned time difference and consider a single move of the TRW-S algorithm as an oracle call. Additionally we count computations needed to estimate a primal solution $\hat{\mu}_\rho(\lambda^t)$ according to (14)-(15) as an oracle call, since the time it requires is close to that of a single oracle call.

For different values of γ and different numbers of inner S-TRWS iterations we measured the number of oracle calls of the A-DSal and WC-DSal algorithms to attain precision 1%. We found $\gamma = 4$ and 3 inner iterations (4 oracle calls) in the optimizing mapping ψ to be optimal for both A-DSal and WC-DSal. Indeed we found the algorithms quite insensitive to the value of γ, unlike for instance the step-size selection in subgradient-based schemes. Our experiments show similar performance for the interval $2 \leq \gamma \leq 5$.

Tsukuba dataset. Fig. 1(bottom left) This dataset seems to be the easiest among investigated. The relative precision 0.1% was achieved by all algorithms within few dozens of oracle calls. Moreover, all algorithms except TRW-S attained the optimum of the non-relaxed problem (1). Number of oracle calls for that, i.e. to get the duality gap less than 1 is the smallest for A-DSal. Other algorithms, described in the paper perform not much worse and indeed much faster than NEST.

Venus dataset. Fig. 1 (top left) Contrary to *tsukuba* there remains a big ($\gg 1$) relaxation gap between obtained integer solutions and the lower (dual) bound. Simultaneously the upper (primal) bound for the relaxed LP problem demonstrates a fast convergence to the lower one, which makes A-DSal quite efficient. Other algorithms described

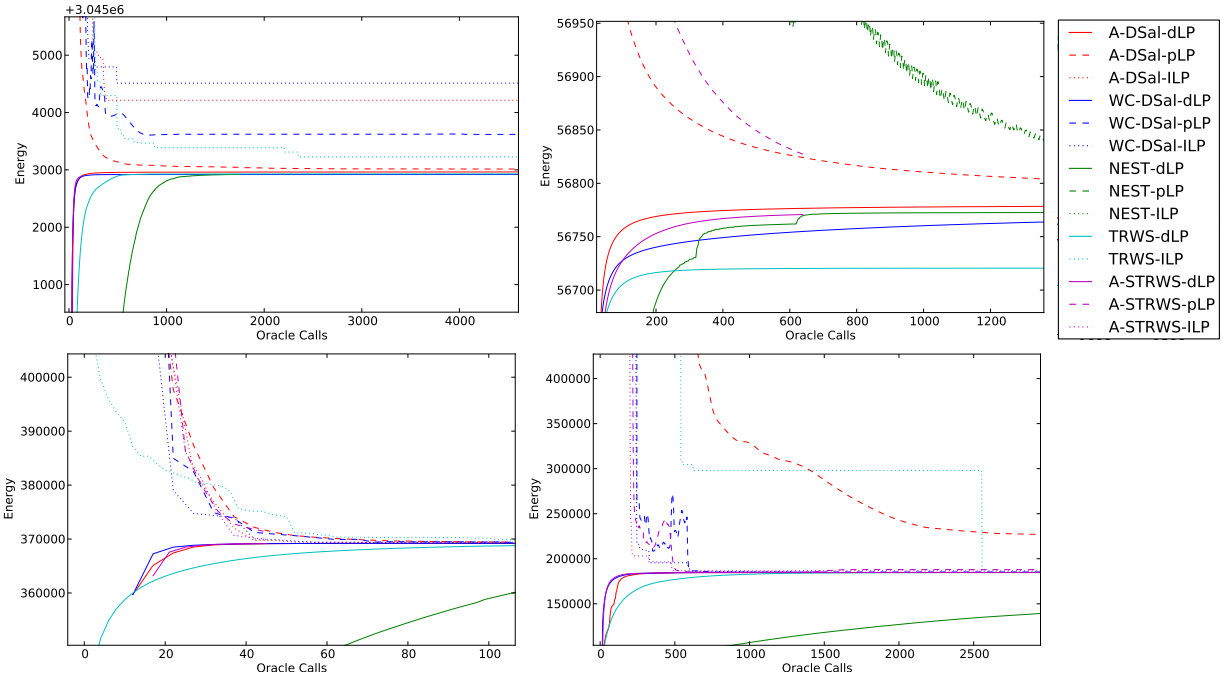

Figure 1: *Venus* (top left), *artificial* (top right), *tsukuba* (bottom left) and *family* (bottom right) datasets. Precision-oriented smoothing algorithms A-STRWS, WC_STRWS and NEST were run with a target precision 0.1%. The curves show primal (upper) (*pLP*) and dual (lower) (*dLP*) LP bounds, as well as the best integer primal bound (*ILP*) achieved. Colors correspond to different algorithms – see legend. For all datasets except *tsukua* the A-DSal demonstrates one of the best convergence rates. For the *family* the primal LP bound of A-DSal shows a very slow convergence, which makes the algorithm significantly less efficient.

in the paper show significantly worse performance. TRW-S is a bit slower at the beginning, but at the end shows the second good result after A-DSal in terms of both upper and lower bounds.

Family dataset. Fig. 1(bottom right) This dataset seems to be quite difficult for dual methods (methods considered in the paper and NEST, TRW-S) because the pairwise factors contain infinite (very large) numbers. This makes dual variables λ badly conditioned, i.e. a small change in their values corresponds to a big change of the estimated primal objective. This is why the estimations of the upper (primal) bound constructed according to Theorem 2 converge very slow and thus the smoothing parameter, selected according to the duality gap estimation, takes too large values. This influences A-DSal at most because it uses additionally adaptive smoothing parameter selection, which makes ρ even larger. However even for this setting the lower bound attained by A-DSal outperforms lower bound of all other approaches except TRW-S (see Table 5), which does not suffer from bad primal estimates.

Artificial dataset. Fig. 1 (top right) This dataset targets the situations when there is no local evidence in the data. This could be a typical setting when the inference is used in a loop of a learning algorithm, e.g. the structural SVM [2]. At the beginning of the learning process the potentials to be learned could take nearly random values, which makes the problem harder. This dataset clearly shows advantage of methods with an adaptive selection of the smoothing parameter: only those methods attained the precision 0.1%. The A-SDal again shows the best performance, whereas TRW-S – the worst one.

Summary. As our experiments show, the proposed adaptive diminishing smoothing algorithm (A-DSal) is competitive to or even outperforms the state-of-the-art methods, except in the case when the pairwise factors contain very large values. This issue has to be considered in future work.

6 CONCLUSIONS

We proposed an adaptive diminishing smoothing optimization algorithm for an LP relaxation of the energy minimization problem. The algorithm enjoys provable and fast convergence to the optimum, and often outperforms even one of the fastest state-of-the-art methods – TRWS, but contrary to that does never get stuck in non-optimal points.

Abstract

Multi-fidelity methods combine inexpensive low-fidelity simulations with costly but high-fidelity simulations to produce an accurate model of a system of interest at minimal cost. They have proven useful in modeling physical systems and have been applied to engineering problems such as wing-design optimization. During human-in-the-loop experimentation, it has become increasingly common to use online platforms, like Mechanical Turk, to run low-fidelity experiments to gather human performance data in an efficient manner. One concern with these experiments is that the results obtained from the online environment generalize poorly to the actual domain of interest. To address this limitation, we extend traditional multi-fidelity approaches to allow us to combine fewer data points from high-fidelity human-in-the-loop experiments with plentiful but less accurate data from low-fidelity experiments to produce accurate models of how humans interact. We present both model-based and model-free methods, and summarize the predictive performance of each method under different conditions.

1 Introduction

The benefit of using high-fidelity simulations of a system of interest is that it produces results that closely match observations of the real-world system. Ideally, algorithmic design optimization would be performed using such accurate models. However, the cost of high-fidelity simulation (computational or financial) often prohibits running more than a few simulations during the optimization process. The high-fidelity models built from such a small number of high-fidelity data points tend not to generalize well. One approach to overcoming this limitation is to use multi-fidelity optimization, where both low-fidelity and high-fidelity data are used together during the optimization process (Robinson et al., 2006).

When the system of interest involves humans, traditionally human-in-the-loop (HITL) experimentation has been used to build models for design optimization. A common approach in HITL experimentation is to make the simulation environment match the true environment as closely as possible (Aponso et al., 2009). A major disadvantage of this approach is that designing a good high-fidelity HITL simulation requires substantial human and technological resources. Experimentation requires highly trained participants who need to physically visit the test location. As a consequence, collecting large amounts of high-fidelity data under different conditions is often infeasible.

In many cases, one could cheaply implement a lower fidelity simulation environment using test subjects who are not as extensively trained, allowing for the collection of large amounts of less accurate data. Indeed, this is the idea behind computational testbeds like Mechanical Turk (Kittur et al., 2008; Paolacci et al., 2010). The goal of this paper is to extend multi-fidelity concepts to HITL experimentation, allowing for the combination of plentiful low-fidelity data with more sparse high-fidelity data. This approach results in an inexpensive model of interacting humans that generalizes well to real-world scenarios.

In this paper, we begin by outlining the self-separation scenario used as a testbed to study multi-fidelity models of interacting humans. In Section 3 we introduce the multi-fidelity methods used in this paper. In Section 4, we present model-free approaches to multi-fidelity prediction, and in Section 5 we present model-

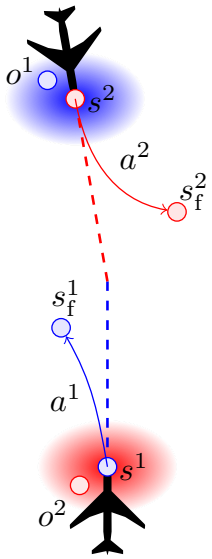
based methods. Results, summarized in Section 6, show the benefit of incorporating low-fidelity data to make high-fidelity predictions and that model-based methods out-perform model-free methods. Section 7 concludes with a summary of our findings and future directions for investigation.

2 Modeling Interacting Humans

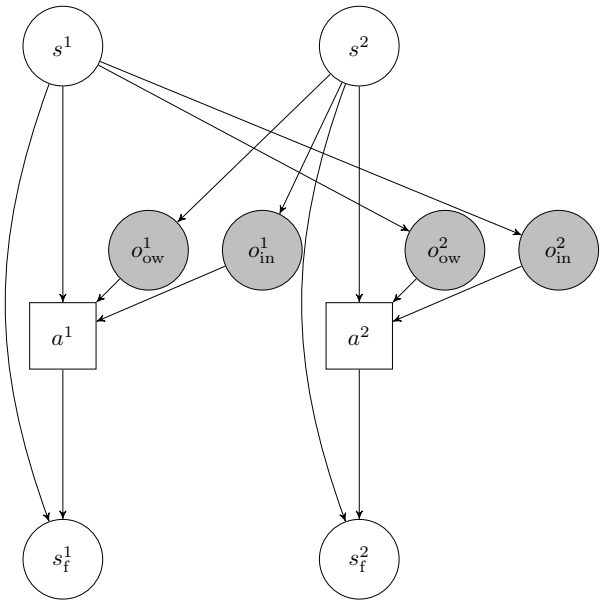
In order to ground our discussion of multi-fidelity methods in a concrete scenario, we will begin by presenting our testbed for studying the behavior of interacting humans. We model the interaction of two pilots whose aircraft are on a near-collision course. Both pilots want to avoid collision (Fig. 1a), but they also want to maintain their heading. For simplicity, we model the pilots as making a single decision in the encounter. Their decisions are based on their beliefs about the other aircraft's position and velocity, their degree of preference for maintaining course, and their prediction of the other pilot's decision.

We use a combination of Bayesian networks and game-theoretic concepts (Lee and Wolpert, 2012) to model this scenario. The structure of the model is shown in Fig. 1b. The state of aircraft i is a four-dimensional vector representing the horizontal position and velocity information. The initial distribution over states is described in Section 3. The action a^i taken by the pilot of aircraft i represents the angular change in heading, away from their current heading. Each pilot observes the state of the other aircraft based on their view out the window o^i_{ow} and their instrumentation o^i_{in}. Each pilot has a weight w^i in their utility function reflecting their relative desire to avoid collision versus maintaining heading. We consider the situation where each player knows their own type (i.e., the value of the weight term in their utility function) in addition to the type of the other player (Myerson, 1997).

As described in this section, the pilots chose their actions based on their observations and utility function. After both pilots select an action, those actions are executed for 5 s, bringing the aircraft to their final states s^i_{f}. Without loss of generality we describe the scenario from the perspective of one of the pilots, Player 1, with the other aircraft corresponding to Player 2. The model assumptions, detailed below, are symmetric between players. It should be noted that the approaches described in this paper are not limited to cases in which there are only two humans interacting, although scenarios with more humans would increase the amount of data required to make accurate predictions.



(a) Example geometry with model variables depicted.



(b) Model structure. Shaded circles are observable variables, white circles are unobservable variables, squares are decision nodes, and arrows represent conditional relationships between variables.

Figure 1: Visual self-separation game.

2.1 Visual inference

Player 1 infers the state of the intruder based on visual information out the window and instrumentation. Player 1 is not able to exactly infer the state of Player 2 as humans are not able to perfectly estimate position and velocity based on visual information (Graf et al., 2005; Schlicht and Schrater, 2007), and the instruments also have noise associated with their measurements (Fig. 1b).

We model the out-the-window visual observation as Gaussian with a mean of the true state of the intruder aircraft and covariance matrix given by $\text{diag}(900\,\text{ft}, 900\,\text{ft}, 318\,\text{ft/s}, 318\,\text{ft/s})$. The instrument observation is Gaussian with a mean of the true state of the intruder with covariance given by $\text{diag}(600\,\text{ft}, 600\,\text{ft}, 318\,\text{ft/s}, 318\,\text{ft/s})$. The out-the-window velocity uncertainties are derived from the visual psychophysics literature (Weis et al., 2002; Graf et al., 2005).

2.2 Decision-making

Theoretical models of multi-agent interaction offer a framework for formalizing decision-making of interacting humans. Past research has focused on game-theoretic approaches (Myerson, 1997) and their graphical representations (Koller and Milch, 2003; Lee and Wolpert, 2012) where agents make a single decision given a particular depth of reasoning between opponents. Such approaches have been successfully used for predicting human decision-making in competitive tasks (Camerer, 2003; Wright and Leyton-Brown, 2010, 2012).

In cases when it is important to capture how people reason across time, sequential models of human interaction can be used (Littman, 1994). Such models can reflect either cooperative settings where agents are attempting to maximize mutual utility (Amato et al., 2009) or competitive contexts where agents are attempting to maximize their own reward (Doshi and Gmytrasiewicz, 2005, 2006). Graphical forms of sequential decision processes have also been developed (Zeng and Xiang, 2010).

Since humans often reason over a relatively short time horizon (Sellitto et al., 2010), especially in sudden, stressful scenarios, we model our interacting pilots scenario as a one-shot game. Like Lee and Wolpert (2012), we use level-k relaxed strategies as a model for human decision-making. A level-0 strategy chooses actions uniformly at random. A level-k strategy assumes that the other players adopt a level-$(k-1)$ strategy (Costa-Gomes et al., 2001). In our work, we assume $k = 1$ because humans tend to use shallow depth-of-reasoning (Wright and Leyton-Brown, 2010), and increasing $k > 1$ had little effect on the predicted joint-decisions for our scenario.

The focus on bounded rationality stems from observing the limitations of human decision making. Humans are unable to evaluate the probability of all outcomes with sufficient precision and often make decisions based on adequacy rather than by finding the true optimum (Simon, 1956, 1982; Caplin et al., 2011). Because decision-makers lack the ability and resources to arrive at the optimal solution, they instead apply their reasoning only after having greatly simplified the choices available. This type of sampling-based, bounded-rational view of perceptual processing has been used in computational models of human visual tracking performance (Vul et al., 2010) and has been shown to predict human decision-making (Vul et al., 2009).

To align our model with a bounded-rational view of human performance, we assume that Player 1 makes decisions based on m' sampled intruder locations and m candidate actions sampled from a uniform distribution over ± 1 radian. In other words,

$$o^{(1)}, \ldots, o^{(m')} \sim p(o^1_{\text{ow}} \mid s^2) p(o^1_{\text{in}} \mid s^2) \quad (1)$$

$$a^{(1)}, \ldots, a^{(m)} \sim \mathcal{U}(-1, 1) \quad (2)$$

Player 1 selects the sampled action that maximizes the expected utility over the m' sampled states of the other aircraft:

$$a = \arg\max_i \sum_j w^1 d(s^1_{\text{f}|a^{(i)}}, s^2_{\text{f}|o^{(j)}}) - (1 - w^1)|a^{(i)}| \quad (3)$$

In the equation above,

- $s^1_{\text{f}|a^{(i)}}$ is the final state of Player 1 after performing action $a^{(i)}$,
- $s^2_{\text{f}|o^{(j)}}$ is the expected final state of Player 2 given observation $o^{(j)}$ and assuming a random heading change,
- $d(\cdot, \cdot)$ represents Euclidean distance, and
- w^1 is the relative desire of Player 1 to avoid the intruder versus maintaining their current heading.

The first term in the utility function rewards distance between aircraft, and the second term penalizes the magnitude of the heading change. Fig. 2 shows how joint-actions change across different w^1 and w^2 combinations. When weights are relatively low (e.g., $w^1 = 0.80$, $w^2 = 0.80$), joint-actions are centered around $(0, 0)$, indicating pilots tend to make very small heading change maneuvers. Conversely, when weights are relatively high (e.g., $w^1 = 0.98$, $w^2 = 0.98$), pilots tend to make large heading change maneuvers.

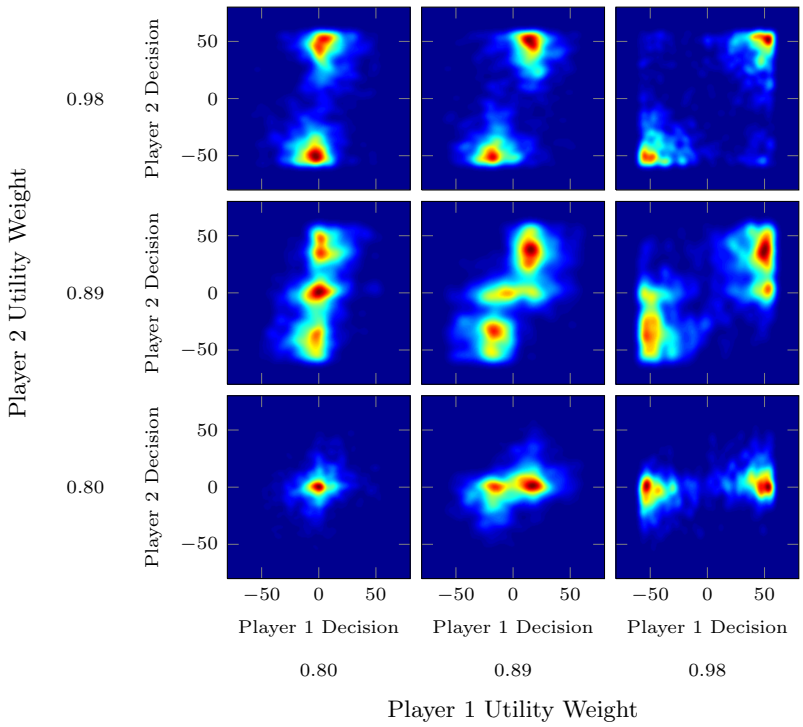


Figure 2: Influence of utility weights on joint-decision densities. Red regions depict areas with high probability joint-decisions (i.e., heading change, in degrees), while blue regions represent low probability joint-decisions.

2.3 Executing Actions

After choosing an appropriate action, the pilots then execute the maneuver. Although it is known that humans have uncertainty associated with their movements (Harris and Wolpert, 1998), we simulate the case in which pilots perfectly execute the action selected by level-k relaxed strategies, since uncertainty in action execution is not a focus of this study.

Recall that the action of the player is the change in heading angle of the aircraft, away from the current heading. From the initial state and the commanded heading change of the aircraft, the final state is obtained by simulating the aircraft for 5 seconds assuming point-mass kinematics, no acceleration, and instantaneous heading change.

3 Multi-fidelity Prediction

There are two ways one could distinguish a low-fidelity and high-fidelity model of this encounter. The first is using "low-fidelity humans" versus "high-fidelity humans," where low-fidelity humans would represent people who have been trained in flight simulators but who are not commercial pilots. The second way is to have both a low-fidelity and high-fidelity simulation environment, say having low-fidelity environment being a flight simulator that does not perfectly match the conditions of an actual commercial jet. For this paper, our low-fidelity simulators are the same as the high-fidelity simulation except there is no instrument panel. The low-fidelity simulation has the o_{in} nodes removed in Fig. 1b.

We used separate training and testing encounters, all sampled with Player 2 being in Player 1's field of view, and a heading such that a collision occurs if an avoidance maneuver is not performed (dashed lines in Fig. 1a). Training encounters were initialized with Player 2 randomly approaching at $-45°$, $0°$, and $+45$. Test encounters were initialized with Player 2 randomly approaching at $-22.5°$ and $+22.5°$. Initial headings for both train and test encounters were sampled from a Gaussian distribution with a mean around a heading direction that would result in a collision with a standard deviation of $5°$.

The goal of multi-fidelity prediction is to combine the data in the high and low-fidelity training encounters to predict the joint-decisions of pilots in the high-fidelity game. The next two sections describe different approaches to achieving this type of prediction, and the notation is summarized in Table 1.

Table 1: Notation used for multi-fidelity prediction

	Description
A	Observed joint-actions (a^1, a^2)
$\hat{A}$	Predicted joint-actions $(\hat{a}^1, \hat{a}^2)$
S	Encounter geometry (s^1, s^2)
N	Number of encounters
w	Joint utility-weights (w^1, w^2)
z	Regression weight
$(.)^{tr}$	Superscript indicating training encounters
$(.)^{te}$	Superscript indicating test encounters
$(.)_l$	Subscript indicating low-fidelity game
$(.)_h$	Subscript indicating high-fidelity game

4 Model-Free Prediction Approaches

A model-free approach is one where we do not use any knowledge of the underlying game or the decision-making process. This section discusses a traditional model-free approach to predicting joint-actions as well as a model-free multi-fidelity method.

4.1 Locally Weighted, High-fidelity

The simplest approach to model-free prediction is to use the state and joint-action information from the high-fidelity training data to predict the joint-actions given the states in the testing data. Using only the high-fidelity training data, we trained a high-fidelity predictor R_h that predicts joint-actions A_h^{tr} given the training encounters S_h^{tr}. Then, the test encounters were used as inputs to the predictor, to predict the joint-actions at the new states $\hat{A}^{te} = R_h(S^{te})$. The regression model we considered was locally weighted (LW) regression, where the predicted high-fidelity joint-decisions for a particular test encounter is the weighted combination of high-fidelity joint-decisions from the training encounters. The weights are determined by the distance between the training encounters and the test encounter:

$$\hat{A}_i^{te} = \sum_j^{N_h^{tr}} z_{i,j} A_{h,j}^{tr} \tag{4}$$

$$z_{i,j} = \frac{e^{-d_{i,j}}}{\sum_j e^{-d_{i,j}}} \tag{5}$$

where $d_{i,j}$ is the standardized Euclidean distance between the state in the ith testing encounter and the jth training encounter. This approach does not use any of the low-fidelity data to make predictions, so the quality of the predictions is strictly a function of the amount of high-fidelity training data. This method represents how well one might do without taking advantage of multi-fidelity data, and serves as a baseline for comparison against the multi-fidelity approach.

4.2 Locally Weighted, Multi-fidelity

Our model-free multi-fidelity method uses an approach similar to the high-fidelity method, but it also takes advantage of the low-fidelity data. We use LW regression on the low-fidelity training data to obtain a low-fidelity predictor R_l that predicts joint-actions $\hat{A}_l^{tr}$ for the training encounters S_l^{tr}.

We use the the low-fidelity predictor to augment the high-fidelity training data. The augmented input $(S_h^{tr}, R_l(S_h^{tr}))$ is used to train our augmented high-fidelity predictor $R_{h'}$ that predicts joint-actions based on the high-fidelity data. The test encounters S^{te} were used as inputs to the augmented high-fidelity predictor to predict the joint-action for the test encounters as $\hat{A}^{te} = R_{h'}(S^{te}, R_l(S^{te}))$. In essence, we are using the predictions from the low-fidelity predictor as features for training the high-fidelity predictor.

5 Model-Based Prediction Approaches

The model-free methods described above ignore what is known about how the pilots make their decisions. In many cases, we have a model of the process with some number of free parameters. In our case, we model the players interacting in a level-k environment, and treat the utility weights w_h as unknown parameters that can be learned from data, allowing the prediction of behavior in new situations. Such an approach is used in the inverse reinforcement learning literature (Baker et al., 2009; Ng and Russell, 2000), where the goal is to learn parameters of the utility function of a single agent from experimental data. This section outlines three model-based approaches where the data comes from experiments of varying fidelities. The first two are based on *maximum a posteriori* (MAP) parameter estimates, and the third is a Bayesian approach.

5.1 MAP High-fidelity

To demonstrate the benefit of multi-fidelity model-based approaches, we use a baseline method that exclusively relies on high-fidelity data to make predictions. Since we have a model of interacting humans, we can simply use the test encounters S^{te} as inputs into the model and use the resulting joint-actions as predictions. However, to make accurate predictions, we must estimate the utility weights used by the pilots. To find the MAP utility weights w_h^*, we first need to estimate $p(A \mid S, w)$, which is the probability of the joint-actions A given encounters S and weight w.

As an approximation, we estimate $p(A \mid S, w)$ by simulating the high-fidelity game using a set of 1000 novel encounters (S^n), under different utility weight combinations. We stored the resulting joint-actions for the jth utility weight combination, and then estimated $p(A_h^n \mid w_h^j) = \sum_S p(A_h^n \mid S^n, w_h^j)$ using kernel density estimation via diffusion (Botev et al., 2010). Fig. 2 shows how $p(A_h^n \mid w_h)$ changes across a subset of w_h settings.

We can find the MAP utility weight combination by using the joint-actions A_h^{tr} we observe for our training encounters S_h^{tr}. For each joint-action from the training data, we find the nearest neighbor joint-action in A_h^n. We sum the log-likelihood of the nearest-neighbor joint-actions for the training encounters, under each utility weight combination. The MAP utility weight combination is defined by

$$w_h^* = \arg\max_{w_h} \left[\ln p(w_h) + \sum_n \ln p(A_h^n \mid w_h)\right] \quad (6)$$

where $p(w_h)$ is the prior of weight vector w_h. In our experiments, we assume $p(w_h)$ is uniform over utility weight combinations. Once we have estimated the MAP utility weights, we can simulate our high-fidelity game using the test encounters and the MAP utility weights to obtain the predicted joint-action. The predicted joint-action is obtained by generating $N_s = 10$ samples from $p(A_h^{te} \mid S_i^{te}, w_h^*)$ and averaging them together:

$$A^{(1)}, \ldots, A^{(N_s)} \sim p(A_h^{te} \mid S_i^{te}, w_h^*) \quad (7)$$

$$\hat{A}_{h,i}^{te} = \frac{1}{N_s} \sum_{\ell=1}^{N_s} A^{(\ell)} \quad (8)$$

The amount of high-fidelity data impacts the quality of the utility-weight estimate (w_h^*), thereby limiting its effectiveness in situations when there is little data. The method described next overcomes this limitation by fusing both high- and low-fidelity data to find the utility weights to use for prediction.

5.2 MAP Multi-fidelity

In situations when there is little high-fidelity data to estimate the utility weights, it is beneficial to fuse both low- and high-fidelity data to increase the reliability of the estimate. In this approach, the predicted high-fidelity joint-actions for test encounters ($\hat{A}^{te}$) are being computed according to Eq. (8), and our MAP utility weight is still found by maximizing Eq. (6). However, instead of only using the high-fidelity data to estimate the utility weights, we use both the low-fidelity and the high-fidelity data to estimate the weights. Specifically, we find the log-likelihood of the nearest-neighbor joint-action A^n for both the low- and high-fidelity joint-actions A_h^{tr} and A_l^{tr}. Once we have estimates for the utility weights in the decision model, we can use the test encounters S^{te} as inputs to the high-fidelity model to obtain predictions $\hat{A}^{te}$, similar to what was done in Eq. (8).

Although this is a straightforward way to use both low- and high-fidelity training data, it assumes that the decision makers in the low-fidelity and high-fidelity encounters are identical. While it is plausible that the decision makers have similar utility functions to make this a valid assumption, it could also be the case that highly trained humans have very different utility functions from lesser-trained ones, or that changes in the simulation environment also cause changes in the utility function (for example, due to the decreased sense of immersion). Therefore, we would like a method that relaxes the equal utility assumption, allowing us to make predictions for games that are different for low- and high-fidelity.

5.3 Bayesian Multi-fidelity

The approaches described above use the test encounters as inputs into the high-fidelity model and sample joint-actions from $p(A_h^{te} \mid S_h^{te}, w_h^*)$ using the MAP utility weight estimate w_h^* to compute the predicted joint-actions $\hat{A}_h^{te}$. In contrast, a Bayesian approach to multi-fidelity makes its predictions by sampling joint-actions from $p(A_h^{te} \mid S^{te}, w_h^j)$ under *each* of the j high-fidelity utility weight combinations, and then weighting the predicted joint-actions by the probability of the utility weights, given the low- and high-fidelity joint-actions observed from the training encounters:

$$\hat{A}_{h,i}^{te} = \sum_j p(A_{h,k}^{te} \mid S_i^{te}, w_h^j) p(w_h^j \mid A_l^{tr}, A_h^{tr}) \quad (9)$$

where

$$p(w_h^j \mid A_l^{tr}, A_h^{tr}) = p(w_h^j \mid A_h^{tr}) \sum_k p(w_l^k \mid A_l^{tr}) p(w_l^k, w_h^j)$$

The probability distribution $p(w_h^j \mid A_h^{tr})$ was estimated using the method outlined in Section 5.1. The low-fidelity version of this distribution $p(w_l^k \mid A_l^{tr})$ was estimated in a similar manner for each of the k low-fidelity utility weight combinations by simulating the low-fidelity game using the same novel encounters S^n and kernel density estimation via diffusion methods.

Finally, $p(w_l, w_h) = p(w_l^1, w_l^2, w_h^1, w_h^2)$ is a prior probability over low- and high-fidelity utility weights, and can be selected based on the degree of similarity between the high-fidelity and low-fidelity simulations. For our case, we assume a Gaussian prior with a mean

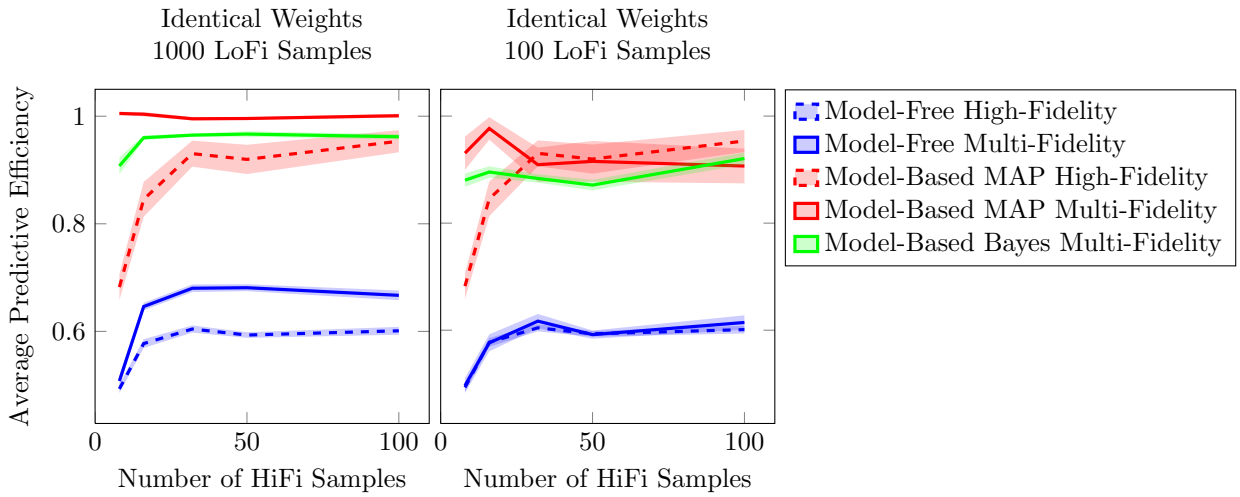

Figure 3: Predictive performance curves for various methods across different numbers of high-fidelity training samples. Lines depict mean predictive efficiency across the 10 simulations per sample-size condition, and the shaded-areas represent standard error. Results are shown for conditions in which the low- and high-fidelity utility weights are identical.

corresponding to the ground-truth utility weights (Section 6) and covariance given by:

$$\begin{bmatrix} .0017 & 0 & .0013 & 0 \\ 0 & .0017 & 0 & .0013 \\ .0013 & 0 & .0017 & 0 \\ 0 & .0013 & 0 & .0017 \end{bmatrix}$$

This covariance assumes that there is variation among players at the same fidelity, but also that the weights of the players are similar (but not identical) across fidelities. However, it assumes that the utilities of the two players within any specific encounter are independent.

A Bayesian approach to multi-fidelity allows for predictions to be made that account for the uncertainty in how well the utility weights account for the joint-actions observed in training. Such an approach also relaxes the assumption of identical utility weights across games through a prior distribution that encodes the coupling of these parameters.

6 Results

In order to assess the performance of both model-free and model-based approaches to multi-fidelity prediction, we evaluated each method with different amounts of high-fidelity training data. We assessed the benefit of incorporating an additional 100 or 1000 low-fidelity training examples, depending on the condition.

Since novices may employ different strategies than domain experts, we also simulated the scenario under different ground-truth utility weight relationships between the low- and high-fidelity games. For the scenario where experts and novices employ similar behavior, the ground-truth utility weights were set to:

$$w_l^{gt} = \{w^1 = 0.89, w^2 = 0.90\} \quad (10)$$

$$w_h^{gt} = \{w^1 = 0.89, w^2 = 0.90\} \quad (11)$$

For the scenario where there is a small difference in how novices act, the ground-truth low-fidelity utility weights were changed to:

$$w_l^{gt} = \{w_l^1 = 0.88, w_l^2 = 0.89\} \quad (12)$$

For the scenario where novices perform much differently than experts, the low-fidelity ground-truth utility weights were:

$$w_l^{gt} = \{w_l^1 = 0.80, w_l^2 = 0.81\} \quad (13)$$

Performance is measured in terms of "predictive efficiency," which is a number typically between 0 and 1. It is possible to obtain a number above 1 because the normalization factor is an estimated lower-bound of the test-set error. The test-set error is given by

$$D = \sum_i d(\hat{A}_i, A_i^{te}), \quad (14)$$

where $d(\cdot,\cdot)$ is the Euclidean distance, $\hat{A}_i$ is the predicted action for the ith encounter, and A_i^{te} is th-e joint-action of the ith test encounter. A lower-bound on the test-set error D^{lb} can be approximated by estimating the error when using the ground-truth model in conjunction with Eq. (8). The predictive efficiency is given by D^{lb}/D.

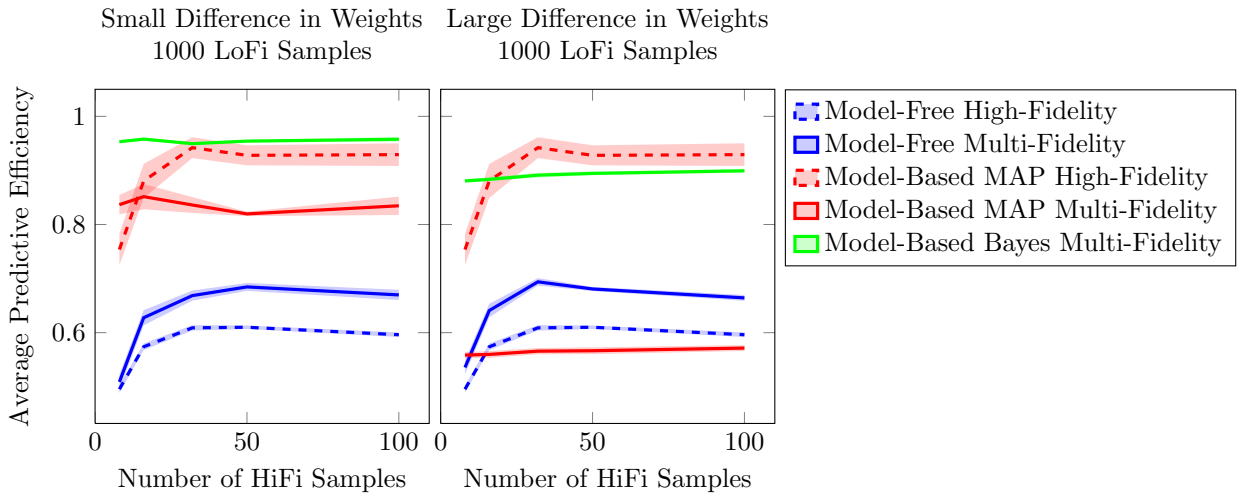

Figure 4: Predictive performance curves for various methods across different numbers of high-fidelity training samples. Lines depict mean predictive efficiency across the 10 simulations per sample-size condition, and the shaded-areas represent standard error. Results are shown for conditions in which the low- and high-fidelity utility weights have small (left) and large (right) differences between them.

Figure 3 shows how average predictive efficiency changes as a function of the amount of low- and high-fidelity training data for the identical utility weight condition. Figure 4 shows how average predictive efficiency is impacted by the level of discrepancy between low- and high-fidelity utility weights.

Multi-fidelity model-free approaches (blue solid lines) predicted better than methods that used only high-fidelity data (blue dashed lines), except for the case in which there was little (100 samples) low-fidelity available to train the model (Figure 3).

Model-based multi-fidelity approaches had better predictive performance (red and green solid lines) than high-fidelity methods (red dashed line) in cases when there was a large amount of low-fidelity data (1000 samples), and there was little or no difference in the utility weights used by the low-fidelity and high-fidelity humans in the task (Figures 3 and 4).

7 Conclusions and Further Work

We developed a multi-fidelity method for predicting the decisions of interacting humans. We investigated the conditions under which these methods produce better performance than exclusively relying on high-fidelity data. In general, our results suggest that multi-fidelity methods provide benefit if there is a sufficient amount of low-fidelity training data available and the differences between expert and novice behavior is not too large. Future effort will investigate these distinctions in greater detail.

This approach can also be extended to many domains beyond aviation. For example, work is currently being conducted that uses a 'power-grid game' to produce low-fidelity data to train algorithms that detect attacks on the system. This data could be combined with relatively sparse high-fidelity data (e.g., historical data involving known attacks) to increase the predictive performance of the model.

Latent Composite Likelihood Learning for the Structured Canonical Correlation Model

Ricardo Silva
Department of Statistical Science and CSML
University College London
RICARDO@STATS.UCL.AC.UK

Abstract

Latent variable models are used to estimate variables of interest – quantities which are observable only up to some measurement error. In many studies, such variables are known but not precisely quantifiable (such as "job satisfaction" in social sciences and marketing, "analytical ability" in educational testing, or "inflation" in economics). This leads to the development of measurement instruments to record noisy indirect evidence for such unobserved variables such as surveys, tests and price indexes. In such problems, there are postulated latent variables and a given measurement model. At the same time, other unantecipated latent variables can add further unmeasured confounding to the observed variables. The problem is how to deal with unantecipated latents variables. In this paper, we provide a method loosely inspired by canonical correlation that makes use of background information concerning the "known" latent variables. Given a partially specified structure, it provides a structure learning approach to detect "unknown unknowns," the confounding effect of potentially infinitely many other latent variables. This is done without explicitly modeling such extra latent factors. Because of the special structure of the problem, we are able to exploit a new variation of composite likelihood fitting to efficiently learn this structure. Validation is provided with experiments in synthetic data and the analysis of a large survey done with a sample of over 100,000 staff members of the National Health Service of the United Kingdom.

1 CONTRIBUTION

We present a method for learning the structure of a latent variable model, where latent variables are divided into two categories: i. latent variables which we would like to estimate, as in any smoothing task (e.g., to generate latent representations of data points for visualization, clustering, and ranking, among other tasks); ii. all other latent variables, which we are not interested in estimating but which can add further confounding among observed variables and as such cannot be ignored. They are nuisance variables.

This setup is motivated by many practical problems in the applied sciences where target latent variables are chosen upfront, with observed variables designed to measure the unobservable variables of interest. Consider the simple illustrative example of Figure 1.

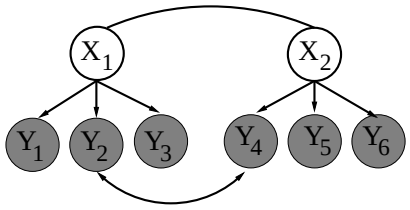

Figure 1: A latent variable model with a mixed graphical representation (that is, more than one type of edge).

Here, each X_i is a latent variable and each Y_i an observed variable. For instance, X_1 could represent a latent variable quantifying the level of job satisfaction, postulated to be measured by answers to questions such as $Y_1 \equiv$ "I can choose my own method of working" and $Y_2 \equiv$ "I have strong support from my manager". X_2 could represent a latent level of job responsibility, measured by questions such as $Y_4 \equiv$ "I know what my responsibilities are" and $Y_5 \equiv$ "I am regularly consulted by my team".

Other nuisance latent factors might correlate, say, the employee support from her manager and the level of interaction with her team. That is, associations not accounted by X_1 and X_2. This is represented graphically in Figure 1 by a bi-directed edge between two observed items, a notation widely used in the structural equation model literature (Bollen, 1989) and futher formalized by Richardson and Spirtes (2002). In a linear Gaussian model, for in-

stance, this could be parameterized by the measurement model equation $Y_i = \mathbf{X}^\mathsf{T}\beta + \epsilon_i$, where the covariance of the error terms for Y_2 and Y_4 is allowed to be non-zero. More details will be given in the sequel.

Conditioned on the background knowledge of a model where we specify the "known unknowns" – the latent features we would like to estimate by a postulated relationship to observations – we would like to identify the remaining dependence structure given by all remaining factors we did not specify in advance – the "unknown unknowns." This provides a meeting point between the common practice of designing measurement models for the practical goal of quantifying specific latent factors (Bollen, 1989), and purely data-driven approaches for discovering latent structure (Elidan et al., 2000; Silva et al., 2006).

The structure of the paper is as follows. A formal problem definition is given in Section 2, where we specifiy precisely the goals, classes of models and assumptions embedded in our procedure. Algorithms for structure learning are described in detail in Section 3, based on variations of the composite likelihood method integrated within a expectation-maximization framework. Further context and related work is discussed in Section 4. Experiments with synthetic and real data are discussed in Section 5, followed by a Conclusion in Section 6.

2 PROBLEM SPECIFICATION AND MODEL SPACE

In this section, we first define the space of graphical models which is assumed to contain the data generating process of interest. We then present further details on the parametric assumptions and a formulation based on *cumulative distribution networks* (Huang and Frey, 2008; Silva et al., 2011).

2.1 Structural Conditions

In our setup, we assume the following:

1. that the data is generated according to $\mathcal{G}$, an underlying directed acyclic graph (DAG) (Koller and Friedman, 2009) composed of latent and observed variables. In $\mathcal{G}$, observed variables are not parents of any other variable, as in typical models of factor analysis (Bartholomew and Knott, 1999);
2. that an expert provides a partition of the set of observed variables $\mathbf{Y}$, such that each set $\mathcal{S}_i \subset \mathbf{Y}$ in this partition corresponds to the observed children of a latent variable X_i. For example, in Figure 1, the partition is given by sets $\mathcal{S}_1 \equiv \{Y_1, Y_2, Y_3\}$ and $\mathcal{S}_2 \equiv \{Y_4, Y_5, Y_6\}$;
3. let $\mathbf{X}_\mathcal{S}$ be this set of latent variables associated with the partition (e.g., $\{X_1, X_2\}$ in Figure 1). We also allow for a (possibly infinite) set of latent variables $\mathbf{X}_\infty$ that is disjoint of $\mathbf{X}_\mathcal{S}$;
4. elements of $\mathbf{X}_\mathcal{S}$ are arbitrarily connected to each other in $\mathcal{G}$, and elements of $\mathbf{X}_\infty$ are also arbitrarily connected to each other. However, any $X_i \in \mathbf{X}_\mathcal{S}$ is marginally independent of any $X_j \in \mathbf{X}_\infty$ in $\mathcal{G}$.

2.2 Problem Specification

We want to account for any association among elements of $\mathbf{Y}$ that is due to $\mathbf{X}_\infty$, so that functionals of the conditional distribution $\mathcal{P}(\mathbf{X}_\mathcal{S} \mid \mathbf{Y})$ can be correctly estimated from data.

Instead of modeling the number of elements in $\mathbf{X}_\infty$ and how they relate to each other as in a nonparametric latent variable model formulation (e.g. Wood et al., 2006), we will treat the existence of $\mathbf{X}_\infty$ as a black-box. We model directly the dependencies that arise from its existence within a *mixed graph* formulation (Richardson and Spirtes, 2002). A mixed graph is a graph with more than one type of edge.

Let $\mathcal{G}_m$ be a graph with vertices $\mathbf{Y} \cup \mathbf{X}_\mathcal{S}$, and directed edges from each X_i to each element of $\mathcal{S}_i$. For simplicity, the structure among elements of $\mathbf{X}_\mathcal{S}$ is assumed to be a fully connected network of undirected edges. If two observed variables Y_i and Y_j have a common ancestor in $\mathbf{X}_\infty$ in $\mathcal{G}$, add a bi-directed edge $Y_i \leftrightarrow Y_j$ to $\mathcal{G}_m$. We say that $\mathcal{G}_m$ is the mixed graph induced by $\mathcal{G}$ and $\mathbf{X}_\mathcal{S}$. The conditional independence constraints entailed by $\mathcal{G}_m$ all hold in $\mathcal{G}$ (Richardson and Spirtes, 2002). Hence, identifiability issues aside, fitting a model based on a graph different from $\mathcal{G}_m$ should in general result in a misspecified distribution and give a inadequate model for $\mathcal{P}(\mathbf{X}_\mathcal{S} \mid \mathbf{Y})$.

Our goal can then be summarized as: *learn the structure of $\mathcal{G}_m$ by finding the correct bi-directed substructure.* In the example of Figure 1, this means returning the information that $Y_2 \leftrightarrow Y_4$ is the only bi-directed edge in $\mathcal{G}_m$.

The *practical* assumption here is that the bi-directed component of $\mathcal{G}_m$ is sparse. Sparsity in a bi-directed component corresponds to a marginal independence constraint among elements of $\mathbf{X}_\infty$: the lack of an edge $Y_i \leftrightarrow Y_j$ corresponds to the parents of Y_i in $\mathbf{X}_\infty$ being marginally independent of the parents of Y_j in $\mathbf{X}_\infty$. The extent to which this assumption is valid will depend on how well the dependence between elements of $\mathbf{Y}$ is captured by $\mathbf{X}_\mathcal{S}$ and it is verified empirically in Section 5. This complements Wood et al. (2006), which makes fewer assumptions but has to deal with a much harder problem.

2.3 Comments

The setup where observed variables are partitioned into sets corresponding to particular semantic groups is a key idea behind *canonical correlation analysis* (CCA). The standard CCA corresponds to a partition into two sets. For rank-one CCA, this corresponds to a graphical model with a single

latent variable being a parent of all observations, variables in each partition connected to each other by bi-directed edges. There are no bi-directed connections across variables in different sets of the partition, but CCA in general allows for several independent latent variables being common parents of all observations. A general latent variable model interpretation of canonical correlation analysis was originally introduced in a series of reports by Wegelin et al. (2001, 2002), and by Bach and Jordan (2005). In contrast, we are assuming that a single latent variable is (explicitly) a parent of each given group of variables, that such latent variables can be mutually dependent, but that extra factors are allowed. Common between our model space and CCA is the idea of having a partition of the observed variables. As such, we refer to the problem of searching for a structure in the space of graphs with a known partition as the *structured canonical correlation analysis* problem. We once again emphasize that a major motivation for this type of analysis is a domain-dependent assumption about which latent variables are being measured, and that such variables have a prior interpretation.

2.4 Parametric Assumptions

For a fixed level of $\mathbf{X}_{\mathcal{S}}$, observed variables $\mathbf{Y}$ should have marginal independence constraints as implied by the corresponding bi-directed structure. In a Gaussian parameterization, for instance, this would mean that the covariance of Y_i and Y_j given $\mathbf{X}_{\mathcal{S}}$ is constrained to be zero if Y_i is not adjacent to Y_j, and free otherwise (Richardson and Spirtes, 2002).

For this paper, we will model binary data. Latent variables $\mathbf{X}_{\mathcal{S}}$ are assumed to follow a zero mean Gausssian with an unknown covariance matrix Σ. For the rest of this section, we discuss models for the conditional distribution of observed variables given $\mathbf{X}_{\mathcal{S}}$. We will assume a linear model for each univariate dependence $\mathcal{P}(Y_i = 0 \mid X_j = x_j) \equiv \Phi(0; \beta_{i1} x_j + \beta_{i0}, 1)$ for $Y_i \in \mathcal{S}_j$. Function $\Phi(0; \mu, \sigma^2)$ is the probability of a Gaussian of mean μ and variance σ^2 being negative. Coefficients $\{\beta_{i1}, \beta_{i0}\}$ are unknown.

Given these univariate conditionals, a conditional joint is needed. Models of marginal independence for binary data can be obtained from a Gaussian parameterization, as discussed by Silva and Ghahramani (2009). However, in our context we will be also interested in performing Bayesian model selection. Although priors for sparse covariance matrices exist, performing model selection in a large space is computationally problematic: we are particularly motivated by the modeling of surveys with a large sample size. More details on that are discussed in Section 4.

2.4.1 Brief review of CDNs

Instead, we will adopt the cumulative distribution network framework (CDN) of Huang and Frey (2008, 2011). Given a symmetric graph, a CDN model defines the cumulative distribution function $F(\mathbf{y})$ of a multivariate distribution by a product of f factors. Each factor $F_i(\cdot)$ has as arguments the variables in a clique $\mathbf{Y}_{f_i}$ of the graph:

$$F(\mathbf{y}) \equiv \prod_{i=1}^{f} F_i(\mathbf{y}_{f_i})$$

As shown by Silva et al. (2011), this can be extended to accommodate conditional distributions and integrated with a copula modeling framework (Nelsen, 2007) [1]. For a fixed instantiation $\mathbf{x}$ of the parents $\mathbf{X}$ of a set of random variables $\mathbf{Y}$, its conditional CDF $\mathcal{P}(\mathbf{Y} \leq \mathbf{y} \mid \mathbf{X} = \mathbf{x}) \equiv F(\mathbf{y} \mid \mathbf{x})$ can be parameterized as

$$F(\mathbf{y} \mid \mathbf{x}) \equiv \prod_{i=1}^{f} C_i(u_{\mathbf{x}}(y_{f_i;1})^{e_{f_i;1}}, \ldots, u_{\mathbf{x}}(y_{f_i;n(i)})^{e_{f_i;n(i)}}) \tag{1}$$

where $C_i(\cdot)$ is a copula function, $y_{f_i;j}$ denotes the instantiation of the j-th variable in clique f_i, exponent $e_{f_i;j}$ is a non-negative parameter, and $n(i)$ the number of elements in clique f_i. Moreover,

$$u_{\mathbf{x}}(y_i) \equiv \mathcal{P}(Y_i \leq y_i \mid \mathbf{x}) \tag{2}$$

Also, for each Y_i, the sum of its respective exponents $e_\star$, across all factors containing Y_i, is equal to 1. For simplicity, we fix each exponent associated with Y_i to be $1/h(i)$, with $h(i)$ being the number of factors containing Y_i.

A powerful property of CDNs is its simple marginalization procedure: calculation of the marginal of a CDF by marginalizing a subset $\mathbf{Y}_{marg}$ consists of evaluating the CDF where $\mathbf{Y}_{marg} = \infty$. For instance, $\mathcal{P}(Y_1 \leq y_1, Y_2 \leq y_2) = \mathcal{P}(Y_1 \leq y_1, Y_2 \leq y_2, Y_3 \leq \infty, \ldots, Y_N \leq \infty)$.

In a graph such as $Y_1 \leftrightarrow Y_2 \leftrightarrow Y_3$, the CDF is given by a CDN model $F_1(y_1, y_2)F_2(y_2, y_3)$ and the corresponding marginal for Y_1 and Y_3 is given by $F_1(y_1, \infty)F_2(\infty, y_3) \equiv g(y_1)h(y_3)$, corroborating the fact that Y_1 and Y_3 should be marginally independent. In the case of a model

[1] A full description of copula models is beyond the scope of this paper. Nelsen (2007) provides further details, and Huang and Frey (2011), Silva et al. (2011) provide examples within the context of CDNs. For the purposes of this paper, it suffices to understand that a copula is nothing but a d-dimensional CDF with (continuous) uniform marginals in $[0, 1]^d$. Its motivation can then be understood: it allows for the construction of a joint distribution where marginals can be parameterized separately. By defining each univariate marginal $\mathcal{P}(y_i \mid \mathbf{x})$ separately, the transformation $u_{\mathbf{x}}(y_i) = \mathcal{P}(Y_i \leq y_i \mid \mathbf{x})$ gives an uniform $[0, 1]$ random variable. These transformed variables can then be plugged into a joint distribution with uniform marginals, which becomes a distribution with arbitrary marginals in the original space. This, among other uses, allows for the use of plug-in estimates for marginals to be combined with other estimators for joints. In this case, no further bias will be introduced into the marginal models even if the joint is misspecified or if the copula estimator is biased.

for $F(y_1, y_2, y_3 \mid \mathbf{x})$, according to (1), we have that $F(y_1, y_2, y_3 \mid \mathbf{x})$ is given by

$$C_1(u_{\mathbf{x}}(y_1), u_{\mathbf{x}}(y_2)^{1/2}) C_2(u_{\mathbf{x}}(y_2)^{1/2}, u_{\mathbf{x}}(y_3))$$

Recall that, if $C(u, v)$ is a copula function, then $C(u, 1) = u$ (since copulas are CDFs with $U(0, 1)$ marginals). One can then verify that $F(y_1, y_3 \mid \mathbf{x}) = \mathcal{P}(Y_1 \leq y_1 \mid \mathbf{x})\mathcal{P}(Y_3 \leq y_3 \mid \mathbf{x})$ and $F(y_2 \mid \mathbf{x}) = \mathcal{P}(Y_2 \leq y_2 \mid \mathbf{x})$ as desired.

Another advantage of the CDN formulation is that parameters across factors are functionally independent. This is in contrast with, for instance, the sparse covariance models of Richardson and Spirtes (2002) and Silva and Ghahramani (2009), where a positive definite constraint ties all parameters. Having no constraints across different factors will be a fundamental property to be exploited in our learning procedure. We call this property *parameter modularity*.

The difficulty with the CDN formulation is that in order to calculate the likelihood function, as required for any likelihood-based learning procedure, one has to convert the conditional CDFs into probability mass functions (PMFs) (Huang and Frey, 2011). This can potentially take an exponential amount of time on the number of variables in the graph. However, the marginalization property and the parameter modularity property of the CDNs leads to an attractive way of performing efficient learning, as we will see in the next section.

3 A LATENT COMPOSITE LIKELIHOOD APPROACH

Let $\mathcal{D} = \{\mathbf{Y}^{(1)}, \ldots, \mathbf{Y}^{(N)}\}$ be our data, a set of binary measurements of dimension p. For a given graphical structure $\mathcal{G}_m$ and fixed coefficient parameters $\{\beta_{i1}, \beta_{i0}\}$ and latent covariance matrix Σ, the marginal likelihood of $\{\mathcal{G}_m, \{\beta_{i1}, \beta_{i0}\}, \Sigma\}$ is

$$\mathcal{P}(\mathcal{D} \mid \mathcal{G}_m, \{\beta_{i1}, \beta_{i0}\}, \Sigma) =$$

$$\int \mathcal{P}(\mathcal{D}, \mathbf{X}^{1:N}, \theta \mid \mathcal{G}_m, \beta, \Sigma)\, d\mathbf{X}^{1:N}\, d\theta \qquad (3)$$

where $\mathbf{X}^{1:N}$ is a shorthand notation for $\{\mathbf{X}^{(1)}, \ldots, \mathbf{X}^{(N)}\}$, β is a shorthand notation for $\{\beta_{1,1}, \beta_{1,0}, \ldots, \beta_{p,1}, \beta_{p,0}\}$, and parameter set θ describes parameters associated with copula functions.

One approach for model selection is to assign a prior $\pi(\mathcal{G}_m)$ over possible graph structures and then choose $\mathcal{G}_m$ that maximizes $\mathcal{P}(\mathcal{D} \mid \mathcal{G}_m, \{\beta_{i1}, \beta_{i0}\}, \Sigma)\pi(\mathcal{G}_m)$. Since $\{\{\beta_{i1}, \beta_{i0}\}, \Sigma\}$ are also unknown, we could marginalize then away. However, such parameters do not affect the complexity of the model, and with the goal of having an efficient computational procedure, we will treat these parameters also as nuisance parameters and maximize with respect to them along with $\mathcal{G}_m$. In this paper, we will assume that individual pairwise factors are associated with each bi-directed edge in $\mathcal{G}_m$. Our prior for θ is independent[2] of $\mathcal{G}_m$ and factorizes as

$$\pi(\theta \mid \mathcal{G}_m) = \pi(\theta) = \prod_{1 \leq i < j \leq p} \pi(\theta_{ij}) \qquad (4)$$

Maximizing any expression that depends on (3) poses a formidable computational problem. Moreover, it depends on conditional probability expressions $\mathcal{P}(\mathbf{Y} \mid \mathbf{x})$. Such conditional mass functions need to be obtained from the canonical CDF $F(\cdot)$ to PMF $\mathcal{P}(\cdot)$ transformation (Joe, 1997), which for binary data boils down to:

$$\mathcal{P}(\mathbf{Y} = \mathbf{y}) = \sum_{z_1=0}^{1} \cdots \sum_{z_p=0}^{1} (-1)^{\sum_{i=1}^{p} z_i} F(\mathbf{y} - \mathbf{z}) \qquad (5)$$

This is of course exponential in p, but if the corresponding bi-directed component is a symmetric graph of low tree-width, the expression can be calculated efficiently by dynamic programming and used by any learning method that requires the likelihood function. The original derivation by Huang et al. (2010) is quite complex and provides insights on how approximate methods should behave. However, in the sequel we will make use of exact methods only, and as such we provide in the Supplementary Material a straighforward reduction of (5) to a standard inference problem in factor graphs – making the method easier to implement.

Integrating away θ and $\mathbf{X}$ is harder in general and large tree-width graphs are still a possibility. As such we avoid methods that attempt to maximize (3). The core procedure is based on structural composite likelihood learning. It is described in Section 3.1, and refined in Section 3.2. Further implementation details are given in Section 3.3. An alternative to these methods is to emulate a constraint-based approach (Spirtes et al., 2000) for structure discovery, providing a non-iterative procedure to identify which bi-directed edges are needed. This is done in Section 3.4. A brief discussion on model identification is provided in the Supplementary Material.

3.1 Basic Structural Composite Likelihood

A composite likelihood function (Varin et al., 2011) for a parameter of interest θ is defined as

$$CL(\theta; \mathcal{D}) = \prod_{k \in K} \mathcal{L}_k(\theta; \mathcal{D})^{w_k}$$

where $\mathcal{L}_k(\cdot)$ is the likelihood function resulting from the conditional probability (or density) function of a subset of

[2]Parameter θ_{ij} will not, of course, affect the likelihood function if $Y_i \leftrightarrow Y_j$ is not in $\mathcal{G}_m$. One could otherwise interpret θ_{ij} as simply not existing in this case, but this way of interpreting θ_{ij} will make the presentation easier without being less precise.

$\mathbf{Y}$ given another subset, and w_k are user-specified weight parameters. It is intuitive to understand why a composite likelihood function can provide consistent estimates of θ: if an unique model is identifiable from the marginal conditional densities used in each $\mathcal{L}_k(\cdot)$, then maximizing the log-composite likelihood is equivalent to minimizing the KL-divergence between each marginal conditional and the empirical distribution. By matching each marginal as the divergence goes to zero, one recovers the parameters.

Joreskog and Moustaki (2001) applied this concept in the context of latent variable models, by fitting a probit model using univariate and bivariate marginals with equal weight. A key fact is that bivariate likelihoods can be integrated numerically, since only two underlying latent variables are present. Although still computationally demanding, this approach does not require any Markov chain Monte Carlo within a stochastic EM procedure, nor requires biased approximations such as mean-field methods. We initially propose a similar idea, where our (penalized) composite likelihood function is given by

$$PCL(\mathcal{G}_m, \beta, \Sigma) \equiv \mathcal{F}_{\mathcal{G}_m}^{(\beta,\Sigma)} + \log \pi(\mathcal{G}_m), \qquad (6)$$

$$\mathcal{F}_{\mathcal{G}_m}^{(\beta,\Sigma)} \equiv \sum_{i<j} \log \mathcal{P}(\mathbf{Y}_i^{1:N}, \mathbf{Y}_j^{1:N} \mid \mathcal{G}_m, \beta, \Sigma)$$

When using one-parameter copula functions (Nelsen, 2007), each bivariate term $\mathcal{P}(\mathbf{Y}_i^{1:N}, \mathbf{Y}_j^{1:N} \mid \mathcal{G}_m, \beta, \Sigma)$ requires the numerical integration of at most three terms: the copula parameter θ_{ij} corresponding to the edge $Y_i \leftrightarrow Y_j$ and up to two latent variables per data point configuration, as explained in Section 3.3.

A greedy procedure for optimizing $PCL(\cdot,\cdot,\cdot)$ is outlined in table Algorithm 1. It takes as input a partition over observed variables ($\mathcal{S}$) and a dataset $\mathcal{D}$. Algorithm 1 alternates between optimizing the objective function with respect to the continuous parameters (Step 5), and optimizing structure (Steps 6). Optimization in Step 5 is done with respect to the coefficient space Ω_β and correlation matrix space Ω_Σ, as explained in further detail in Section 3.3. The structural update is a standard greedy algorithm that picks the best choice of graph within the graph space $\mathcal{G}_m^{+/-}$: the space that includes $\mathcal{G}_m$ and all mixed graphs that differ from $\mathcal{G}_m$ by exactly one bi-directed edge. Finally, procedure GETDAG($\mathcal{S}$) at the beginning of Algorithm 1 just returns the variable space ($\mathbf{Y}$, $\mathbf{X}_\mathcal{S}$) and the initial mixed graph without any bi-directed edges. The initialization of parameters is discussed in the Supplementary Material.

Algorithm 1 Pairwise Structured CCA Learning

1: **procedure** LEARNSTRUCTUREDCCA-I($\mathcal{S}$,$\mathcal{D}$)
2: $\{\mathbf{Y}, \mathbf{X}_\mathcal{S}, \mathcal{G}_m\} \leftarrow$ GETDAG($\mathcal{S}$)
3: $\{\beta, \Sigma\} \leftarrow$ INITPARAMETERS($\mathcal{G}_m, \mathcal{D}$)
4: **repeat**
5: $\{\beta, \Sigma\} \leftarrow \arg\max_{(\Omega_\beta, \Omega_\Sigma)} PCL(\mathcal{G}_m, \beta, \Sigma)$
6: $\mathcal{G}_m \leftarrow \arg\max_{(\mathcal{G}_m^{+/-})} PCL(\mathcal{G}_m, \beta, \Sigma)$
7: **until** $\mathcal{G}_m$ has not changed.
8: **return** $\mathcal{G}_m$
9: **end procedure**

3.2 Learning via Distributed EM Bounds

Even for problems with large sample sizes, one might be concerned that using only pairwise regions might imply low statistical efficiency. Higher (statistical) efficiency can be obtained by using components with more than two observed variables. This is undesirable, as it might require sophisticated integration methods, including MCMC. We present a different way of sharing statistical power among different pairwise likelihood functions without requiring an integration procedure on dimensions higher than in the pairwise procedure of the previous Section. It is based on ideas adapted from the expectation-maximization (EM) family of optimization methods (Dempster et al., 1977).

Using the standard Jensen bound for convex combinations, but applied independently to different terms in a summation, it is possible to lower-bound $\mathcal{F}_{\mathcal{G}_m}^{(\beta,\Sigma)}$ as

$$\sum_{i<j} \int q_{ij}(\theta_{ij}) \log \frac{\mathcal{P}_{ij}(\mathbf{Y}_i^{1:N}, \mathbf{Y}_j^{1:N}, \theta_{ij} \mid \mathcal{G}_m, \beta, \Sigma)}{q_{ij}(\theta_{ij})} d\,\theta_{ij} \qquad (7)$$

The bound holds for any choice of $q_{ij}(\cdot)$ and it is well-known to be maximized by choosing $q_{ij}(\cdot)$ to be $\mathcal{P}(\theta \mid \mathbf{Y}_i^{1:N}, \mathbf{Y}_j^{1:N}, \mathcal{G}_m, \beta, \Sigma)$ (Neal and Hinton, 1998).

We will further modify the idea in (7) with a different matching between functionals $q_{ij}(\cdot)$ and log-likelihood functions. Let $X_i \in \mathbf{X}_\mathcal{S}$ and recall $\mathcal{S}_i$ are the observed children of X_i in $\mathbf{Y}$. Let $|\mathcal{S}|$ be the number of latent variables. The trick is to first rewrite $\mathcal{F}_{\mathcal{G}_m}^{(\beta,\Sigma)}$ as in Equation (8) displayed in Table 1. Using an arbitrary set of distributions $\{q_{mn}(\cdot)\}$, $1 \le m < n \le |\mathcal{S}|$, $PCL(\mathcal{G}_m, \beta, \Sigma)$ can then be rewritten and elementwise bounded as

$$PCL(\mathcal{G}_m, \beta, \Sigma) \ge \mathcal{Q}_{\mathcal{G}_m}^{(\beta,\Sigma,\{q_{mn}(\cdot)\})} + \log \pi(\mathcal{G}_m) + \kappa \qquad (10)$$

where $\mathcal{Q}_{\mathcal{G}_m}^{(\beta,\Sigma)}$ is defined as Equation (9) in Table 1, and constant κ does not depend on the free parameters $\{\mathcal{G}_m, \beta, \Sigma\}$.

Given this setup, we finally define $q_{mn}(\Theta_{mn})$ to be the joint distribution $\mathcal{P}(\Theta_{mn} \mid \mathbf{Y}_{mn}^{1:N}, \mathcal{G}_m, \beta, \Sigma)$, where $\mathbf{Y}_{mn}$ are the *joint children* of X_m and X_n, and Θ_{mn} are the copula parameters used in the corresponding marginal model for $\mathbf{Y}_{mn}$. Function $q_{mn}(\theta_{ij})$ is then the corresponding (univariate) marginal of $q_{mn}(\Theta_{mn})$.

The desirable property of (10) is that, while it still requires only a three-dimensional integration (details in Section 3.3), information from Y_k, not in $\{Y_i, Y_j\}$, can be

Table 1: Components of a Pairwise Composite Likelihood Score Function

$$\mathcal{F}_{\mathcal{G}_m}^{(\beta,\Sigma)} = \sum_{m<n} \sum_{Y_i \in \mathcal{S}_m} \sum_{Y_j \in \mathcal{S}_n} \log \mathcal{P}(\mathbf{Y}_i^{1:N}, \mathbf{Y}_j^{1:N} \mid \mathcal{G}_m, \beta, \Sigma) + \sum_{m=1}^{|\mathcal{S}|} \frac{1}{|\mathcal{S}|-1} \sum_{n=1}^{|\mathcal{S}|-1} \sum_{\{Y_i,Y_j\} \subset \mathcal{S}_m} \log \mathcal{P}(\mathbf{Y}_i^{1:N}, \mathbf{Y}_j^{1:N} \mid \mathcal{G}_m, \beta, \Sigma) \tag{8}$$

$$\begin{aligned} \mathcal{Q}_{\mathcal{G}_m}^{(\beta,\Sigma,\{q_{mn}(\cdot)\})} \quad = \quad & \sum_{m<n} \sum_{Y_i \in \mathcal{S}_m} \sum_{Y_j \in \mathcal{S}_n} \int q_{mn}(\theta_{ij}) \log \mathcal{P}(\mathbf{Y}_i^{1:N}, \mathbf{Y}_j^{1:N} \mid \mathcal{G}_m, \beta, \Sigma, \theta_{ij}) d\,\theta_{ij} + \\ & \frac{1}{|\mathcal{S}|-1} \sum_{m=1}^{|\mathcal{S}|} \sum_{n \neq m} \sum_{\{Y_i,Y_j\} \subset \mathcal{S}_m} \int q_{mn}(\theta_{ij}) \log \mathcal{P}(\mathbf{Y}_i^{1:N}, \mathbf{Y}_j^{1:N} \mid \mathcal{G}_m, \beta, \Sigma, \theta_{ij}) d\,\theta_{ij} \end{aligned} \tag{9}$$

Algorithm 2 Modified Pairwise Structured CCA Learning

1: **procedure** LEARNSTRUCTUREDCCA-II($\mathcal{S}$,$\mathcal{D}$)
2: $\{\mathbf{Y}, \mathbf{X}_\mathcal{S}, \mathcal{G}_m\} \leftarrow$ GETDAG($\mathcal{S}$)
3: $\{\beta, \Sigma\} \leftarrow$ INITPARAMETERS($\mathcal{G}_m, \mathcal{D}$)
4: **repeat**
5: **for** $1 \leq m < n \leq |\mathcal{S}|$ **do**
6: $q_{mn}(\cdot) \leftarrow \mathcal{P}(\Theta_{mn} \mid \mathbf{Y}_{mn}^{1:N}, \beta, \Sigma, \mathcal{G}_m)$
7: **end for**
8: $\{\beta, \Sigma\} \leftarrow \arg\max_{(\Omega_\beta, \Omega_\Sigma)} Q_{\mathcal{G}_m}^{(\beta,\Sigma,\{q_{mn}(\cdot)\})}$
9: $\mathcal{G}_m \leftarrow \arg\max_{(\mathcal{G}_m^{+/-})} PCL(\mathcal{G}_m, \beta, \Sigma)$
10: **until** $\mathcal{G}_m$ has not changed.
11: **return** $\mathcal{G}_m$
12: **end procedure**

passed around. Consider the graph in Figure 1 again. There is a d-connecting path between Y_2 and Y_6 given Y_4 (or "m-connecting," using the nomenclature from Richardson and Spirtes, 2002). Hence, there is a three-way interaction between Y_2, Y_4 and Y_6 that varies according to the copula between $Y_2 \leftrightarrow Y_4$, and information from $\mathbf{Y}_6$ is propagated to the estimation of $\beta_{2;1}$ and $\beta_{4;1}$ via the distribution of $\theta_{2;4}$.

A modification of Algorithm 1 is shown in Algorithm 2. The parameter fitting procedure is now expanded into Steps 5-8, with the structure learning step unmodified. The posterior $\mathcal{P}(\Theta_{mn} \mid \mathbf{Y}_{mn}^{1:N}, \mathcal{G}_m, \beta, \Sigma)$ needs to be calculated efficiently and it has to lead to efficient integration in Step 8. This is discussed in Section 3.3. Moreover, it might be surprising that in Step 9 we do not optimize structure with respect to the same function of Step 8. Optimizing the bound of Equation (10) with respect to the graph is equivalent to a composite likelihood Structural EM procedure (Friedman, 1998). While Structural EM procedures are definitely useful, we prefer to not apply it uncritically to our special situation. EM is a coordinate ascent method (Neal and Hinton, 1998), and as such it is more prone to get stuck in a local maxima compared to optimizing marginal likelihoods directly. This is particularly true when optimizing with respect to a discrete structure – in this case, it is common to prematurely converge to a structure with fewer bi-directed edges than expected if we optimize the Structural EM lower bound starting with an empty bi-directed component. Since for each data point we have no more than two latent variables per log-likelihood term in $PCL(\cdot,\cdot,\cdot)$, we avoid maximizing a lower bound in Step 9. Convergence issues are discussed in the Supplementary Material.

3.3 Implementation Details

For Algorithm 2, we obtain the posterior distribution $q_{mn}(\Theta_{mn})$ using the Laplace approximation (MacKay, 2003). Our goal is to use Algorithms 1 and 2 in problems with large sample sizes, and hence such an approximation can provide a reasonably accurate replacement for the exact posterior – which has no closed form and would require a numerical method in any case.

Even the Laplace approximation procedure requires another inner approximation. Recall that in order to obtain the mean vector and covariance matrix required to approximate the distribution of Θ_{mn} with a Gaussian, we need to maximize $\log \mathcal{P}(\mathbf{Y}_{mn}^{1:N} \mid \mathcal{G}_m, \beta, \Sigma, \Theta_{ij}) + \log \pi(\Theta_{mn})$. Let P be the total number of children between X_i and X_j. Then $\mathcal{P}(\mathbf{Y}_{mn}^{1:N} \mid \Theta_{mn}, \mathcal{G}_m, \beta, \Sigma)$ can be rewritten as

$$\prod_{\mathbf{y}_{mn} \in \{0,1\}^P} \left(\int \mathcal{P}(\mathbf{y}_{mn}, x_m, x_n \mid \Theta_{mn}, \dots) d\,x_m d\,x_n\right)^{N_{mn}}$$

which takes constant time in sample size[3] given precomputed sufficient statistics N_{mn}, the count of events $\mathbf{Y}_{mn} = \mathbf{y}_{mn}$ in dataset $\mathcal{D}$, and under an approximation to each of the two-dimensional integrals.

In our implementation, we use an approximation for the

[3] Assuming that the marginal of $\mathcal{G}_m$ over $\mathbf{Y}_{mn}$ has a bounded tree-width, this expression is tractable in the dimensionality of the problem using the CDN inference method to obtain the likelihood function (Huang and Frey, 2011, see also the Supplementary Material). The full graph $\mathcal{G}_m$ might have a large tree-width, as long as the subgraph given by $\mathbf{Y}_{mn}$ does not.

integral of $\mathcal{P}(\mathbf{y}_{mn}, x_m, x_n \mid \Theta_{mn}, \beta, \Sigma, \mathcal{G}_m)$ of the form

$$\approx \sum_k w_k(\sigma_{mn}) \mathcal{P}(\mathbf{y}_{mn}, x_m^{(k)}, x_n^{(k)} \mid \Theta_{mn}, \beta, \Sigma, \mathcal{G}_m) \tag{11}$$

for a fixed set of grid points $\{(x_m^{(k)}, x_n^{(k)})\}$ regardless of the values of m and n, but a function of the covariance $\sigma_{mn} \equiv (\Sigma)_{mn}$. Any quadrature method could be used.

We opted for an admittely crude but simple implementation which uses an arguably excessive number of points compared to adaptive quadrature methods, but which is relatively amortized taken into account such integrations need to be done several thousand times – we need to calculate our weights w_k only once. Without loss of generality, Σ can be assumed to be a correlation matrix. For each marginal $\{x_m, x_n\}$, we naively space the grid points uniformly between the 0.01 and 0.99 quantiles of the standard Gaussian. The result is a division of the space into squares centered at each $\{(x_m^{(k)}, x_n^{(k)})\}$ which does not depend on m and n. We define $w_k(\sigma_{mn})$ to be the probability mass of each square. This can be pre-computed only once in the whole procedure, also using the following simplification of Σ: we allow each entry σ_{mn} to lie only within the discrete set of choices $\{-0.99, -0.97, \ldots, 0.97, 0.99\}$ and cache $w_k(\sigma_{mn})$ for every k and possible value of σ_{mn}. Since they correspond to bivariate Gaussian integrals, recomputing these weights $\mathcal{O}(p^2)$ times at each iteration would otherwise be very costly.

Equations (8) and (9) require integrals over θ_{mn}. Given the approximation for the bivariate likelihood of each pairwise data point configuration, we introduced a discrete approximation for the prior $\pi(\theta_{mn})$ (Algorithm 1) or univariate Gaussian marginal $q_{mn}(\theta_{mn})$ that results from the Laplace approximation (Algorithm 2). The grid points are naively a number of quantiles corresponding to uniformly spread cumulative probabilities in $[0, 1]$. These quantiles are recomputed at every iteration, since this is relatively cheap.

When optimizing parameters, we optimize β for a fixed Σ by gradient methods[4]. We then optimize Σ given $\{\beta_{i1}, \beta_{i0}\}$ without enforcing positive definiteness: the evaluation of $\mathcal{F}$ and $\mathcal{Q}$ does not require this condition. The objective functions decouple over the entries of Σ and hence each entry σ_{mn} can be optimized separately – by searching over the discretized space $\{-0.99, -0.97, \ldots, 0.97, 0.99\}$, as required to allow for the caching of $w_k(\sigma_{mn})$.

3.4 Bivariate Residual Search

An alternative to the expensive iterative methods from the previous section is to do a single hypothesis test for each bi-directed edge. If one knew parameters $\{\beta, \Sigma\}$, a possibility is to do a χ^2-like measure of fitness of the implied bivariate contingency table for each $\{Y_i, Y_j\}$, and add the corresponding bi-directed edge if there is evidence of misfit. Without knowledge of $\{\beta, \Sigma\}$, a possibility is to fit the model without bi-directed edges as a surrogate, in the hope that such estimates are good enough to detect misfit. In Algorithm 3, we outline a procedure where the test of misfit is to choose between two models with the single edge $Y_i \leftrightarrow Y_j$ and none (our definition of the space $\mathcal{G}_m^{ij(+/-)}$) based on $PCL(\cdot, \cdot, \cdot)$ – essentially a Bayesian test for the edge in the bivariate model $\mathcal{P}(Y_i, Y_j \mid \beta, \Sigma)$. The final graph is given by the union of all edges that were selected by the bivariate tests. The shortcoming of course is that the initial parameter estimate might be bad if there are reasonably strong dependencies due to the unaccounted latent variables. Iterating the procedure, however, gives a procedure that is essentially Algorithm 1, albeit with a "parallel" testing of the edges. For simplicity, we do not consider the continuum between sequential and parallel tests (e.g., methods where initial iterations would modify one edge only per parameter update, allowing multiple edge modifications later on) and evaluate Algorithm 3 only.

Algorithm 3 Single-shot Structured CCA Learning

4 RELATED WORK

More conventional uses of EM in the context of composite likelihod have been discussed by Varin et al. (2011) and Gao and Song (2011). CCA has been applied in other contexts in machine learning, such as analysing text data under different languages (Hardoon et al., 2004). This setup and usage is very different from our motivation, which focus on applications with several small sets of measurements, and where the special structure of the latent space (a one-to-one association between latent variables and groups of observable variables) is motivated by particular applications in measurement error problems (Bollen, 1989). Concerning model selection in structured latent spaces, Silva and Ghahramani (2009) provides an approach based on Gaussian distributions, and a Gaussian copula method can be readily applied to the binary modeling case. However, we want to avoid a full likelihood approach for scalability reasons. While Silva and Ghahramani (2009) provides priors over sparse covariance matrices, it is not clear what

[4]In order to reduce the number of parameters, we calculate each intercept β_{i0} as a function of the slope β_{i1} such that the marginal probability $\mathcal{P}(Y_i = 0 \mid \beta, \Sigma)$ matches the empirical probability. Hence the only free parameters are the slopes $\{\beta_{i1}\}$.

the marginals of such priors are over subsets of the observations: sparse inverse Wishart priors do not have a closed form for their marginals. This makes the Bayesian Gaussian approach seemingly hard to apply in the composite likelihood scenario. The use of composite likelihood methods in model selection (Varin and Vidoni, 2005) has been increasing in recent years, including variations where parameters across different likelihood components do not need to be constrained to be the same: a postprocessing method can be used to combine estimates from different regions into a single point estimate (e.g., Meinshausen and Buehlmann, 2006). Further consequences of ignoring association due to unspecified factors in a latent variable model are discussed by Westfall et al. (2012). It is also important to mention that the method here introduced generalizes the learning methods of Huang and Frey (2011), since the CDN is a special case. It is also an alternative to maximum likelihood estimation for networks of large tree-width.

5 EVALUATION

We evaluate the approach with a synthetic and a real-world experiment. The prior over graphical structures is given by an independent probability of 0.1 for each bi-directed edge. We use Frank copulas for the dependence structure (Nelsen, 2007). The prior for parameter θ_{ij} is defined by first sampling a standard Gaussian $Z \sim \mathcal{N}(0,1)$ and squashing it as $\theta_{ij} = [1/(1+e^{-z})] \times 50 - 25$, which generates θ_{ij} in the interval $[-25, 25]$ – beyond which the Frank copula gives numerically unstable results in our code.

5.1 Synthetic Studies

We simulate[5] 20 networks with 4 latent variables and 4 children per latent variable. Bi-directed edges were added independently with probability 0.2. The network is then pruned randomly so that each latent variable d-separates at least three children, and that each observed variable has no more than 3 adjacent bi-directed edges. The average number of resulting edges was approximately 18. Results for three evaluation measures are shown in Figure 2. We compare the three methods of Section 3, doing a comparison at three different sample sizes (1000, 5000 and 10000). We show the average paired difference over 20 trials between LEARNSTRUCTUREDCCA-II (LSC-II) and LSC-I, and between LSC-II and LSC-0. The first criterion is the root mean squared error of the average slope coefficients $\{\beta_1\}$ with respect to the true model; the second criterion is "edge omission," the number of incorrectly removed edges divided by the total number of edges; the third criterion is "edge commission," incorrect addition of an edge divided by the total number of possible additions. The number of times where the difference is positive with the corresponding p-values for a Wilcoxon signed rank test are given below (stars indicate numbers less than 0.05):

	1000		5000		10000	
Slope	I	0	I	0	I	0
number	13	6	17	15	15	13
p-value	0.22	0.25	*	*	*	0.06
Omission	I	0	I	0	I	0
number	11	18	6	14	6	9
p-value	0.17	*	0.82	*	0.62	0.22
Commision	I	0	I	0	I	0
number	5	2	15	16	16	18
p-value	0.28	*	*	*	*	*

The upshot is that Algorithm 2 does at least as well as the others concerning edge omission, but with substantially fewer false positives – a problem that particularly affects the single-shot algorithm. Algorithm 2 is also more robust concerning parameter estimation. It has to be said, however, that all methods do badly concerning edge omission at sample size 1000: in more than 10 trials, Algorithm 2 had edge omission rates over 0.5. At sample size 5000, this substantially decreased (17 trials under 0.2, 10 under 0.15). Algorithm 2 commission errors are typically low (< 0.05) for all datasets. It is also relevant that Algorithm 2 typically converges faster than Algorithm 1 despite the extra step on approximating posteriors with the Laplace approximation.

5.2 Analysis of the NHS Staff Survey

We present a simple application to the modeling of response patterns in the 2009 National NHS Staff Survey (Care Quality Comission and Aston University, 2010). We now emphasize less an evaluation of the structure and more the initial goal described in Section 2.2 on showing how finding bi-directed structures helps in estimating functionals of $\mathcal{P}(\mathbf{X}_{\mathcal{S}} \mid \mathbf{Y})$. The NHS (National Health Service) is the public healthcare system of the United Kingdom. A survey concerning different aspects of job satisfaction, work conditions, training and other factors takes place regularly. We provide an analysis of the 2009 survey, which was returned by 156,951 respondents. Under the assumption that sections in the questionnaire translate to particular trait factors, we evaluate how much is gained by allowing a latent variable model to be adaptive to external factors not originally included in the model. Responses to questions are either binary Yes/No questions or encoded in an ordinal scale (varying in 5 points from strong disagreement to strong agreement). We en-

[5]Other details about the simulation: a "signal factor" (the ratio between the variance β_{i1}^2 implied by the Gaussian X_m, and $\beta_{i1}^2 + 1$ given by the added variance of the probit model) is the sampled uniformly within the interval $[0.2, 0.6]$ for each variable Y_i. Slope β_{i1} is then set accordingly as a function of the signal factor, with its sign chosen with probability 0.5. A "marginal factor" (the marginal probability $\mathcal{P}(Y_i = 0)$) is uniformly sampled within the interval $[0.1, 0.9]$, and intercept β_{i0} is set according to the marginal factor and the sampled value of β_{i1}. We sample each copula parameter independently, uniformly in the interval $[10, 15]$. Finally, we generate Σ by rescaling as a correlation matrix the result of $\sum_{k=1}^{4} z_k z_k^{\mathsf{T}}$, where $Z_K \sim \mathcal{N}(0,1)$.

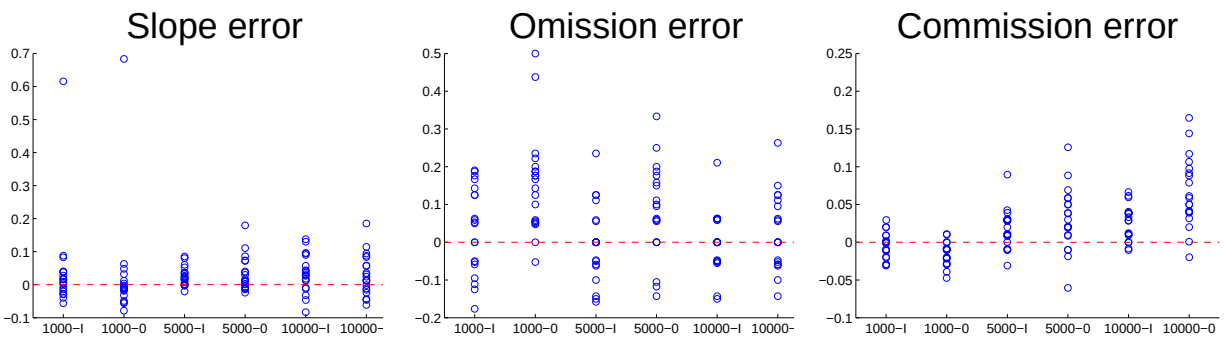

Figure 2: Differences between LEARNSTRUCTUREDCCA-II (LSC-II) and LSC-I are labeled, at three different samples sizes, as 1000-I, 5000-I and 10000-I. Differences between LSC-II and LSC-0 are labeled analogously.

coded ordinal data as binary, assigning the value of 1 to "Agree" and "Strongly agree" responses, and 0 otherwise (including missing or not applicable responses). We generated 9 factors out of the questionnaire with a total of 50 observed variables. The selection and partitioning process is described in detail in the Supplementary Material. We randomly selected 100,000 respondents as a training set and fit a model using LEARNSTRUCTUREDCCA-II. A total of about 40 bi-directed edges was generated. We also fit the model without any bi-directed edges. Since we cannot calculate marginal likelihoods easily as a way of comparing the models, we resort to evaluating the predictive ability of the latent representations. Given these two models, we generate latent embeddings of the observations[6] in the test set by maximizing $\sum_{ij} \log \mathcal{P}(Y_i^{(d)}, Y_j^{(d)}, X_i^{(d)}, X_j^{(d)} \mid \beta, \Sigma, \mathcal{G}_m)$, for each data point d, with respect to the latent variables. Here X_i and X_j are the (possibly unique) latent parents of Y_i and Y_j. This results in over 50,000 points in a 9-dimensional space. Half of these points were used to build 11 logistic regression models to predict answers to questions not included in the model[7]. We calculated the area under the curve for predictions done in the test set of approximately 28,000 points. Results are shown in the Table 2, which illustrates that the mixed model does at least as well or better at generating a latent representation of the observations, while preserving the interpretability of the model.

Table 2: Comparison of the mixed graph CCA model (MCCA) against the standard, fixed structure, model (SCCA) in 11 binary classification tasks, as measured by the area under the curve.

	MCCA	SCCA		MCCA	SCCA
Q1	0.71	0.71	Q7	0.80	0.79
Q2	0.75	0.75	Q8	0.82	0.81
Q3	0.86	0.82	Q9	0.86	0.83
Q4	0.90	0.82	Q10	0.69	0.69
Q5	0.79	0.80	Q11	0.78	0.75
Q6	0.73	0.72			

6 CONCLUSION

We summarize the main features of our method:

- it searchs only over a projection of an infinite dimensional latent space into a mixed graph structure, instead of explicitly adding latent variables. Conditioned on $\mathbf{X}_S$, the composite likelihood function can be calculated analytically. This is possible due to the *implicit latent variable representation* of the CDN;
- assuming no missing data, it requires only the sufficient statistics for regions of bounded size, computable with a single pass through the data, possible due to the *marginalization property* of the CDN;
- optimization is unconstrained, thanks to the *parameter modularity* property of the copula formulation;
- it allows for the use of simple deterministic integration methods, while still providing a mechanism to propagate information beyond simple pairs of observed variables – a *novel variation of composite likelihood estimation*, to the best of our knowledge.

Although the approach scales well in the sample size, the parameter fitting step is still particularly expensive in high-dimensions, as also noted by Joreskog and Moustaki (2001). A more efficient algorithm can be achieved by a smarter implementation of the gradient optimization method, or by relaxing the restriction that parameter estimates need to be the same across different likelihood components (Meinshausen and Buehlmann, 2006). Moreover, having an adaptive structure for the partition of the random variables is also an important direction.

[6] After fitting both models, 5 of the observed variables were given extreme coefficients in their measurement equations (in both models). In order to make the embedding process numerically stable, we removed these 5 variables from the testing.

[7] Questions concerned job satisfaction. See Supp. Material.

Abstract

Shotgun proteomics is a high-throughput technology used to identify unknown proteins in a complex mixture. At the heart of this process is a prediction task, the *spectrum identification problem*, in which each fragmentation spectrum produced by a shotgun proteomics experiment must be mapped to the peptide (protein subsequence) which generated the spectrum. We propose a new algorithm for spectrum identification, based on dynamic Bayesian networks, which significantly outperforms the de-facto standard tools for this task: SEQUEST and Mascot.

1 Introduction

Shotgun proteomics is the dominant technology used to identify which proteins are present in a cell or tissue sample, and is widely used in the biological sciences (Marcotte, 2007; Steen and Mann, 2004). At the heart of shotgun proteomics is a machine learning problem. Proteins are broken down into small fragments, called peptides. Although shotgun proteomics cannot directly determine the sequence of these peptides, the technology can rapidly generate indirect information about peptide sequences, called fragmentation spectra. The task of identifying the peptide string responsible for generating an observed fragmentation spectrum is known as the *spectrum identification problem*. This problem is similar in form to speech recognition, in which a spoken utterance (fragmentation spectrum) is mapped to its corresponding natural language string (peptide sequence).

This paper applies dynamic Bayesian networks (DBNs) to the spectrum identification problem. We draw on ideas from the graphical models community to build an algorithm for spectrum identification which is significantly more accurate than the most popular tools in wet-lab use, SEQUEST (Eng et al., 1994) and Mascot (Perkins et al., 1999), as well as other representative tools which have been proposed for spectrum identification. We call our algorithm Didea[1].

2 Background

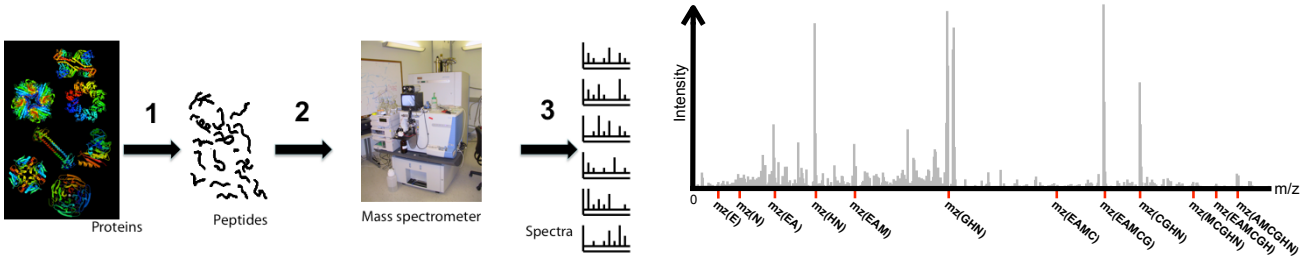
Spectrum identification is a machine learning problem, but like many problems in computational biology, one which has a high barrier to entry for computer scientists. Therefore, we present a self-contained introduction to shotgun proteomics, explaining how peptides generate fragmentation spectra (Section 2.1). One of the reasons for using a dynamic Bayesian network is that it allows us to use qualitative knowledge about the physics of peptide fragmentation (in the structure of the DBN) and a small number of trainable parameters to improve predictive power.

We review the literature on spectrum identification, which falls into two broad categories: database search (Section 2.2) and *de novo* identification (Section 2.3). Database search uses additional biological information about the sample being analyzed to constrain the statistical complexity of spectrum identification. Database search is more accurate than *de novo*, and is the preferred technique in practice (Kim et al., 2010). The two most popular tools in wet-lab practice, SEQUEST and Mascot, are both database search tools, as is Didea.

2.1 Shotgun Proteomics

A typical shotgun proteomics experiment proceeds in three steps, as illustrated in Figure 1(a). The input to the experiment is a collection of proteins, which have been isolated from a complex mixture. Each protein can be represented as a string of amino acids, where the alphabet is size 20 and the proteins range in length from 50–1500 amino acids. A typical complex mixture may

[1] A portmanteau of the words 'Dynamic', 'Peptide', and 'Algorithm'.



(a) The three steps—(1) cleaving proteins into peptides, (2) separation of the peptides using liquid chromatography, and (3) tandem mass spectrometry analysis.

(b) Red ticks indicate where we expect to detect ions from the fragmentation of peptide EAMCGHN.

Figure 1: The schematic for a typical shotgun proteomics experiment (a), with an example of a real fragmentation spectrum annotated by the theoretical spectrum, in red, of a candidate peptide EAMCGHN (b).

contain a few thousand proteins, ranging in abundance from tens to hundreds of thousands of copies.

In the first experimental step, the proteins are digested into peptides, or protein subsequences, using a molecular agent called trypsin. On average, the length of the peptides for the model organisms we consider is 14-15, with no peptides being longer than 50 amino acids. Digestion is necessary because whole proteins are too massive to be subject to direct mass spectrometry analysis without using very expensive equipment. In the second experimental step, peptides are subjected to a process called *liquid chromatography*, in which the peptides pass through a thin glass column that separates the mixture of peptides based on a particular chemical property (e.g., hydrophobicity). This separation step reduces the complexity of the mixtures of peptides going into a mass spectrometer. The third experimental step, which occurs inside the mass spectrometer, involves two rounds of mass spectrometry. Approximately every second, the device analyzes the population of approximately 20,000 intact peptides that most recently exited from the liquid chromatography column. Then, based on this initial analysis, the machine selects five distinct peptide species for fragmentation. Each of these fragmented species is subjected to a second round of mass spectrometry analysis. The resulting "fragmentation spectra" are the primary output of a shotgun proteomics experiment.

A fragmentation spectrum is shown in Figure 1(b). We explain how such a spectrum is generated using a concrete example. Assume that, from the population of 20,000 intact peptides, we isolate a distinct peptide species: a collection of peptide molecules, each with sequence EAMCGHN. Each peptide molecule has extra protons, which allows it to be isolated and accelerated using magnetic fields. Molecules with extra protons are called ions; the number of extra protons, its charge. These isolated peptide molecules are collided into a neutral gas, which causes each molecule to break, typically along one of the amino acid bonds at random. For a peptide of length n, there are $n-1$ bonds which can be broken, each yielding a (prefix, suffix) pair: e.g., (E, AMCGHN), (EA, MCGHN), ..., (EAMCGH, N). When an amino acid bond is broken, the extra protons migrate to either the prefix or suffix, at random. The charged prefix is called a b-ion; the charged suffix is called a y-ion. Collectively, the ionized products of fragmentation are called product ions. We assume all product ions are either b- or y-ions. The sequence of peptides or product ions cannot be directly measured, but we can measure how often product ions with a particular mass-to-charge (m/z) ratio are detected. These measurements are represented in a plot with m/z (measured in Daltons) on the horizontal axis and intensity (unitless, but roughly proportional to ion abundance) on the vertical axis.

Real fragmentation spectra are noisy. The isolation of peptide species is imperfect, so fragmentation spectra can contain product ions from peptides with different sequences (chimeric spectra). Mass analyzers can measure subatomic mass differences, so even the smallest unfiltered contaminant adds noise to the fragmentation spectrum. Product ions without charge cannot be detected, and we do not always know how many protons are adopted by a product ion—i.e., variable charge. There are a host of secondary fragmentations and degradations of product ions, which are measured. Finally, intensity measurements are quite noisy.

The input to the spectrum identification problem is a fragmentation spectrum, along with the observed (approximate) mass of the intact peptide whose fragmentation produced the spectrum. The output is the sequence of the unknown peptide, the fragmentation of which generated the spectrum. A peptide paired with a spectrum is called a peptide-spectrum match (PSM).

2.2 Database Search

A tandem mass spectrometry experiment produces a set of fragmentation spectra $S = \{s_1, \ldots, s_r\}$. Each spectrum is also associated with a measurement of the mass of the unknown peptide which generated the spectrum, $m(s_i)$. Let U be the universe of all peptides. We assume as input a database of possible peptides, $P \subset U$. The key assumptions behind database search are that (i) we know the organisms from which the proteins came from, and (ii) we have a set of all known proteins for the organism, which can be computed given the organism's genome. We need only search over peptides in P, not all peptides in U. Formally, spectrum identification is the task of assigning a peptide $p_i \in P$ to each spectrum s_i. Let $\Psi : S \times P \to \mathbb{R}$ denote a scoring function, where a higher score corresponds to a higher confidence that a peptide-spectrum match is correct (i.e., the peptide generated the spectrum).

Since we have measured $m(s_i)$, we can further constrain the search space over peptides to those whose mass is close to $m(s_i)$, a set of candidate peptides,

$$C(s_i, P, \delta) = \{p : p \in P, |m(p) - m(s_i)| < \delta\}, \quad (1)$$

where $m(p)$ is the mass of the peptide p. In our experiments, we use $\delta = 3.0$ Daltons. The database search itself involves scoring all candidate peptides, returning the highest scoring one for each spectrum. For $i = 1 \ldots r$,

$$p_i = \underset{p \in C(s_i, P, \delta)}{\operatorname{argmax}} \Psi(s_i, p). \quad (2)$$

The first computer program to use a database search procedure to identify fragmentation spectra was SEQUEST (Eng et al., 1994), whose scoring function is defined in terms of inner products between the quantized observed spectrum and a theoretical spectrum $\phi(p)$ generated from a simple model of peptide fragmentation. Observed and theoretical spectra are vectors of real numbers, so a peptide can be compared to a spectrum using inner products,

$$\begin{aligned} \text{XCorr}(s, \phi(p)) &= \alpha_x - \beta_x, \quad \text{where} \\ \alpha_x = \langle s, \phi(p) \rangle, \;\; \beta_x &= \frac{1}{150} \sum_{\tau=-75}^{75} \langle s, \phi_\tau(p) \rangle, \end{aligned} \quad (3)$$

and where $\phi_\tau(p)$ is just $\phi(p)$ shifted by $|\tau|$ units to the right ($\tau > 0$) or left ($\tau < 0$). Intuitively, a peptide is a good match if the observed spectrum s is highly correlated to the theoretical spectrum (α_x high), but not to shifted versions of the theoretical spectrum (β_x low). Didea's scoring function has an analogous $\alpha - \beta$ representation, where the analogues of correlation (α) and cross-correlation (β) are calculated using graphical model inference (Section 3.2).

There are a number of different tools for database search: e.g., SEQUEST (Eng et al., 1994), Mascot (Perkins et al., 1999), OMMSA (Geer et al., 2004), X!Tandem (Craig and Beavis, 2004), PepHMM (Wan et al., 2006), Riptide (Klammer et al., 2008), Andromeda (Cox et al., 2011), InsPecT (Tanner et al., 2005) and MS-GFDB (Kim et al., 2010). Separate from these approaches are post-processors, such as PeptideProphet (Keller et al., 2002) and Percolator (Käll et al., 2007), which refine the scores of a set of prescored peptide-spectrum matches, instead of scoring spectra in a streaming fashion. We note that statistical tools also exist for identifying proteins from peptide identifications, which can also refine peptide scores like a post-processor (e.g., (Li et al., 2010)). Some of the tools cited do not have implementations available for benchmarking (e.g., Riptide). Indeed, each of the above papers supports its predictive power claims by benchmarking against a representative subset of prior work. We have opted for a large set of competitors, on a diverse panel of data sets: SEQUEST, Mascot, MS-GFDB, OMMSA. SEQUEST and Mascot are the two most popular tools in wet-lab practice: e.g., each has been cited over 3000 times in Google Scholar, and both are commercial products.[2] MS-GFDB is a new scoring tool; the authors have demonstrated superior performance on the same kinds of fragmentation spectra that we study (collision-induced dissociation of tryptic peptides) against many of the tools listed above. OMMSA is open-source, and readily available. We do not compare against post-processors, as they use information not available to the other tools.

2.3 De Novo vs. Database Search

Early work on spectrum identification framed the problem as an exhaustive search over all possible peptides (Sakurai et al., 1984), an approach which came to be known as *de novo* spectrum identification, a.k.a. de novo peptide sequencing (Bafna and Edwards, 2003; Bandeira et al., 2008; Bartels, 1990; Bern and Goldberg, 2005; Bhatia et al., 2011; Dancik et al., 1999a,b; Datta and Bern, 2008; Fischer et al., 2004; Frank and Pevzner, 2005; Frank et al., 2005; Jeong et al., 2010). De novo tools select all candidate peptides that are within a mass tolerance of $m(s_i)$, not just those peptides that occur in a per-organism peptide database P.

De novo and database search methods cannot be equitably compared. Database search uses knowledge about the organism from which the protein sample is drawn, as well as knowledge of the proteome of that organism. De novo does not assume that such information is available. De novo searches over pep-

[2]Mascot is a black box, the details of its spectrum identification engine, as currently implemented, are proprietary.

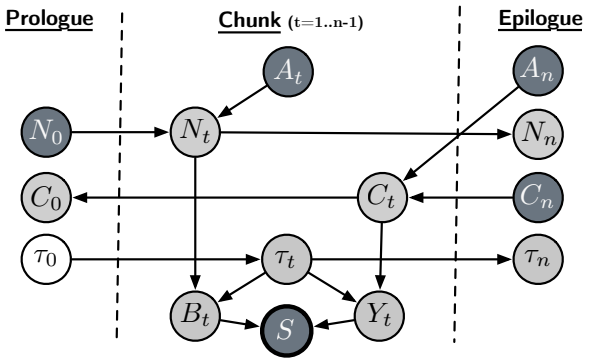


Figure 2: Basic Didea model. Dark gray nodes are observed random variables, light gray nodes are variables whose value is a deterministic function of its parents, and unshaded nodes are hidden random variables. Bold circles indicate vectors of random variables.

tides in $C(s_i, U, \delta)$; database search searches over peptides in $C(s_i, P, \delta)$, where for any reasonable value of δ, $|C(s_i, P, \delta)| \ll |C(s_i, U, \delta)|$.

3 Generative Model of Peptide Fragmentation

Didea encodes much of the physical process of peptide fragmentation by collision-induced dissociation within a dynamic Bayesian network. To maximize predictive performance, we take advantage of the idea of spectrum shifting (Equation 3) within our model, to derive a scoring function for peptide-spectrum matches based on inference within the DBN. The resulting inference-based scoring function can be viewed as an $\alpha - \beta$ score, where instead of dot products, we use the DBN to induce analogues of correlation and cross-correlation.

Figure 2 shows the basic Didea model; Sections 3.1–3.3 describe all the conditional probability distributions. Many of the conditional probability distributions are deterministic, which allows the scoring function to be computed in polynomial time.

An advantage of Didea is that adding more knowledge to the model (e.g., Sections 3.4-3.5) yields a new scoring function without any changes to the code. We just compute the same posterior on a new model.

3.1 Mapping the peptide to theoretical product ions

A DBN is a structured probability distribution over variable-length sequences of random variables, and is a strict generalization of the more familiar hidden Markov model (HMM). In Didea, a peptide containing n amino acids is represented by a sequence of random variables $(A_t : t = 1 \dots n)$. Each variable A_t takes on the value of one of the 20 standard amino acids. In database search the peptide is given, so the amino acid variables are observed: $\mathbf{p} = (A_t = a_t : t = 1 \dots n)$. To simplify the main text, we equivalently refer to a peptide as a sequence of amino acids $p = a_1 a_2 \dots a_n$.

In collision-induced dissociation, most of the product ions are either b- or y-ions. If the peptide p is cleaved between a_t and a_{t+1}, then the resulting (respectively b- and y-) product ions are referred to as $b_t = a_1 \dots a_t$ and $y_t = a_{t+1} \dots a_n$. We use the function $c(\cdot)$ to denote the charge of a peptide, $c(p)$; the charge of the product ions, $c(b_t)$ and $c(y_t)$; and the observed charge(s) of the fragmentation spectrum, $c(s) \subseteq \{+1, +2, +3\}$.[3] For now, we assume that $c(p) = +2$ (two adopted protons) and that the product ions each adopt one proton from the peptide during fragmentation, i.e., $\forall t, c(b_t) = c(y_t) = +1$. These charge assumptions simplify exposition, and are relaxed in Section 3.5.

The structure of the Didea model is shown in Figure 2. Random variables are grouped into *frames*, indexed by $t = 0 \dots n$. The first frame (frame 0) is referred to as the prologue; the last frame (frame n), the epilogue. The variables in the prologue and epilogue do not themselves correspond to b- or y-ions, but do contain variables needed to define recursions used to compute the mass of product ions. For a peptide of length n, the chunk frame is repeated once for $a_1, \dots, a_{n-1}$, in the same way that variables are repeated in an HMM to accommodate variable length sequences.

A product ion (a.k.a. fragmentation) spectrum s is a collection of peaks $s = \{(x_j, h_j)\}_j$, where x_j is a point on the mass-to-charge, or m/z, axis (x-axis), and h_j is the corresponding intensity. To check whether the b_t or y_t ion appears in the observed spectrum, we need the mass of each product ion. The neutral masses of the b_t and y_t ions are represented by random variables $N_t \equiv m(A_1 \dots A_t)$ and $C_t \equiv m(A_{t+1} \dots A_n)$, where $m(\cdot)$ returns the neutral masses of a sequence of amino acids. In Didea, the mass of each amino acid is rounded to the nearest whole Dalton, so that N_t and C_t are multinomial random variables over the neutral mass of the b_t and y_t ions—$N_t, C_t \in \{0, \dots, D\} \subset \mathbb{Z}_{++}$. By definition, $N_0 = 0$ and $C_n = 0$, so that the masses of the product ions can be computed recursively: $N_t = N_{t-1} + m(A_t)$, $C_t = C_{t+1} + m(A_t)$. Note that $C_0 = N_n = m(A_1 \dots A_n)$. Unlike HMMs, DBNs can have both left-to-right and right-to-left arcs (as long as there are no directed cycles), which allows us to implement the two recursions in the same model. Since $\{A_t\}_t$ are observed, both N_t and C_t become deterministic

[3] In our experiments, the mass spectrometer operates in positive-ion mode, and the reported charge of each spectrum is either $c(s) = +1$, $c(s) = +2$, or $c(s) \in \{+2, +3\}$.

random variables: $p(N_t = m(a_1 \dots a_t)) = 1$ and $p(C_t = m(a_{t+1} \dots a_n)) = 1$.

3.2 Mapping theoretical product ions to the fragmentation spectrum

We now have the mass of each product ion, and we have assumed that the charge of each product ion is +1. To finish the basic Didea model, we need to *(i)* encode the spectrum as observed random variables, *(ii)* introduce random variables which map from mass and charge to a specific m/z region in the spectrum, and *(iii)* define a conditional probability distribution which measures the value of finding a peak of intensity h in the m/z region where a product ion is expected to be.

From the settings used to collect our spectra, we know that $x_j \in [0, 2000]$ m/z units. For simplicity, we quantize the m/z scanning range into bins that are 1Da wide. In Figure 2, the bins correspond to a vector of random variables $\mathbf{S} = (S_i : i = 1 \dots B = 2000)$. A spectrum is an instantiation of the random variables $\mathbf{s} = (S_i = s_i : i = 1 \dots B)$, where each $s_i \geq 0$.

Spectra may differ by orders of magnitude in both total intensity ($\sum_j h_j$) and maximum intensity ($\max\{h_j\}$). To control for intensity variation, we rank-normalize each spectrum: peaks are sorted in order of increasing intensity, and the i^{th} peak is assigned intensity $i/|s|$, so $\max\{h_j\} = 1.0$. If bin i contains no peak, then $s_i = 0$. Otherwise, s_i is the highest rank-normalized peak, so $s_i \in [0, 1]$. We represent the vector of random variables $\mathbf{S}$ using a single, bold-edged node in Figure 2.

Each repetition of the chunk frame represents one pair of b- and y-ions, denoted (b_t, y_t). The random variables $B_t, Y_t \in \{1, \dots B\}$ represent, respectively, the bin where the b_t and y_t ions are to be expected.[4] We want to be able to shift the theoretical spectrum, in much the same fashion as Equation 3. We do so using the discrete random variables $\tau_t \in [-M \dots + M]$, for some $M \in \{1 \dots B\}$ (we use $M = 37$). We expect to see a peak corresponding to the b_t ion in S_{B_t}, and a peak corresponding to the y_t ion in S_{Y_t}. The mass-to-m/z mappings are $B_t = \text{round}(N_t + 1)$ and $Y_t = \text{round}(C_t + 19)$, where 1 is the mass of a proton, and 19 the mass of a proton plus a water molecule. τ_t shifts all the theoretical product ion peaks. To ensure that $B_t, Y_y \in [0, \dots B]$, values less than 1 are changed to 1; values greater than B are changed to B. To ensure that all the product ion peaks are shifted by the same amount, we copy the value of τ_0 from the prologue frame into each subsequent one: $\forall t = 1 \dots n$, $\tau_t = \tau_{t-1}$. As will be seen in Equation 6, to mimic the arithmetic average over shifts in the background term in XCorr, we assume that τ_0 is uniformly distributed over all shifts, $p(\tau_0) = (2M + 1)^{-1}$.

Most of the conditional probability distributions in Figure 2 are deterministic, which leads to a concise form for the joint distribution. For now, we refer to the contribution of a spectrum peak to the likelihood as non-negative function g:

$$p(\tau_0, \mathbf{s}, \mathbf{p}) = p(\tau_0) \prod_{t=1}^{n-1} \prod_{i=1}^{B} g(S, i, b_t, y_t, \tau_t), \tag{4}$$

$$g(\cdots) \triangleq P(S_i \,|\, b_t, y_t, \tau_t)^{\mathbf{1}(i=b_t+\tau_t \vee i=y_t+\tau_t)}. \tag{5}$$

Equation 4 is the likelihood of the model in Figure 2.

The values of B_t and Y_t, for each t, are deterministically determined from the peptide sequence. Assignment $\{B_t = b_t\}_t$ forces the model to assign some score, based on the intensity of the peaks found in $\{S_{b_t}\}_t$ (likewise with $\{Y_t = y_t\}_t$). The choice of $P(S_i \,|\, b_t, y_t, \tau_t)$ determines how the spectrum influences the score; details are deferred to Section 3.3.

One way to use the proposed model to score a PSM would be to set $\tau_0 = 0$ and use Equation 4, which would be analogous to dropping the β_x term in XCorr. Instead, to achieve an analogue to XCorr, we propose a score that can be interpreted as the difference between the Didea analogues of spectrum correlation (α_d) and cross-correlation (β_d):

$$\begin{aligned} \theta(\mathbf{s}, \mathbf{p}) &\triangleq \log p(\tau_0 = 0 \,|\, \mathbf{p}, \mathbf{s}) = \alpha_d - \beta_d, \\ \alpha_d &= \log p(\tau_0 = 0, \mathbf{p}, \mathbf{s}), \\ \beta_d &= \log p(\tau_0) \sum_{\tau_0} p(\mathbf{p}, \mathbf{s} \,|\, \tau_0). \end{aligned} \tag{6}$$

Both α_x and α_d are biased, assigning higher scores to spectra that tend to be close matches to many peptides (e.g., spectra with more non-zero peaks will tend to have higher α, regardless of which peptide is evaluated against it). The β_d term, like the β_x term, penalizes spectra which tend to match many peptides, which is why $\alpha - \beta$ scores tend to be more discriminative than α. Equation 6 is a (posterior) probability; Equation 3 is not probabilistic.

3.3 Modeling spectrum peak intensity

Here, we define Equation 5, which determines the influence of the spectrum on the likelihood, and thus the PSM score $\theta(\mathbf{s}, \mathbf{p})$. The cost of inference is proportional to the number of times $P(S_i \,|\, b_t, y_t, \tau_t)$ is evaluated. Since the spectrum is fixed across all $t = 1 \dots n - 1$, the values of $P(S_i \,|\, b_t, y_t, \tau_t)$, for all $(S_i = s_i, b_t, y_t, \tau_t)$, can be precomputed and stored in a lookup table:

[4] Since there is no ambiguity, we also use b_t and y_t to represent assignments to random variables, $B_t = b_t$ and $Y_t = y_t$.

$w : \{1 \dots B\} \to \mathbb{R}_+$, a transformation of the spectrum into non-negative weights. When a predicted product ion matches peak s_i in the spectrum, $w(i)$ is the contribution of that peak match to the PSM score.

In a graphical model, any conditional probability distribution on discrete variables can be reparameterized into a lookup table using virtual evidence (Pearl, 1998), allowing us to re-express Equation 4 as

$$p(\tau_0, \mathbf{p}, \mathbf{s}) \propto p(\tau_0) \prod_{t=1}^{n-1} w(B_t + \tau_t) w(Y_t + \tau_t), \qquad (7)$$

where $w(i) = f(s_i)$, for user-chosen transformation $f > 0$. Logically, we prefer to match theoretical product ions to higher intensity peaks in the observed spectrum. Our experiments with f focused on scaled and shifted exponential distributions, restricted to $[0, 1]$, since $s_i \in [0, 1]$. Based on these experiments, a class of f which performs well on a wide variety of data sets is

$$f_\lambda(S) = 1 - \lambda e^{-\lambda} + \lambda e^{-\lambda(1-S)}. \qquad (8)$$

The parameter, $\lambda > 0$, dictates the value placed on matching higher intensity peaks in the scoring function. The larger λ is, the higher the preference for matching b- and y-ions to high intensity peaks. There is no simple threshold for determining peak relevance based only on intensity; a PSM can have a high score even if most of the peaks identified are of low intensity. The unusual form of f_λ came out of an attempt to use exponential distributions to model peak intensity. Since $f_\lambda(S)$ is nearly log-linear on $[0, 1]$, one can instead use $f'_{\lambda_2}(S) = \exp(\lambda_2 S)$, where $\lambda_2 > 0$ is chosen to make $f'_{\lambda_2} \approx f_\lambda$. We get slightly better results using f_λ.

To optimize λ with respect to $\theta(\mathbf{s}, \mathbf{p})$, we use a grid search on a development set of 1000 yeast spectra; $\lambda = 0.5$ yielded the best results. λ acts as a tuning parameter for soft peak filtering. Both SEQUEST and MS-GFDB have to decide whether a peak is relevant before scoring, which can affect which PSM is selected.

3.4 Modeling fragmentation of charge +3 peptide ions

Thus far, we have assumed that the precursor ion has two protons, which are divided equally between product ions. However, electrospray ionization frequently produces peptide precursor ions with more than two protons (Trauger et al., 2002). That is, the charge of the spectrum is higher than +2. In this section, we extend Didea to model the fragmentation of charge +3 peptides.[5]

Here, we have that $c(p) = +3$, with $c(b_t)$ and $c(y_t)$ denoting the charges of the product ions. Since charge is conserved in fragmentation we have $\forall t,\ c(p) = c(b_t) + c(y_t)$. The charge of b_t is modeled as a multinomial $\xi_t \in \{0, +1, +2, +3\}$. It is unusual for a product ion to consume all the protons, and uncharged products are not detectable. In the absence of prior knowledge, we assume that the remaining choices are equally probable, $p(\xi_t = +1) = p(\xi_t = +2) = 0.5$. Figure 3(a) is the model for charge +3 peptide ions.

The definition of the scoring function, Equation 6, remains unchanged. The inference still uses $\log p(\tau_n = 0 \mid \mathbf{p}, \mathbf{s})$ as the score of a PSM. However, the values of α_d and β_d change, because the joint distribution over PSMs has changed:

$$p_{\text{ch3}}(\tau_0, \mathbf{p}, \mathbf{s}) \propto p(\tau_0) \prod_{t=1}^{n-1} \sum_{\xi_t} p(\xi_t) \Omega(t), \qquad (9)$$

$$\Omega(t) = \left[w(B_t(N_t, \xi_t) + \tau_t) w(Y_t(C_t, \xi_t) + \tau_t) \right],$$

$$B_t(N_t, \xi_t) = \text{round}\left((N_t + \xi_t)/\xi_t \right), \qquad (10)$$

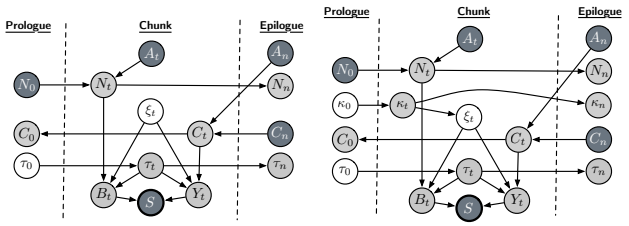
$$Y_t(C_t, \xi_t) = \text{round}\left((C_t + 18 + \xi_t)/\xi_t \right). \qquad (11)$$

Equations 10–11 are the mass to quantized m/z mappings for b- and y-ions. For each pair of ions (b_t, y_t), inference integrates over all divisions of the charge.

SEQUEST has a very different treatment of charge-variants of product ions. The theoretical spectrum in SEQUEST consists of the union of peaks where $c(b_t) = +1$ and $c(b_t) = +2$. As a thought experiment, consider what peaks need to be in the observed spectrum to maximize the SEQUEST score. The α_x term is maximized when all the theoretical peaks appear in the spectrum; the β_x term is minimized when no shifted version of the spectrum matches the theoretical peaks. To maximize the SEQUEST score, the observed spectrum would have to contain all peaks corresponding to all charge variants of the product ions, except those that would contribute significantly to the β_x term. There can be an exponentially large gap between the number of peaks in the SEQUEST theoretical spectrum, and the observed spectrum. In contrast, our approach averages the score over all 2^{n-1} assignments to $\xi = (\xi_1 \dots \xi_{n-1})$.[6] Each assignment to ξ corresponds to a particular combination of product ion peaks. Maximizing the score with respect to a peptide does not make the assumption that all charge-variants of the

[5] It is possible for electrospray ionization of tryptic peptides to produce peptide ions with a higher charge than +3, though doing so depends both on the mass spectrometer, and properties of the peptide (Kinter and Sherman, 2000, p. 69). Our data does not include such spectra, but it is straightforward to extend the model described here to charge $> +3$ spectra.

[6] Because of conditional independencies in Figure 3(a), $p(\xi)$ factors such that integrating over ξ is done in $O(n)$ time.



(a) Didea for database search (Section 3.4)

(b) Didea for multiply-charged spectra (Section 3.5)

Figure 3: Didea models which are used to handle multiply-charged spectra *(a)* ξ_n is the charge of the b-ion. *(b)* κ_0 is a Bernoulli random variable over spectrum charge $\{+2, +3\}$, and is copied in each frame, $\forall t, \kappa_t = \kappa_0$.

product ions exist in the spectrum. In our approach, if many possible peaks are missing from the spectrum, then $p(\xi)$ will get smaller as the disagreement between ξ and the spectrum increases. It is possible for $p(\xi)$ to be infinitesimally small for all but a few values of ξ. That is, a high score can be achieved even if only a few ξ have significant probability.

3.5 Multiply-charged spectra

Electrospray ionization routinely produces peptide precursor ions where charge $c(s) \in \{+1, +2, +3\}$. When $c(s) = +1$, the spectrum is referred to as *singly-charged*; when $c(s) = +2$, the spectrum is referred to as *doubly-charged*; when $c(s)$ has more than one possible value, we are unable to distinguish which charge with certainty, and the spectrum is referred to as *multiply-charged*.[7]

Existing database search algorithms analyze multiply-charged spectra by doubling the amount of computation (Eng et al., 1994). Each peptide-spectrum match is searched at $c(s) = +2$ and again at $c(s) = +3$, and the higher scoring match is used. If Ψ_c is the search algorithm specialized to charge c, replace Equation 2 with

$$p^* = \operatorname*{argmax}_{p \in C(m,P,\delta)} \max_{c \in \{+2,+3\}} \Psi_c(s, p). \qquad (12)$$

We could do the same search over charges with Didea. Evaluating $\theta(\cdot, \cdot)$ using Figure 2 corresponds to Ψ_{+2}; using Figure 3(a) corresponds to Ψ_{+3}. However, a concern with Equation 12 is that it assumes that the per-charge scoring functions are calibrated,

$$\mathbf{E}_{s \sim S, p \sim P} \left[\Psi_{+2}(s, p) \right] = \mathbf{E}_{s \sim S, p \sim P} \left[\Psi_{+3}(s, p) \right]. \qquad (13)$$

[7]The only multiply-charged spectra in our data have $c(s) \in \{+2, +3\}$. Extending the material of this section to other forms of multiply-charged spectra is straightforward.

A multiply-charged spectrum is an expression of uncertainty as to the charge state of the precursor. The mass window in the MS1 step is such that selecting the same peptide, at different charges, in the same MS2 scan, is almost impossible. It is not plausible that a single spectrum represents a mixture of the same peptide at different charges. So while taking the max of a set of charge-specific scoring function $\{\Psi_c\}_c$ allows one to make identification decisions, it provides no measure of uncertainty as to a spectrum's true charge—either charge +2 or charge +3 is selected, but no distribution over spectrum charge state can be produced.

Thus, rather than taking a maximum over scores for different charge states, we alter Didea to model uncertainty as to the value of $c(s)$. In Figure 3(b) we introduce a Bernoulli random variable $\kappa_0 \in \{+2, +3\}$, which is copied into each chunk frame. Moreover,

$$p(\xi_t \mid \kappa_t) = \begin{cases} p(\xi_t = +1) = 1.0 & \kappa_t = +2, \\ p(\xi_t = +1) = 0.5 & \kappa_t = +3, \end{cases} \qquad (14)$$

We assume no prior knowledge about the distribution of $c(s)$, $p(\kappa_0 = +2) = 0.5$. The rest of the parameters remain unchanged from Section 3.4. When $\kappa_0 = +2$, the model is identical to Figure 2. When $\kappa_0 = +3$, the model is identical to Figure 3(a). Since κ_0 is uncertain, when $\theta(\cdot, \cdot)$ is computed the score will be an average of both models. Note, however, that the resulting score is not the same as averaging the scores output by the +2 and +3 model. In each frame $t > 0$, the scoring inference is using an estimate of the spectrum charge based on the product ions considered—i.e., $p(\kappa_t)$ differs at each t. We conjecture that $p(\kappa_n \mid a_1, \ldots, a_n)$ can be used as an estimate of the uncertainty in the charge of the peptide-spectrum match chosen by Didea.

4 Experiments

Evaluating spectrum identification algorithms is complicated by the lack of test data. One cannot collect realistic spectra from known peptides. Section 4.1 describes how to estimate *absolute ranking curves*, which are the standard approach for comparing spectrum identification algorithms. We benchmark Didea against a panel of spectra from three different organisms (Section 4.2), presenting results in Section 4.3.

4.1 Evaluation Without Ground Truth

A correct peptide-spectrum match (PSM) (p_i, s_i) is one where s_i is the result of the fragmentation of peptide p_i, and an incorrect PSM is any match that is not correct. Clearly, database search scores vastly more incorrect PSMs than correct ones. Moreover, evaluation is greatly complicated by the lack of ground truth. Con-

ceptually, ground truth for a spectrum identification could be generated by feeding a purified peptide p_* into the tandem mass spectrometer. Unfortunately, there is no way of purifying p_* to the point where contaminants are undetectable. Moreover, even if one could run a pure peptide sample through the mass spectrometer, the resulting spectrum s_* would exhibit an unrealistically low level of noise; the test data would not reflect a real shotgun proteomics experiment. The standard solution in shotgun proteomics is to perform an evaluation without ground truth: measure the number of matches at a bound on the false discovery rate (Elias and Gygi, 2007; Käll et al., 2008).

For any peptide-spectrum match (p_i, s_i) with score v_i, there are two possibilities: either the peptide p_i generated spectrum s_i, or it did not. We refer to these events as hypotheses H_1 and H_0, respectively. If the scoring function is any good, then we expect the likelihood of v_i to be low under H_0, if (p_i, s_i) is the correct match. We can quantify what "low" means here using a hypothesis test,

$$H_0 : v_i \leq c, \qquad H_1 : v_i > c, \tag{15}$$

where the choice of $c \in \mathbb{R}$ determines the stringency of the test. Informally, the null hypothesis (H_0) is that the match is incorrect; the alternate (H_1) is that the match is correct.

Characterizing the accuracy at different values of c is greatly simplified by converting the scores to p-values, the probability of obtaining a score at least as large as c under the null hypothesis. Denote the cumulative distribution of scores under the null $G_0(c) \triangleq \mathbb{P}(T \leq c \,|\, H_0)$, where T is a random variable representing the PSM score. Given PSM scores $\{v_i\}_i$ the corresponding p-values are $p_i = 1 - G_0(v_i)$. Computing p-values for a wide range of scores v_i is tantamount to estimating the null distribution. Estimated p-values $\{\hat{p}_i\}_i$ are generated by replacing the exact (unknown) null distribution with an estimate $\hat{G}_0(c)$.

For spectrum identification, a widespread approach for estimating the null distribution is *target-decoy search* (Balgley et al., 2007; Elias and Gygi, 2007; Käll et al., 2008), in which a second search is performed against each spectrum using a set of decoy peptides $d \in D$, each of which could not have generated the spectrum. The original peptides $t \in P$ are referred to as targets. Under the constraint that $P \cap D = \emptyset$, decoys are used to generate a sample from the null distribution

$$\bar{v}_i = \max_{d \in D} \Psi(s_i, d), \quad \forall i = 1 \ldots r. \tag{16}$$

The samples $\{\bar{v}_i\}_i$ are then used in a Monte Carlo estimate of the p-values: $\hat{p}_i$ is just the fraction of sampled decoy scores that exceed v_i. In our experiments, decoy peptides are generated by randomly permuting the reference proteome, which induces a set of random peptides under a trypsin digest.

Since there are r hypothesis tests (spectra), we can measure the tradeoff between the number of PSMs that are accepted and the stringency of the threshold on the score using false discovery rates. Visually, the tradeoff is represented using an *absolute ranking plot* (Figure 4), where each point on the x-axis is a q value $\tilde{q} \in [0, 1]$, a measure of the false discovery rate (Storey, 2002), and the corresponding value on the y-axis is the number of PSMs accepted at that q-value. At $q = 1$, all r identifications are accepted. Because peptide-spectrum matches are often used as input to another estimation task (e.g., protein identification or quantification) our concern is with maximizing performance at small q-values, so we only plot $q \in [0, 0.1]$. One method dominates another if its absolute ranking curve is strictly above the absolute ranking curve for the other method.

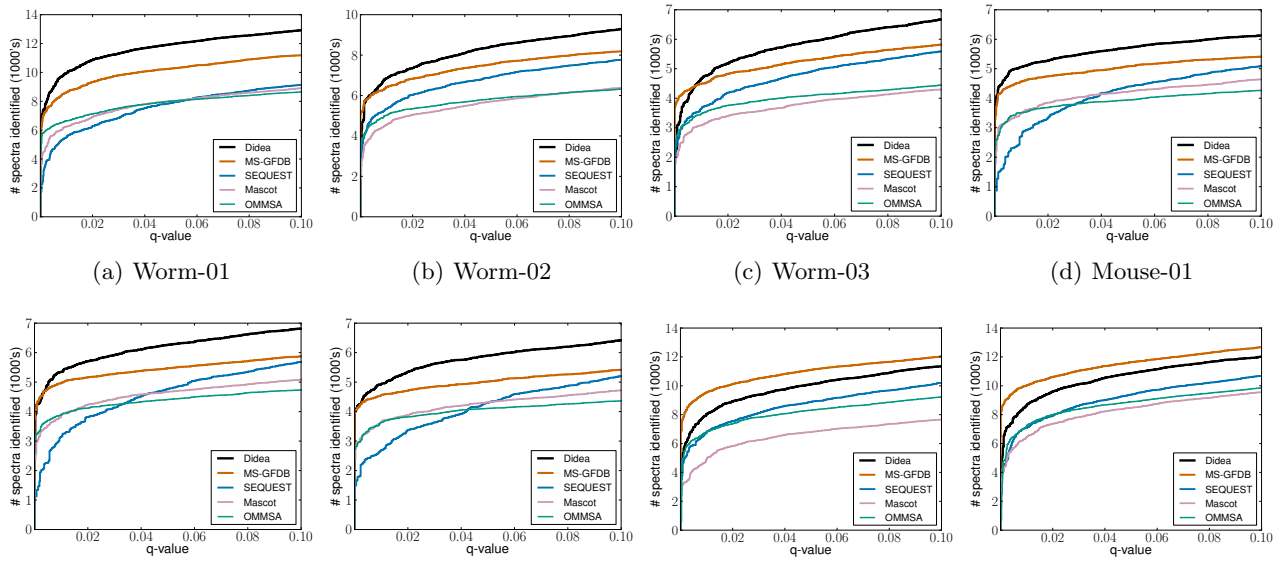
Absolute ranking measures what the end-user cares about: maximizing the number of spectra identified at their chosen false discovery rate tolerance.

4.2 Data sets

The spectra we study are generated from complex proteins samples drawn from three organisms: tryptic digests of a whole-cell lysate of *Saccharomyces cerevisiae* (yeast), whole-cell lysate of *Caenorhabditis elegans* (worm), and liver tissue from *Mus musculus* (mouse). The yeast and worm data are freely available at `http://noble.gs.washington.edu/proj/percolator`, with a description of the sample preparation procedure, liquid chromatography protocol, and mass spectrometer settings in Käll et al. (2007).

4.3 Results

Our primary claim is that Didea outperforms competing systems under absolute ranking, the metric that end-users actually care about. To support our empirical claim, we benchmark Didea against competitors. All algorithms have access to the same peptide database, created by a fully-tryptic *in silico* digest of reference yeast, worm, and mouse proteomes. Candidate peptides are chosen using a mass tolerance of $\delta = 3.0$ Daltons. A static modification is applied to account for cysteine carbidomethylation in all the algorithms. No variable modifications to amino acids are permitted. All spectra are either singly-charged or multiply-charged. All Didea-type scoring functions preprocess the spectra using Equation 8 and use exact inference to compute the PSM score. For Didea, we use the version of the model which integrates over uncertainty in the precursor charge (Section 3.5).



(a) Worm-01 (b) Worm-02 (c) Worm-03 (d) Mouse-01

(e) Mouse-02 (f) Mouse-03 (g) Yeast-01 (h) Yeast-02

Figure 4: Absolute ranking curves on eight different data sets. Didea significantly outperforms all competitors in (a-f). Didea significantly outperforms all competitors, save MS-GFDB (g-h). If $q = 0.05$, then the expected fraction of false discoveries (incorrect PSMs) in the matches accepted is 0.05. The goal is to maximize the number of spectra identified for $q \in [0, 0.1]$.

The absolute ranking plots for the benchmark are in Figure 4. At an estimated 1% false discovery rate, Didea outperforms MS-GFDB. While we often outperform MS-GFDB, there are cases where it beats Didea (Figures 4(g)-4(h)). Surprisingly, Didea is able to beat MS-GFDB even though it models less of the complexity of peptide fragmentation physics: we use no a-ions, nor neutral losses, nor do we account for errors in the m/z measurements in a fragmentation spectrum, like MS-GFDB does. Even more surprising is that Didea achieves high predictive power with only one trained parameter, λ. Even using a coarse grid search, the chosen value of λ works well across a variety of data sets. Training λ on a per-organism basis does not significantly increase the absolute ranking curve for Didea. Furthermore, we filter no peaks from the spectrum, even though real spectra are extremely noisy. In contrast, both SEQUEST and MS-GFDB require extensive preprocessing of the spectrum to work well.

All spectrum identification tools make an empirical claim, that their system identifies more spectra at a given q-value, or range of q-values. We compare favorably on such evaluations, against a wide range of competitors, using a relatively simple model and probabilistic inference.

5 Summary and Future Work

We have formulated a scoring function for spectrum identification based on a polynomial-time inference in a dynamic Bayesian network. Didea is significantly more accurate than both SEQUEST and Mascot, the primary tools used for this task in real-world use. Moreover, we outperform even recently developed competitors, like MS-GFDB, on many spectra. We anticipate that adding additional information, e.g., a-ions, neutral losses, relationships between ion yield and ion composition, will further improve the accuracy of Didea.

We believe that Didea is suggestive of the promise of applying techniques popular in speech recognition, such as dynamic Bayesian networks, to spectrum identification. For example, natural language processing often uses a compressed representation of a natural language corpora, which can be seen as analogous to compressed representations of a peptide database. Especially exciting would be a variant of Didea which replaces database search with direct Viterbi decoding of the peptide sequence.

Abstract

As a new method for detecting change-points in high-resolution time series, we apply Maximum Mean Discrepancy to the distributions of ordinal patterns in different parts of a time series. The main advantage of this approach is its computational simplicity and robustness with respect to (non-linear) monotonic transformations, which makes it particularly well-suited for the analysis of long biophysical time series where the exact calibration of measurement devices is unknown or varies with time. We establish consistency of the method and evaluate its performance in simulation studies. Furthermore, we demonstrate the application to the analysis of electroencephalography (EEG) and electrocardiography (ECG) recordings.

1 INTRODUCTION

Detecting changes in the temporal evolution of a system (biological, physical, mechanical, etc.) is of major importance, e.g. in medical diagnostics, industrial quality control, or the analysis of financial markets. In statistics, the problem of inferring the time point of a change from a sequence of observations is known as change-point detection. There is a vast literature on parametric and non-parametric methods for testing the presence of change-points and for estimating their locations. For an overview, we refer to the monographs of Chen and Gupta (2000) and Brodsky and Darkhovsky (1993, 2000). Recently, Harchaoui et al. (2009) have introduced an estimator for change-points based on kernels.

In this paper, we propose to detect change-points by comparing the distributions of ordinal patterns in different parts of a time series. In order to capture differences among the distributions automatically, we apply the Maximum Mean Discrepancy (MMD) criterion recently introduced by Gretton et al. (2007a, 2007b). The proposed method is computationally fast and robust with respect to (non-linear) monotonic transformations of the observations, which makes it particularly attractive for the exploration of high-resolution biophysical time series where the exact calibration of measurement devices is unknown or varies with time. In real-life applications, such changes in the calibration occur, e.g., for electroencephalography (EEG) recordings where small displacements of electrodes result in changes of the conductivity.

Detecting changes in the dynamics of a time series by looking at ordinal pattern distributions has first been proposed by Bandt and Pompe (2002). More specifically, they consider permutation entropy, which is the Shannon entropy of ordinal pattern distributions, as a measure for detecting changes in the complexity of time series. Permutation entropy has been applied to the analysis of epileptic activity in EEG data (Li et al., 2007; Bruzzo et al., 2008) and to measuring anaesthetic drug effects (Li et al., 2008; Olofsen et al., 2008). In methodological studies, Keller et al. (2007a, 2007b) define further statistics of ordinal pattern distributions besides permutation entropy and investigate properties of the distributions themselves. Bandt and Shiha (2007) derive formulas for ordinal pattern probabilities in stochastic processes; Sinn and Keller (2011) study statistical properties of estimators of these probabilities.

This paper is organized as follows: In Section 2, we formalize the change-point problem and review the definition of ordinal pattern distributions. Section 3 shows how MMD can be used to automatically detect change-points and discusses related work. In Section 4, we evaluate the performance of our methods in simulation studies and demonstrate the application to real-life time series. Section 5 concludes the paper.

2 OUTLINE OF THE METHOD

In this paper, we consider the problem of inferring the time point of a change in the distribution of an observed time series. The basic idea is to look at the order structure in different parts of the time series; if we find a time point with a clear difference between the order structure before and afterwards, we conclude that it is a change-point.

Formally, we describe the problem as follows: Let $\mathbb{N}$ denote the set of natural numbers and $\mathbb{Z}$ the set of integers. Consider a real-valued stochastic process $\mathbf{X} = (X_t)_{t\in\mathbb{Z}}$ on some probability space $(\Omega, \mathcal{A}, \mathbb{P})$, where Ω denotes the sample space, $\mathcal{A}$ the set of measurable events and $\mathbb{P}$ the probability measure. Let $\mathbf{Y} = (Y_t)_{t\in\mathbb{Z}}$ be the process of increments given by $Y_t := X_t - X_{t-1}$ for $t \in \mathbb{Z}$. Throughout this paper, we always assume the following holds:

(A1) The process $\mathbf{Y}$ is non-degenerate, i.e., all finite-dimensional distributions of $\mathbf{Y}$ are absolutely continuous with respect to the Lebesgue measure.

(A2) The processes $(Y_0, Y_{-1}, \ldots)$ and $(Y_1, Y_2, \ldots)$ are strictly stationary and ergodic.

Note that as a consequence of (A1), the values of $\mathbf{X}$ are pairwise distinct $\mathbb{P}$-almost surely, that is,

$$\mathbb{P}(X_{t_1} \neq X_{t_2}) \quad = \quad 1 \tag{1}$$

for all $t_1, t_2 \in \mathbb{Z}$ with $t_1 \neq t_2$.

Now let $m, n \in \mathbb{N}$. Suppose that we observe a time series of length $m+n$ with a change in the underlying distribution after the first m time points, and m, n are unknown (only the length $m+n$ is observable). Then finding the location of the change-point is equivalent to estimating the pair (m, n). We model this situation by assuming the observed time series is a realization of $\mathbf{X}$ at times $t = -m, -m+1, \ldots, n-2, n-1$. If the distributions of $(Y_0, Y_{-1}, \ldots)$ and $(Y_1, Y_2, \ldots)$ are different, then $t = 0$ is a change-point in $\mathbf{X}$ and we obtain m observations before and n observations afterwards.

A generalization of the situation with only one change in the distribution is the multiple change-point problem where the time series potentially has more than one change-point. A common approach to solve this problem is to iteratively apply a method for detecting single change-points, i.e., after the detection of the first change-point, the method is applied to the time segments before and afterwards to search for further change-points. In Section 4.1, we will consider this approach in more detail.

2.1 ORDINAL PATTERN DISTRIBUTIONS

We use the concept of ordinal pattern distributions to describe the order structure of a time series. An ordinal pattern represents the order relations among successive values of a time series; if the values are pairwise different, it is natural to identify ordinal patterns with permutations. Counting the number of occurrences of the permutations in a time series (or parts of it) yields the empirical distribution of ordinal patterns.

Here we give a formal definition of ordinal patterns. Let $d \in \mathbb{N}$ be fixed. By $\mathbf{\Pi}$ we denote the set of permutations $\{0, 1, \ldots, d\}$, which we represent by $(d+1)$-tuples containing each of the numbers $0, 1, \ldots, d$ exactly one time. Let the permutations be denoted by $\boldsymbol{\pi}_1, \boldsymbol{\pi}_2, \ldots, \boldsymbol{\pi}_{(d+1)!}$ so that $\mathbf{\Pi} = \{\boldsymbol{\pi}_1, \boldsymbol{\pi}_2, \ldots, \boldsymbol{\pi}_{(d+1)!}\}$. Now consider the partition of $\mathbb{R}^{d+1}$ obtained by identifying vectors whose components are correspondingly ordered: For $\boldsymbol{\pi} = (r_0, r_1, \ldots, r_d) \in \mathbf{\Pi}$, let $B(\boldsymbol{\pi})$ be the subset of $\mathbb{R}^{d+1}$ containing every vector $(x_0, x_1, \ldots, x_d)$ satisfying

(*i*) $x_{r_0} \geq x_{r_1} \geq \ldots \geq x_{r_d}$,

(*ii*) if $x_{r_i} = x_{r_{i+1}}$, then $r_i > r_{i+1}$.

Obviously, the union of all subsets $B(\boldsymbol{\pi}_1)$, $B(\boldsymbol{\pi}_2)$, ..., $B(\boldsymbol{\pi}_{(d+1)!})$ is equal to $\mathbb{R}^{d+1}$, and by condition (*ii*) the pair of subsets $B(\boldsymbol{\pi}_i)$, $B(\boldsymbol{\pi}_j)$ is disjoint if $i \neq j$. By saying that the *ordinal pattern* of *order* d at *time* $t \in \mathbb{Z}$ is given by $\boldsymbol{\pi} = (r_0, r_1, \ldots, r_d)$, we designate the event

$$(X_t,\, X_{t-1},\, X_{t-2}, \ldots,\, X_{t-d}) \quad \in \quad B(\boldsymbol{\pi}).$$

According to (1), this event is equivalent to

$$X_{t-r_0} \,>\, X_{t-r_1} \,>\, \ldots \,>\, X_{t-r_d}$$

$\mathbb{P}$-almost surely. Note that a more general definition of ordinal patterns includes an additional parameter $\tau \in \mathbb{N}$ (called the *delay*) which allows us to consider the events $(X_t,\, X_{t-\tau}, \ldots,\, X_{t-d\tau}) \in B(\boldsymbol{\pi})$ (see Keller et al. (2007a)).

Figure 1 shows all the possible outcomes for ordinal patterns of order $d = 3$. For example, if $\omega \in \Omega$ is such that $X_t(\omega) > X_{t-1}(\omega) > X_{t-2}(\omega) > X_{t-3}(\omega)$ (thus, the time series roughly looks like the upper left plot in Figure 1), then the ordinal pattern at time t is given by (0,1,2,3). If $X_t(\omega) > X_{t-1}(\omega) > X_{t-3}(\omega) > X_{t-2}(\omega)$, then the ordinal pattern is given by $(0, 1, 3, 2)$, and so on. The dark gray patterns $(0, 1, 2, 3)$ and $(3, 2, 1, 0)$ in Figure 1 occur if the underlying time series is monotonically increasing and decreasing, respectively. The light gray patterns occur if the past two increments

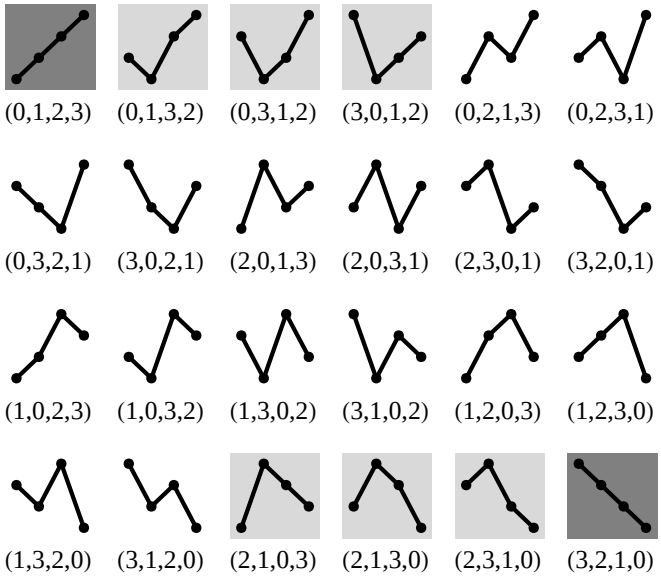

Figure 1: Possible outcomes for ordinal patterns of order $d = 3$.

have the same sign, and the white patterns occur after changes between "upwards" and "downwards".

Next, we consider the distribution of ordinal patterns in the process $\mathbf{X}$. For $t \in \mathbb{Z}$ and $k = 1, 2, \ldots, (d+1)!$ define

$$p_k(t) \;:=\; \mathbb{P}(\,(X_t,\, X_{t-1},\, \ldots,\, X_{t-d}) \,\in\, B(\boldsymbol{\pi}_k)\,),$$

that is, $p_k(t)$ denotes the probability that the ordinal pattern at time t is given by $\boldsymbol{\pi}_k$. By the *distribution* of ordinal patterns at time t we mean the stochastic vector

$$\mathbf{p}(t) \;:=\; (p_1(t),\, p_2(t),\, \ldots,\, p_{(d+1)!}(t))\,.$$

Note that the ordinal pattern at time t actually only depends on the increments $Y_t, Y_{t-1}, \ldots, Y_{t-d+1}$ (see Sinn and Keller (2011)). Hence, a sufficient condition for the ordinal pattern distributions $\mathbf{p}(t_1)$ and $\mathbf{p}(t_2)$ to be identical is that the random vectors $(Y_{t_1}, Y_{t_1-1}, \ldots, Y_{t_1-d+1})$ and $(Y_{t_2}, Y_{t_2-1}, \ldots, Y_{t_2-d+1})$ have the same distribution. According to assumption (A2), we obtain that

$$\ldots \,=\, \mathbf{p}(-1) \,=\, \mathbf{p}(0) \quad \text{and} \quad \mathbf{p}(d) \,=\, \mathbf{p}(d+1) \,=\, \ldots,$$

i.e., the ordinal pattern distribution at times $t \leq 0$ and $t \geq d$, respectively, are identical. In general, the distributions $\mathbf{p}(t)$ with $t = 1, 2, \ldots, d-1$ are equal neither to $\mathbf{p}(0)$ nor to $\mathbf{p}(d)$ because they depend on increments both before and after $t = 0$.

In the following, we write $\mathbf{p}_-$ and $\mathbf{p}_+$ to denote the generic distributions $\mathbf{p}(0)$ and $\mathbf{p}(d)$, respectively. Obviously, a necessary condition for $\mathbf{p}_- \neq \mathbf{p}_+$ is that $\mathbf{X}$ has a change-point at $t = 0$. The key idea of our method for change-point detection is to measure the difference between the empirical ordinal pattern distributions in different parts of a time series.

2.2 EMPIRICAL ORDINAL PATTERN DISTRIBUTIONS

In the following, let $\mathbf{1}\{\cdot\}$ denote the function which evaluates to 1 if the statement in the brackets is true, and to 0 otherwise. For $w \in \mathbb{N}$ and $t \in \mathbb{Z}$, define

$$\hat{p}_k(w,t) \;:=\; \frac{1}{w} \sum_{s=wt+1}^{wt+w} \mathbf{1}\big\{\,(X_s,\, X_{s-1},\, \ldots,\, X_{s-d}) \,\in\, B(\boldsymbol{\pi}_k)\,\big\},$$

that is, $\hat{p}_k(w,t)$ is the relative frequency of time points in the time window $\{wt+1, wt+2, \ldots, wt+w\}$ at which the ordinal pattern is $\boldsymbol{\pi}_k$. The parameter w determines the size of the time window; as we will see in Theorem 1 below, the larger w, the closer we can expect $\hat{p}_k(w,t)$ be to $p_k(t)$.

Now, taking into account all the estimates $\hat{p}_k(w,t)$ for $k = 1, 2, \ldots, (d+1)!$ gives us the empirical ordinal pattern distribution

$$\hat{\mathbf{p}}(w,t) \;:=\; \big(\hat{p}_1(w,t),\, \hat{p}_2(w,t),\, \ldots,\, \hat{p}_{(d+1)!}(w,t)\big)\,.$$

As the following theorem shows, $\hat{\mathbf{p}}(w,t)$ converges to $\mathbf{p}_-$ if $t < 0$, and to $\mathbf{p}_+$ if $t \geq 0$ ($\mathbb{P}$-almost surely). This result also holds if the "calibration" of $\mathbf{X}$ changes at a number of points that grows sublinearly in time.

Theorem 1 *Suppose that conditions* (A1)*and* (A2) *hold. Then*

$$\lim_{w\to\infty} \hat{\mathbf{p}}(w,t) \quad = \quad \begin{cases} \mathbf{p}_- & \text{if } t<0, \\ \mathbf{p}_+ & \text{if } t\geq 0, \end{cases}$$

$\mathbb{P}$*-almost surely. This result also holds if we observe the "distorted" process* $(h(X_t,t))_{t\in\mathbb{Z}}$ *instead of* $(X_t)_{t\in\mathbb{Z}}$ *with*

$$h(x,t) \quad := \quad \sum_{j\in\mathbb{Z}} \mathbf{1}\{t\in(t_{j-1},t_j]\}\, h_j(x),$$

where the mappings $h_j:\mathbb{R}\to\mathbb{R}$ *are strictly increasing for all* $j\in\mathbb{Z}$*, and* $(t_j)_{j\in\mathbb{Z}}$ *is an increasing sequence in* $\mathbb{Z}$ *which satisfies*

$$\lim_{w\to\infty} \frac{\sharp\{j\in\mathbb{Z}:\ t_j\in[-w,w]\}}{w} \quad = \quad 0.$$

Proof. First, we consider the case $t<0$. Since $(Y_0,Y_{-1},\ldots)$ is ergodic and

$$\mathbb{E}\big[\,\mathbf{1}\{(X_s,\,X_{s-1},\ldots,\,X_{s-d})\,\in\,B(\boldsymbol{\pi}_k)\}\,\big] \quad = \quad p_k(0)$$

for all $s\leq w(t+1)$ with $w\in\mathbb{N}$, the Ergodic Theorem shows that $\hat{p}_k(w,t)$ converges to $p_k(0)$ $\mathbb{P}$-almost surely (Cornfeld et al., 1982). If $t>0$, then $wt+1\geq d$ for sufficiently large w, and hence

$$\mathbb{E}\big[\,\mathbf{1}\{(X_s,\,X_{s-1},\ldots,\,X_{s-d})\,\in\,B(\boldsymbol{\pi}_k)\}\,\big] \quad = \quad p_k(d)$$

for all $s\geq wt+1$. Since $(Y_1,Y_2,\ldots)$ is ergodic, the Ergodic Theorem shows that $\hat{p}_k(w,t)$ converges to $p_k(d)$ $\mathbb{P}$-almost surely. In the case $t=0$, we have

$$\begin{aligned}
&\hat{p}_k(w,t) \\
&\quad = \quad \frac{1}{w}\sum_{s=1}^{d-1} \mathbf{1}\{(X_s,\,X_{s-1},\,\ldots,\,X_{s-d})\,\in\,B(\boldsymbol{\pi}_k)\} \\
&\quad + \quad \frac{1}{w}\sum_{s=d}^{w} \mathbf{1}\,\{(X_s,\,X_{s-1},\,\ldots,\,X_{s-d})\,\in\,B(\boldsymbol{\pi}_k)\}.
\end{aligned}$$

Since the first term on the right hand side tends to 0 and the second one converges to $p_k(d)$ $\mathbb{P}$-almost surely, the result follows.

Now suppose that we observe $(h(X_t,t))_{t\in\mathbb{Z}}$ instead of $\mathbf{X}$. Note that if $t,j\in\mathbb{Z}$ satisfy $t-d\geq t_{j-1}$ and $t\leq t_j$, then $(h(X_t),h(X_{t-1}),\ldots,h(X_{t-d}))$ lies in $B(\boldsymbol{\pi}_k)$ if and only if $(X_t,\,X_{t-1},\,\ldots,\,X_{t-d})$ lies in $B(\boldsymbol{\pi}_k)$. Therefore, for any $t\in\mathbb{Z}$, the number of time points $s\in\{wt+1,\,wt+2,\,\ldots,\,wt+w\}$ at which the indicator functions of these two events are unequal is bounded by $(d+1)$-times the number of $j\in\mathbb{Z}$ for which $t_j\in[wt+1,wt+w]$. Since the latter number divided by w tends to 0 as $w\to\infty$, we obtain the result. □

2.3 DETECTING CHANGE-POINTS

Based on the definition of ordinal pattern distributions and the consistency result of Theorem 1, we now present our method for change-point detection. Suppose that $\mathbf{X}$ has a change-point at time $t=0$ which results in a difference between the ordinal pattern distributions $\mathbf{p}_-$ and $\mathbf{p}_+$. Furthermore, suppose that we observe $\mathbf{X}$ at times $t=-wm+1,-wm+2,\ldots,wn-1,wn$ where $w\in\mathbb{N}$ is "large" and $m,n\in\mathbb{N}$ are unknown (only the sum $m+n$ is observed). In this setting, the problem of estimating the location of the change-point is equivalent to estimating the unknown values m and n. Our proposed method proceeds as follows:

1. We partition the observations of $\mathbf{X}$ into $(m+n)$ non-overlapping blocks of size w each.

2. For each block, we compute the empirical ordinal pattern distribution, which gives us the $(m+n)$-dimensional vector

$$\begin{aligned}
&\mathbf{z}(w) := \qquad\qquad (2)\\
&\quad (\hat{\mathbf{p}}(w,-m),\,\hat{\mathbf{p}}(w,-m+1),\,\ldots,\,\hat{\mathbf{p}}(w,n-1)).
\end{aligned}$$

According to Theorem 1, we have

$$\lim_{w\to\infty} \mathbf{z}(w) \quad = \quad (\underbrace{\mathbf{p}_-,\,\ldots,\,\mathbf{p}_-}_{m\text{ times}},\underbrace{\mathbf{p}_+,\,\ldots,\,\mathbf{p}_+}_{n\text{ times}}) \quad (3)$$

$\mathbb{P}$-almost surely. Thus, if the $m+n$ ordinal pattern distributions can be divided into two clearly distinct groups, the sizes of these groups can be taken as estimates for m and n. In the following section, we apply Maximum Mean Discrepancy to determine these groups.

Before discussing related work, let us make some remarks:

Remark 1. Our method is robust with respect to changes in the "calibration" of the process $\mathbf{X}$. In particular, if h_- and h_+ are both strictly increasing functions, then the ordinal pattern distributions $\mathbf{p}_-$ and $\mathbf{p}_+$ in the transformed process $(\ldots,\,h_-(X_{-1}),\,h_-(X_0),\,h_+(X_1),\,h_+(X_2),\,\ldots)$ are identical. As mentioned in the introduction, this robustness is often desirable for the analysis of biophysical time series the exact calibration of which is unknown or varies with time.

Remark 2. If d is large enough, then our method does detect changes of the complexity of $\mathbf{X}$ measured by the permutation entropy (Bandt and Pompe, 2002; Keller and Sinn, 2009). Furthermore, it is capable to detect changes in the autocorrelation structure of Gaussian processes (Bandt and Shiha, 2007).

Remark 3. There is some trade-off between the choice of the order of the ordinal patterns d and the time window size w. In general, a larger order d permits to detect changes of the higher-order autocorrelations of $\mathbf{Y}$ or, equivalently, in the lower frequency domain. On the other hand, the time window size w needs to be much larger than $(d+1)!$ in order to obtain reliable estimates of all the ordinal pattern probabilities, however, the larger w, the less accurate the localization of the change-points. For our experiments in Section 4, we have chosen $d = 3$ and $w = 500$, that is, we consider 24 different ordinal patterns and are capable to localize change-points with a precision of ± 250 time points which, for the EEG and ECG recordings, corresponds to approximately ± 1 second. See also Section 3.3 for a further discussion on this issue.

3 MAXIMUM MEAN DISCREPANCY

In order to group the components of the vector $\mathbf{z}(w)$ defined in (2), we use a recently proposed criterion called Maximum Mean Discrepancy (MMD). Let $\mathcal{Z}$ be an arbitrary set and $\mathbf{z} = (z_1, z_2, \ldots, z_{m+n}) \in \mathcal{Z}^{m+n}$ with $m, n \in \mathbb{N}$. MMD is a new criterion for testing whether $z_1, z_2, \ldots, z_m$ and $z_{m+1}, z_{m+2}, \ldots, z_{m+n}$ come from different distributions (Gretton et al., 2007a, 2007b). The basic approach is to measure the similarity of points $z, z' \in \mathcal{Z}$ using a kernel $k(z, z')$. In our case, $\mathcal{Z}$ is the set of $(d+1)!$-dimensional stochastic vectors, and for $k(z, z')$ we choose the Radial Basis Function (RBF) kernel

$$k(z, z') \;=\; \exp\left(-\frac{\|z - z'\|^2}{2\sigma^2}\right)$$

where $\|\cdot\|$ denotes the Euclidean norm and $\sigma^2 > 0$ is a smoothing parameter. For $m', n' \in \mathbb{N}$ with $m' + n' = m + n$, the *Maximum Mean Discrepancy* is given by

$$\mathrm{MMD}(\mathbf{z}, m', n') \;:=\; \left(\frac{\mathrm{K}_1(\mathbf{z}, m', n')}{m'm'} - \frac{2\,\mathrm{K}_2(\mathbf{z}, m', n')}{m'n'} + \frac{\mathrm{K}_3(\mathbf{z}, m', n')}{n'n'}\right)^{\frac{1}{2}}$$

where

$$\begin{aligned}
\mathrm{K}_1(\mathbf{z}, m', n') &:= \sum_{i=1}^{m'}\sum_{j=1}^{m'} k(z_i, z_j)\,,\\
\mathrm{K}_2(\mathbf{z}, m', n') &:= \sum_{i=1}^{m'}\sum_{j=1}^{n'} k(z_i, z_{m'+j})\,,\\
\mathrm{K}_3(\mathbf{z}, m', n') &:= \sum_{i=1}^{n'}\sum_{j=1}^{n'} k(z_{m'+i}, z_{m'+j})\,.
\end{aligned}$$

The terms $\frac{1}{m'm'}\mathrm{K}_1(\mathbf{z}, m', n')$ and $\frac{1}{n'n'}\mathrm{K}_3(\mathbf{z}, m', n')$ can be regarded as the average similarity of points within the groups $z_1,\ z_2,\ \ldots,\ z_{m'}$ and $z_{m'+1},\ z_{m'+2},\ \ldots,\ z_{m'+n'}$, respectively, while $\frac{1}{m'n'}\mathrm{K}_2(\mathbf{z}, m', n')$ measures the average similarity between the two groups. The maximal MMD value is obtained for that partition of $\mathbf{z}$ which yields maximum similarity within the groups and maximum dissimilarity between them. The next theorem shows how the MMD criterion can be used to locate change-points in $\mathbf{X}$.

Theorem 2 *Suppose that conditions* (A1) *and* (A2) *hold and let* $\mathbf{z}(w)$ *be as defined in* (2). *Then for all* $m', n' \in \mathbb{N}$ *with* $m' + n' = m + n$, *we have*

$$\lim_{w\to\infty} \mathrm{MMD}(\mathbf{z}(w), m', n') \;=\; \min\left\{\frac{n}{n'}\,,\,\frac{m}{m'}\right\}\sqrt{2\left(1 - k(\mathbf{p}_-, \mathbf{p}_+)\right)}$$

$\mathbb{P}$-*almost surely. In particular, if* $\mathbf{p}_- \neq \mathbf{p}_+$, *then*

$$\lim_{w\to\infty}\left(\arg\max_{\substack{(m',n')\in\mathbb{N}^2,\\ m'+n'=m+n}} \mathrm{MMD}(\mathbf{z}(w), m', n')\right) \;=\; (m, n)$$

$\mathbb{P}$-*almost surely.*

Proof. Suppose that $m' \leq m$. By equation (3) and the fact that $k(z, z) = 1$ for all $z \in \mathcal{X}$, the limits of $\mathrm{K}_1(\mathbf{z}(w), m', n')$, $\mathrm{K}_2(\mathbf{z}(w), m', n')$ and $\mathrm{K}_3(\mathbf{z}(w), m', n')$ are given by $m'm'$, $m'(m - m') + m'n\,k(\mathbf{p}_-, \mathbf{p}_+)$ and $n'(n'-2n)+2n(n'-n)\,k(\mathbf{p}_-, \mathbf{p}_+)$, respectively. Putting all terms together, we obtain

$$\lim_{w\to\infty} \mathrm{MMD}(\mathbf{z}(w), m', n') \;=\; \frac{n}{n'}\sqrt{2\left(1 - k(\mathbf{p}_-, \mathbf{p}_+)\right)}.$$

In the case $m' > m$, which is equivalent to $n' \leq n$, the result follows by symmetry. Now the second statement is obvious. □

3.1 BIAS CORRECTION

Theorem 2 shows that if the ordinal pattern distributions $\mathbf{p}_-$ and $\mathbf{p}_+$ are different, then the argument (m', n') which maximizes $\mathrm{MMD}(\mathbf{z}(w), m', n')$ is a strongly consistent estimator of (m, n). For finite w, however, practical experiments suggest that this estimator is biased towards $(1, m+n-1)$ and $(m+n-1, 1)$, particularly when the difference between $\mathbf{p}_-$ and $\mathbf{p}_+$ is small (see Section 4.1). Here we give a heuristic explanation: suppose that the similarity between any two components of $\mathbf{z} = (z_1, z_2, \ldots, z_{m+n})$, as measured by the RBF kernel, is approximately equal to some constant $\delta > 0$. For the random vector $\mathbf{z}(w)$, this is likely to be the case if the difference between $\mathbf{p}_-$ and $\mathbf{p}_+$ is so small that all estimates are scattered in the same region. A simple calculation shows that

$$\mathrm{MMD}(\mathbf{z}, m', n') \;\approx\; \left(1 - \delta\right)\frac{m+n}{m'n'} \qquad (4)$$

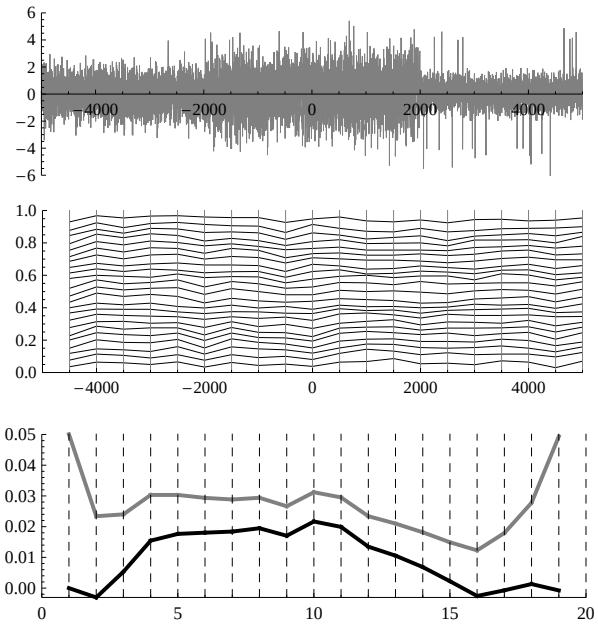

Figure 2: Top: Realization of an AR(1) process with a change-point at $t = 0$. Middle: Ordinal pattern distributions in time windows of size $w = 500$. Bottom: Resulting values for MMD (gray) and CMMD (black).

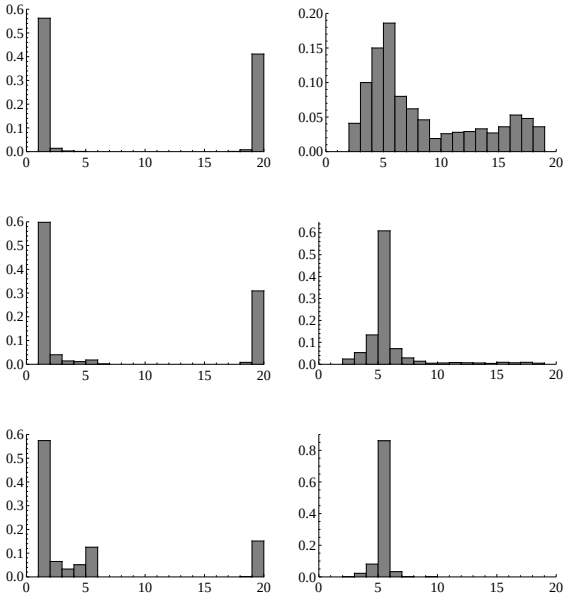

Figure 3: Distribution of the change-point estimators based on MMD (left) and CMMD (right).

for $m', n' \in \mathbb{N}$ with $m' + n' = m + n$, and hence the argument maximizing $\mathrm{MMD}(\mathbf{z}, m', n')$ is likely to be $(m', n') = (1, m + n - 1)$ or $(m', n') = (m + n - 1, 1)$. Next we propose a correction for the bias: define the *Corrected Maximum Mean Discrepancy*

$$\begin{aligned}\mathrm{CMMD}(\mathbf{z}, m', n') &:= \mathrm{MMD}(\mathbf{z}, m', n') \\ &\quad - \frac{m+n-1}{m'n'} \max_{\substack{(\tilde{m},\tilde{n})\in\mathbb{N}^2,\\ \tilde{m}+\tilde{n}=m+n}} \mathrm{MMD}(\mathbf{z}, \tilde{m}, \tilde{n}).\end{aligned}$$

The correction term on the right hand side can be regarded as an estimate of the bias of the MMD statistic (compare to (4)). Experimental results show the superiority of using CMMD instead of MMD (see Section 4.1). Note that the estimator of (m, n) based on CMMD is no longer consistent; in order to preserve consistency, the correction term would have to be scaled by a factor that tends to 0 as $w \to \infty$.

3.2 EFFICIENT COMPUTATION

Let us discuss the computational complexity of our method. The computation of the ordinal pattern distributions is linear in the length of the input sequence and can be realized by very efficient algorithms (Keller et al., 2007b). Computing the estimate of (m, n) by directly evaluating $\mathrm{MMD}(\mathbf{z}(w), m', n')$ for all $m', n' \in \mathbb{N}$ with $m' + n' = m + n$ requires $O((m+n)^3)$ arithmetic operations (Gretton et al., 2007a). For a more efficient computation, note that

$$\begin{aligned}\mathrm{K}_1(\mathbf{z}, m'+1, n'-1) &= \mathrm{K}_1(\mathbf{z}, m', n') \\ &\quad + 2\sum_{i=1}^{m'} k(z_i, z_{m'+1}) + k(z_{m'+1}, z_{m'+1}), \\ \mathrm{K}_2(\mathbf{z}, m'+1, n'-1) &= \mathrm{K}_2(\mathbf{z}, m', n') \\ &\quad - \sum_{i=1}^{m'} k(z_i, z_{m'+1}) + \sum_{i=1}^{n'-1} k(z_{m'+1}, z_{m'+1+i}), \\ \mathrm{K}_3(\mathbf{z}, m'+1, n'-1) &= \mathrm{K}_3(\mathbf{z}, m', n') \\ &\quad - 2\sum_{i=1}^{n'} k(z_{m'+1}, z_{m'+i}) + k(z_{m'+1}, z_{m'+1}).\end{aligned}$$

Using these formulas, $\mathrm{MMD}(\mathbf{z}(w), m', n')$ can be evaluated iteratively for all $(m', n') = (1, m + n - 1), \ldots, (m + n - 1, 1)$. Thus, computing the argument which maximizes $\mathrm{MMD}(\mathbf{z}(w), m', n')$ requires $O((m+n)^2)$ arithmetic operations.

3.3 RELATED WORK

There is an extensive literature on change-point detection, including both parameteric and non-parametric approaches (Chen and Gupta, 2000; Brodsky and Darkhovsky, 1993, 2000). Recently, a kernel-based method been proposed by Harchaoui et al. (2009). The main difference to our approach is that all these methods aim to find the *exact* location of change-points and give some guarantees on the significance level.

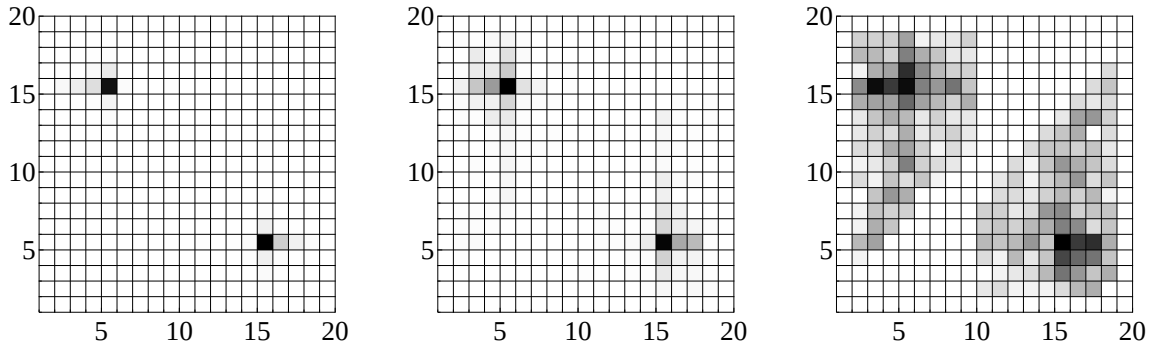

Figure 4: Detection of multiple change-points. The black coloring corresponds to the maximum frequencies 34.0% (left), 15.1% (middle) and 2.2% (right), the white coloring corresponds to 0%.

This precision comes at the price of a high computational burden; for example, Harchaoui's method has a running time which is cubic in the input size. Our method is designed to find the *approximate* location of change-points, where the precision is controlled by the time window size w. Because of its computational efficiency, our method is particularly attractive for the fast exploration of high-resolution time series such as EEG recordings, which often consist of hundreds of thousands of data points. Note that our approach can be combined with existing methods in order to first obtain the approximate locations of a set of candidate change-points before determining their exact locations and testing for significance.

4 EXPERIMENTS

4.1 SIMULATED DATA

Change of the autoregressive coefficient. Let us first illustrate our method for simulated data. The top plot of Figure 2 shows a realization of a first order autoregressive (AR(1)) process with standard normal innovations where, at time $t = 0$, the autoregressive coefficient changes from 0.1 to 0.3. There are two changes of the process "calibration": at time $t = -2000$, the variance increases from 1 to 2, and at time $t = 2000$, the variance decreases to $\frac{1}{2}$ and values greater than 2 and smaller than -2, respectively, are scaled by the factor 2. According to Remark 1 at the end of Section 2, we are not interested in detecting these changes of the calibration, but only in the change-point at $t = 0$.

The middle plot of Figure 2 shows the distribution of ordinal patterns in time windows of size $w = 500$. The order is $d = 3$, so there are 24 different patterns (compare to Figure 1). Their relative frequencies are represented by the space between horizontal lines: the space between the bottom line and the first line from below represents the relative frequency of the ordinal pattern (0,1,2,3) (the first pattern in Figure 1), the space between the first and the second line from below represents the relative frequency of (0,1,3,2) (the second pattern in Figure 1), and so on. In the framework of Section 2, we have $m = n = 10$, i.e., there are 10 time windows before and after the change-point. As can be seen, the distributions before and after the change-point are slightly different. The bottom plot of Figure 2 shows the resulting MMD and CMMD values for $(m', n') = (1, 19)$, $(2, 18)$, $\ldots$, $(19, 1)$. In all our experiments, we used $\sigma^2 = 1$ in the RBF kernel, however, we found that the results were not very sensitive with respect to the choice of σ^2. The maximal MMD value is obtained for $(m', n') = (19, 1)$, while maximizing the argument of CMMD yields the true value $(10, 10)$.

Comparing MMD and CMMD. In Figure 3, we compare the distribution of the change-point estimators based on MMD and CMMD. Again, the underlying model is an AR(1) process of length $10,000$ and the time window size is $w = 500$. In this experiment, we chose $(m, n) = (5, 15)$, and the autoregressive coefficient changes from 0.1 to 0.2 (top), from 0.1 to 0.3 (middle) and from 0.1 to 0.4 (bottom). The distributions of the estimators are obtained by $1,000$ Monte Carlo replications. As can be seen, the estimator based on CMMD performs better in all three cases; the one based on MMD is biased towards (1,19) and (19,1), particularly if the change of the autoregressive coefficient is small.

Multiple change-point detection. Figure 4 shows the results obtained for the detection of multiple change-points. The underlying model is an AR(1) process of length $10,000$ with a change of the autoregressive coefficient at $2,500$ and $7,500$

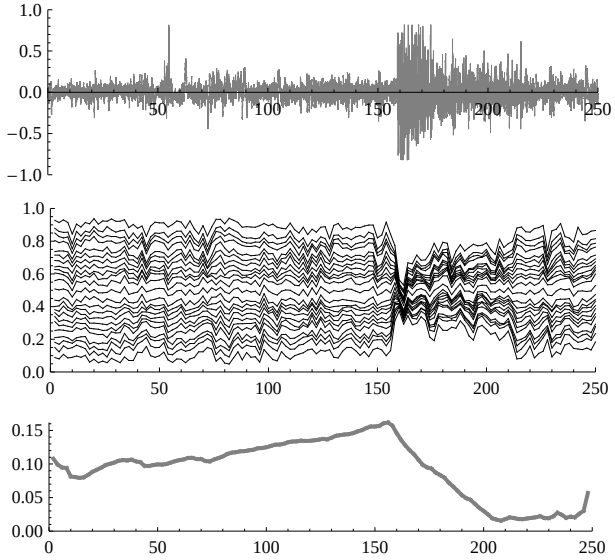

Figure 5: Top: 250 seconds long part of an EEG recording. Middle: Ordinal pattern distributions. Bottom: Resulting MMD values.

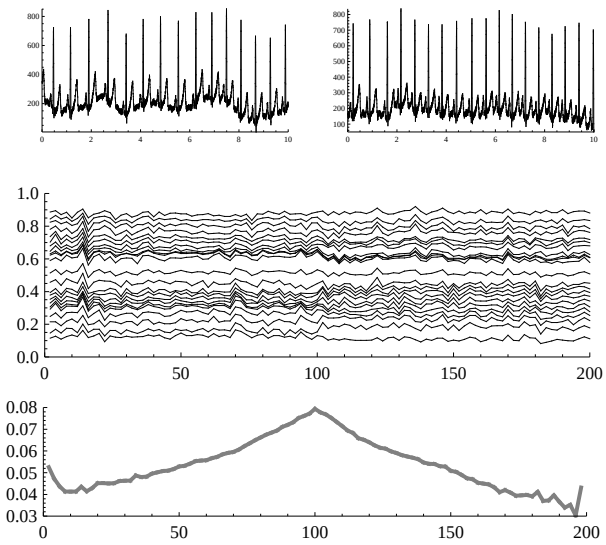

Figure 6: Top: 10 seconds of an ECG before and after an increase of the heart rate. Middle: Ordinal pattern distributions. Bottom: Resulting MMD values.

time points, namely, from 0.1 to 0.4 and 0.4 to 0.1 (left), from 0.1 to 0.3 and 0.3 to 0.1 (middle), and from 0.1 to 0.2 and 0.2 to 0.1 (right). To localize these change-points, we applied our method twice: first to the entire sequence, then to the longer one of the resulting two time segments. Figure 4 displays the distribution of the estimates obtained by $1,000$ Monte Carlo replications. The coloring of the cell (x, y) represents the frequency of replications with the first change-point detected at $500x$ time points and the second one at $500y$ time points. As can be seen, the localization in the first two experiments is fairly precise. In the third experiment, the estimates are more scattered, however, this is true even in the single change-point setting (compare to Figure 3).

4.2 REAL-LIFE TIME SERIES

Epileptic activity in EEG time series. The top plot of Figure 5 shows a 250 seconds long part of an EEG recording which was digitized with a sampling rate of 256 Hertz, so the time series consists of $250 \cdot 256 = 64,000$ data points. The increase in amplitude after 160 seconds is related to the onset of an epileptic seizure. The middle plot shows the distribution of ordinal patterns in non-overlapping time windows of 2 seconds, that is, $w = 512$. Same as in Figure 2, the order of the patterns is $d = 3$. The bottom plot displays the resulting MMD values. The maximum is obtained at the onset of the seizure, thus indicating the presence of a change-point after 160 seconds.

Heart rate changes in ECG data. Figure 6 shows the application of our method to the detection of heart rate changes in electrocardiography (ECG) recordings. The middle plot displays the distribution of ordinal patterns in 100 non-overlapping time windows of 2 seconds, again corresponding to the time window size $w = 512$. After 100 seconds, there is a slight change in the heart rate from approximately 90 to 105 beats per minute (compare to the plots in the top row). As the bottom plot shows, this change-point is easily detected even by the non-corrected MMD values.

5 CONCLUSIONS

We have presented a new method for detecting change-point in time series based on measuring the maximum mean discrepancy of ordinal pattern distributions. The main advantages of our approach are its computational efficiency and robustness towards (non-linear) signal distortions. These properties make it particularly attractive for the fast exploration of biophysical time series the exact calibration of which is unknown or varies with time. We believe that our approach can be efficiently combined with existing change-point detection methods to first approximately localize of a set of candidates before determining the exact location and testing for significance. We have established asymptotical properties of our method and evaluated its performance both for simulated and real-life data, including the application to multiple change-point problems.

Efficiently Searching for Frustrated Cycles in MAP Inference

David Sontag, Do Kook Choe, Yitao Li
Department of Computer Science
Courant Institute of Mathematical Sciences
New York University

Abstract

Dual decomposition provides a tractable framework for designing algorithms for finding the most probable (MAP) configuration in graphical models. However, for many real-world inference problems, the typical decomposition has a large integrality gap, due to frustrated cycles. One way to tighten the relaxation is to introduce additional constraints that explicitly enforce cycle consistency. Earlier work showed that cluster-pursuit algorithms, which iteratively introduce cycle and other higher-order consistency constraints, allows one to exactly solve many hard inference problems. However, these algorithms explicitly enumerate a candidate set of clusters, limiting them to triplets or other short cycles. We solve the search problem for cycle constraints, giving a nearly linear time algorithm for finding the most frustrated cycle of arbitrary length. We show how to use this search algorithm together with the dual decomposition framework and cluster-pursuit. The new algorithm exactly solves MAP inference problems arising from relational classification and stereo vision.

1 Introduction

Graphical models such as Markov random fields have been successfully applied to many fields, from computer vision and natural language processing, to computational biology. Exact probabilistic inference is generally intractable in complex models having many dependencies between the variables. Here we consider the problem of finding the most probable (MAP) assignment in graphical models with discrete states.

Dual decomposition provides a powerful framework for designing tractable MAP inference algorithms [19]. This approach attempts to minimize an upper bound on the MAP assignment by reparameterization of the potentials. Many optimization algorithms have been proposed to minimize the dual, such as those based on subgradients [10, 13], message-passing approaches based on block coordinate-descent [6, 11, 14, 23], and provably convergent algorithms [7, 9, 16]. Every decomposition corresponds to a particular linear programming (LP) relaxation. The dual LP that is most frequently solved by these algorithms corresponds to the pairwise LP relaxation, which enforces local consistency constraints between factors that share variables.

However, for many real-world inference problems, the pairwise LP relaxation has a large integrality gap. These situations arise because there are frustrated cycles where a fractional solution can obtain a higher objective value by letting the edge marginals along the cycle be globally inconsistent. We can try to avoid these fractional solutions by instead optimizing over a tighter LP relaxation. There are well-known methods for tightening relaxations, such as the Sherali-Adams hierarchy of relaxations which uses cluster consistency constraints to enforce the consistency of all edge marginals in a cluster, for all clusters of some fixed size [15]. However, these linear programs are typically computationally infeasible to solve because they tighten the relaxation uniformly across all of the problem. For graphical models of moderate size, even the first lifting of the Sherali-Adams hierarchy (all triplet clusters, also called the *cycle relaxation*) is too slow to optimize over.

Several authors have proposed cluster-pursuit algorithms that iteratively tighten the dual using cycle

consistency constraints [3, 9, 12, 21, 24]. These approaches are based on dictionary enumeration. They consider a small set of candidate cycles (e.g., all 3-cycles in a graph, or 4-cycles for grids), and evaluate a score to decide which cycle clusters to add to the decomposition. This explicit enumeration limits the applicability of these algorithms to graphical models where it is obvious where to look for the candidate cycles. However, many difficult inference problems are on sparse graphical models with few short cycles, such as the factor graphs used for low-density parity check codes, or Markov random fields whose structure follows that of a social network or the web graph (frequently used for relational classification).

In this paper, we address the most significant shortcoming of these cluster-pursuit algorithms: the difficulty of finding where to tighten the relaxation in sparse graphs. We show in Section 4 that, for non-binary graphical models, it is NP-hard to find the best cycle according to the bound criterion score used in earlier work [21]. Thus, we need an alternative approach to address the search problem of finding where to tighten the relaxation.

We describe a new approach where, as before, we solve the dual of the pairwise LP relaxation, but where we now search for k-ary cycle inequalities [20] to tighten the relaxation rather than cluster consistency constraints. We consider the same greedy bound minimization criterion used earlier for cluster consistency constraints, corresponding to the amount that the dual objective would decrease with just one coordinate descent step on the new dual variable(s). We show that one can, in near-linear time (in the size of the projection graph), find a k-ary cycle inequality whose guaranteed bound decrease is a constant fraction of the best possible bound decrease according to this criterion. The resulting algorithm is similar to the separation algorithm given in [20] for finding the most violated cycle inequality in the primal, but is not based on shortest paths. We use the cycle inequalities only as a means of obtaining an efficient search algorithm, and we add the full cycle cluster to the dual decomposition as in previous work.

Somewhat surprisingly, in Section 4 we show that, for *binary* graphical models and when the dual has been solved to optimality, the two bound criterions (the one given in [21] and this one) coincide. Thus, at least for binary graphical models, the algorithm that we present completely solves the open problem from [21] of how to efficiently search over cycle clusters.

2 Background

We consider MAP inference problems on factor graphs with n variables $X_1, \ldots, X_n$, where each variable takes discrete states $x_i \in \text{Vals}(X_i)$. The MAP inference problem is then

$$\text{MAP}(\theta) = \max_{\mathbf{x}} \sum_{\mathbf{c} \in C} \theta_{\mathbf{c}}(\mathbf{x_c}), \tag{1}$$

where C denotes the set of factors, and $\theta_{\mathbf{c}}(\mathbf{x_c})$ is the log of the potential function for factor $\mathbf{c}$. Let $G = (V, E)$ be the Markov network corresponding to this factor graph, with one edge $ij \in E$ for every two variables i and j that appear together in some factor. The notation $N(i)$ refers to the set of variables that neighbor i in the Markov network.

2.1 Dual Decomposition

The dual decomposition approach [19] attempts to address the intractability of the joint maximization in Eq. 1 by introducing dual variables δ and minimizing an upper bound on the MAP assignment:

$$\min_{\delta} L(\delta), \quad L(\delta) = \sum_{\mathbf{c} \in C} \max_{\mathbf{x_c}} \theta^{\delta}_{\mathbf{c}}(\mathbf{x_c}), \tag{2}$$

where the reparameterizations $\theta^{\delta}_{\mathbf{c}}(\mathbf{x_c})$ are given by

$$\begin{aligned}
\theta^{\delta}_i(x_i) &= \theta_i(x_i) + \sum_{j \in N(i)} \delta_{ij \to i}(x_i) \qquad \forall i \in V, \\
\theta^{\delta}_{ij}(x_i, x_j) &= \theta_{ij}(x_i, x_j) - \delta_{ij \to i}(x_i) - \delta_{ij \to j}(x_j) \\
&\quad + \sum_{\mathbf{c}: |\mathbf{c}| \geq 3,\ i,j \in \mathbf{c}} \delta_{\mathbf{c} \to ij}(x_i, x_j) \quad \forall ij \in E, \\
\theta^{\delta}_{\mathbf{c}}(\mathbf{x_c}) &= \theta_{\mathbf{c}}(\mathbf{x_c}) - \sum_{i,j \in \mathbf{c}} \delta_{\mathbf{c} \to ij}(x_i, x_j) \quad \forall |\mathbf{c}| \geq 3.
\end{aligned}$$

The key property of the function $L(\delta)$ is that it only involves maximization over local assignments $\mathbf{x_c}$, a task which we assume to be tractable. The dual thus decouples the original problem, resulting in a problem that can be optimized using local operations.

If we ever find a global assignment $\mathbf{x}$ which locally maximizes all of the subproblems, then $\mathbf{x}$ is guaranteed to be the MAP assignment. Thus, the dual solution δ has the ability to provide a *certificate of optimality*. Even in cases when the relaxation is loose, the dual provides an upper bound, $\text{MAP}(\theta) \leq L(\delta)$, that can be useful within branch-and-bound.

The algorithms described in this paper make use of the reparameterized edge potentials $\theta^{\delta}_{ij}(x_i, x_j)$ when searching for frustrated cycles. For notational clarity and to be consistent with earlier work, we use

$b_{ij}(x_i, x_j)$ to denote $\theta^{\delta}_{ij}(x_i, x_j)$ for the current dual variables δ, also calling these the edge "beliefs".

2.2 Cluster Pursuit

If there still remains an integrality gap after solving the current dual, i.e. $\text{MAP}(\theta) < L(\delta^*)$, one can *tighten* the relaxation by introducing new zero-valued potentials $\theta_{\mathbf{c}}(\mathbf{x_c})$ for clusters $\mathbf{c}$ not originally in the factor graph [21, 24]. The advantage of doing this together with dual decomposition is that one can *warm start*, initializing the new dual's variables using the previous dual solution. The resulting algorithm alternates between minimizing the current dual for some number of iterations (not necessarily to optimality) and searching for new clusters to use in tightening the relaxation. If the dual is solved using coordinate-descent, then every step of the algorithm monotonically improves the upper bound on the MAP value.

The key problem addressed by earlier work was how to choose *which* clusters to use to tighten the relaxation. In particular, Sontag et al. [21] proposed to evaluate the utility of adding a cycle C to the relaxation by the greedy bound minimization criterion

$$d(C) = \sum_{e \in C} \max_{\mathbf{x}_e} b_e(\mathbf{x}_e) - \max_{\mathbf{x}_C} \left[\sum_{e \in C} b_e(\mathbf{x}_e) \right]. \quad (3)$$

Note that only the edges in the cycle C are used in the maximization over $\mathbf{x}_C$. As a result, $d(C)$ can be computed in $O(k^3|C|)$ time, where k is the number of states for each variable. The criterion corresponds to the amount that the dual would decrease if we add this cycle cluster and perform one block coordinate descent step on all dual variables corresponding to the new cluster. Once a cycle is selected for addition, [21] triangulates the cycle and adds each of the triplet clusters; we do this too.

2.3 Linear Programming Relaxation

The dual decomposition for MAP inference given in Eq. 2 can be shown to be equivalent, by LP duality, to the following linear programming relaxation:

$$\max_{\boldsymbol{\mu} \in M_L} \sum_{\mathbf{c}} \sum_{\mathbf{x_c}} \theta_{\mathbf{c}}(\mathbf{x_c}) \mu_{\mathbf{c}}(\mathbf{x_c}) \quad (4)$$

where the *local marginal polytope* M_L enforces that $\{\mu_i(x_i), \forall x_i\}$ and $\{\mu_{\mathbf{c}}(\mathbf{x_c}), \forall \mathbf{x_c}\}$ correspond to valid (local) probability distributions and that, for each factor $\mathbf{c}$, $\mu_{\mathbf{c}}(\mathbf{x_c})$ is consistent with $\mu_i(x_i)$ for all $i \in \mathbf{c}, x_i$:

$$M_L = \left\{ \boldsymbol{\mu} \geq 0 : \begin{array}{ll} \sum_{x_i} \mu_i(x_i) = 1, & \forall i \\ \sum_{\mathbf{x}_{\mathbf{c}\setminus i}} \mu_{\mathbf{c}}(\mathbf{x_c}) = \mu_i(x_i) & \\ \sum_{\mathbf{x}_{\mathbf{c}\setminus\{i,j\}}} \mu_{\mathbf{c}}(\mathbf{x_c}) = \mu_{ij}(x_i, x_j) & \end{array} \right\},$$

where the second set of constraints is for all $\mathbf{c}, i \in \mathbf{c}, x_i$, and the third set of constraints is for all factors $\mathbf{c}$ such that $|\mathbf{c}| \geq 3$, $i, j \in \mathbf{c}, x_i, x_j$.

The exact MAP inference problem would be obtained if we instead had maximized Eq. 4 over the *marginal polytope* [22], which enforces that all feasible points $\boldsymbol{\mu}$ correspond to marginals arising from some exponential family distribution with the same sufficient statistics. For most graphical models the marginal polytope is intractable to optimize over, which is why we use the relaxation M_L.

2.4 k-ary Cycle Inequalities

The main contribution of this paper is to show how to solve the search problem for cycle consistency constraints (within the framework of dual decomposition) by introducing a new bound criterion based on the k-ary cycle inequalities [20].

The cycle inequalities [1, 2, 4] are a set of constraints for the marginal polytope of graphical models with binary variables, which arises from the observation that a cycle must have an even (possibly zero) number of cut edges. Suppose we start at node i, where $x_i = 0$. As we traverse the cycle, the assignment changes each time we cross a cut edge. Since we must return to $x_i = 0$, the assignment can only change an even number of times. This concept can be generalized to obtain the k-ary cycle inequalities, which are valid constraints for graphical models with non-binary variables [20].

For each variable i, let π_i^q be a *partition* of all of its states into two disjoint non-empty sets. Let π_i denote the set of all partitions of variable i. The k-ary cycle inequalities are defined using the *projection graph* $G_\pi = (V_\pi, E_\pi)$, which has one node for each partition in each set π_i and all such nodes are fully connected across adjacent variables. That is, we have $V_\pi = \bigcup_{i \in V} \pi_i$, and

$$E_\pi = \{(\pi_i^q, \pi_j^r) \mid (i,j) \in E,\, q \leq |\pi_i|,\, r \leq |\pi_j|\}. \quad (5)$$

We obtain a different projection graph depending on the quantity and type of partitions that we choose for each variable. The algorithms in this paper are applicable for *any* projection graph. In our experimental results, we primarily use the k-projection

graph, which simply has a partition $\pi_i^{x_i} = \{x_i\}$ (versus all other states) for every variable i and state x_i. Thus, if every variable takes k states, the projection graph will have $k|V|$ nodes and $k^2|E|$ edges. In the supplementary material we describe an algorithm which finds the optimal partition for each variable with respect to each edge. If using the k-projection graph does not succeed in finding a frustrated cycle, we re-run the cycle search method using this expanded set of partitions.

There is one k-ary cycle inequality for every cycle C in the projection graph G_π and for every set of edges $F \subseteq C$ such that $|F|$ is odd:

$$\sum_{mn \in C \setminus F} \sum_{\substack{x_i, x_j : \\ \pi_i^q(x_i) \neq \\ \pi_j^r(x_j)}} \mu_{ij}(x_i, x_j) + \sum_{mn \in F} \sum_{\substack{x_i, x_j : \\ \pi_i^q(x_i) = \\ \pi_j^r(x_j)}} \mu_{ij}(x_i, x_j) \geq 1$$

where $mn = (\pi_i^q, \pi_j^r) \in E_\pi$. Although there are exponentially many k-ary cycle inequalities, [20] showed how the most violated inequality can be found in polynomial time, using a shortest-path algorithm. However, unlike [20] we use these inequalities in the *dual*. In the next section, we will give a new algorithm to efficiently find violated k-ary cycle inequalities while working within the framework of dual decomposition.

3 Cycle Inequalities in the Dual

In this section we give a column-generation approach for adding cycle inequalities within the dual decomposition framework. Consider the terms of the dual objective (Eq. 2) that would be affected by adding a single dual variable $\lambda_{C,F,\pi}$ corresponding to one k-ary cycle inequality specified by $C \subseteq E$, $F \subseteq C$ (recall that $|F|$ must be odd), and π.[1] After adding $\lambda_{C,F,\pi}$, the new dual has the following terms (see supplementary material for derivation):

$$\sum_{ij \in F} \max_{x_i, x_j} \Big(b_{ij}(x_i, x_j) + \lambda_{C,F,\pi} \mathbf{1}[\pi_i(x_i) = \pi_j(x_j)] \Big)$$
$$+ \sum_{ij \in C \setminus F} \max_{x_i, x_j} \Big(b_{ij}(x_i, x_j) + \lambda_{C,F,\pi} \mathbf{1}[\pi_i(x_i) \neq \pi_j(x_j)] \Big)$$
$$- \lambda_{C,F,\pi}.$$

For each edge $ij \in C$, define the weight

$$s_{ij}^\pi = \max_{x_i, x_j \,:\, \pi_i(x_i) = \pi_j(x_j)} b_{ij}(x_i, x_j) - \max_{x_i, x_j \,:\, \pi_i(x_i) \neq \pi_j(x_j)} b_{ij}(x_i, x_j).$$

[1] When used in the context of a cycle in the graphical model, $C \subseteq E$, as opposed to a cycle in the projection graph, the notation π specifies a particular partition for each variable along the cycle.

We show in the supplementary material that the coordinate descent step for $\lambda_{C,F,\pi}$ is given by $\lambda_{C,F,\pi} = \min_{ij \in C} w_{ij}^{\pi,F}$, where $w_{ij}^{\pi,F} = s_{ij}^\pi$ for $ij \notin F$ and $w_{ij}^{\pi,F} = -s_{ij}^\pi$ for $ij \in F$.

The amount that the dual objective decreases with one coordinate descent step on $\lambda_{C,F,\pi}$, assuming that $\lambda_{C,F,\pi}$ was previously zero, is

$$d(C, F, \pi) = \max(0, \min_{ij \in C} w_{ij}^{\pi,F}). \tag{6}$$

Example 1. Consider a triangle on three edges ($C = \{12, 23, 31\}$), with $x_i \in \{0, 1\}$, where $\theta_i(x_i) = 0$ $\forall i, x_i$ and $\theta_{ij}(x_i, x_j) = 1$ if $x_i \neq x_j$, and 0 otherwise. Since this example is binary, we simply use $\pi_i(x_i) = x_i$. Let all of the dual variables δ be 0, and assume that initially there are no cycle inequalities. The best integer solution has value 2, while the pairwise LP relaxation gives only a loose upper bound of 3 (note: δ as defined can be shown to be optimal for the dual, i.e. Eq. 2).

Consider the problem of finding the best cycle inequality according to $\arg\max_{C,F} d(C, F)$. First, note that $b_{ij}(x_i, x_j) = \theta_{ij}(x_i, x_j)$, so $w_{ij}^F = 1$ for $ij \in F$ and $w_{ij}^F = -1$ for $ij \notin F$. If $F = \emptyset$, then $w_{ij}^F = -1$ for all edges, and so $d(C, F) = 0$. On the other hand, if $F = C$, then $w_{ij}^F = 1$ for all edges, which gives a bound decrease of $d(C, F) = 1$, corresponding to $\lambda_{C,F} = 1$.

3.1 Separation Algorithm

The bound criterion $d(C, F, \pi)$ given in Eq. 6 is analogous to the bound criterion $d(C)$ used by [21] (see Eq. 3) to evaluate the utility of adding a cycle C to the relaxation. We now consider the algorithmic problem of finding the *best* dual variable $\lambda_{C,F,\pi}$ to add, according to $d(C, F, \pi)$:

$$\max_{C, F \subseteq C \text{ s.t. } |F| \text{ odd}, \pi} d(C, F, \pi). \tag{7}$$

We show that this can be computed efficiently using a variation on the shortest-path based separation algorithm for k-ary cycle inequalities [20]. We first note that Eq. 7 is equal to

$$\max \Big(0, \max_{C, F \subseteq C \text{ s.t. } |F| \text{ odd}, \pi} \min_{ij \in C} w_{ij}^{\pi,F}\Big). \tag{8}$$

We can simplify this further by noticing that for $d(C, F, \pi)$ to be positive, we need $ij \in F$ when $s_{ij}^\pi < 0$, and $ij \notin F$ when $s_{ij}^\pi > 0$. Thus, ignoring the maximization over the partitioning π, Eq. 8

Algorithm FindOddCycle (Graph G_π, edge weights $\{s_{mn} : (m,n) \in E_\pi\}$)

```
Construct a spanning tree T of G_π. Set r to be the root of T.
sign[r] ← +1
for each vertex t ∈ T (in order of increasing distance from r in T):
    sign[t] ← sign[pa(t)] · s_{t,pa(t)}
for each (m,n) ∈ E_π \ T:
    if sign[m] ≠ sign[n] · s_mn
        return cycle given by the edge (m,n) and the path m ⇝ r ⇝ n in T

return no odd signed cycle found
```

Figure 1: Assuming that the edge weights s_{mn} are in $\{-1, 1\}$, this algorithm will find a cycle with an odd number of -1 edges, if one exists. $\text{pa}(t)$ refers to the parent of node t in the spanning tree T.

is equivalent to

$$\max\Big(0, \max_{\substack{C \subseteq E \text{ s.t.} \\ \prod_{ij \in C} \text{sign}(s^\pi_{ij}) = -1}} \min_{ij \in C} |s^\pi_{ij}|\Big). \quad (9)$$

We conclude that the maximum bound decrease is achieved by the cycle in G with an odd number of negative weight edges that maximizes the minimum of the absolute value of the weights along the cycle.

For Markov networks with non-binary variables, we also wish to maximize over the partition for each variable. Let G_π denote the projection graph, where the variables and edges are as defined in Eq. 5. All subsequent quantities will use the partitions for the variables specified by the edges $mn = (\pi^q_i, \pi^r_j) \in E_\pi$ in the projection graph. Assign weights to the edges[2]

$$s_{mn} = \max_{x_i, x_j : \pi^q_i(x_i) = \pi^r_j(x_j)} b_{ij}(x_i, x_j) - \max_{x_i, x_j : \pi^q_i(x_i) \neq \pi^r_j(x_j)} b_{ij}(x_i, x_j), \quad (10)$$

and remove all edges with $s_{mn} = 0$. The algorithm that we describe next will find the maximum of

$$\max\Big(0, \max_{\substack{C \subseteq E_\pi \text{ s.t.} \\ \prod_{mn \in C} \text{sign}(s_{mn}) = -1}} \min_{mn \in C} |s_{mn}|\Big). \quad (11)$$

Suppose that $s_{mn} \in \{+1, -1\}$. Then, $\min_{mn \in C} |s_{mn}| = 1$ and the optimization problem simplifies to finding a cycle with an odd number of -1 edges. This can be solved in linear time by the algorithm given in Figure 1 (if the graph is not connected, do this for each component).[3]

[2]For the k-projection graph, this step can be implemented efficiently, taking time $O(k^2|E|)$ to compute all edge weights instead of $O(k^2|E_\pi|)$.

[3]In the case when there is more than one cycle with an odd number of -1 edges, the particular cycle that we find depends on the choice of spanning tree. However, the algorithm is always guaranteed to find *some* cycle with an odd number of -1 edges, when one exists, regardless of the choice of spanning tree.

Now consider the case of general s_{mn}. We can solve the optimization in Eq. 11 by doing a binary search on $|s_{mn}|$. There are only $|E_\pi|$ possible edge weights, so to do this search we first sort the values $\{|s_{mn}| : mn \in E_\pi\}$. At each step, we consider the subgraph G' consisting of all $mn \in E_\pi$ such that $|s_{mn}| > R$, where R is the threshold used in the binary search. We then let $s_{m'n'} = \text{sign}(s_{mn})$ for $m'n' \in G'$, and search for a cycle with an odd number of negative edges using the algorithm described in Figure 1. The binary search will find the largest R such that there is a negative-signed cycle $C \in G'$, if one exists. The best choice of $\lambda_{C,F,\pi}$ is then given by this cycle C, the edges F corresponding to the negative-weight edges in C, and π given by the partitions used in C. The total running time is only $O(|E_\pi| \log |E_\pi|)$.

If the cycle that is returned uses each variable only once (i.e., does not consider more than one partition for a single variable), the corresponding cycle and choice of partitions will be optimal for Eq. 8. Otherwise, one can show that the guaranteed bound decrease after one coordinate descent step on the new cycle inequality's dual variable is a constant fraction of that guaranteed by Eq. 8.

When we use this algorithm in the experiments of Section 6, we ignore F and π, instead fully enforcing cycle consistency for the cycle C that is best according to this bound criterion.

4 Theoretical Results

Consider the restricted set of clusters $\mathcal{C}_{\text{cycles}}(G)$ corresponding to cycles of arbitrary length,

$$\mathcal{C}_{\text{cycles}}(G) = \Big\{C \subseteq E \mid C \text{ forms a cycle in } G\Big\}. \quad (12)$$

A natural question is whether it is possible to find the best cycle cluster to add to the relaxation according to the greedy bound minimization criteria $d(C)$

[21]. It is easily shown that $\max_{F,\pi} d(C,F,\pi) \leq d(C)$ for all cycles C. Thus, if it were not for computational concerns, searching using $d(C)$ would be optimal. Unfortunately, we show a number of negative results proving that searching for the best cycle according to $d(C)$ is computationally intractable.

We show the following, where k refers to the number of states per node.

1. For $k = 2$, when the beliefs $b_e(\mathbf{x}_e)$ are dual optimal, maximizing Eq. 3 is *equivalent* to finding the best cycle inequality in the dual.[4]
2. For $k = 2$, maximizing Eq. 3 is NP-hard when the beliefs $b_e(\mathbf{x}_e)$ are not dual optimal.
3. For $k > 2$, maximizing Eq. 3 is always NP-hard.

By dual optimal, we mean that the beliefs correspond to a dual optimal solution of the current LP relaxation. Note that, before solving the dual LP to optimality, $b_e(\mathbf{x}_e)$ can be almost anything. For example, we can set $\theta_e(\mathbf{x}_e)$ arbitrarily and consider the separation problem at the first iteration.

Theorem 4.1. *When $k = 2$ and the beliefs $b_{ij}(x_i, x_j)$ correspond to a dual optimal solution, $\max_{C \in \mathcal{C}_{cycles}(G)} d(C) = \max_{C,F:|F| \text{ odd}} d(C,F)$.*

The proof of Theorem 4.1 makes use of the assumption that $b_{ij}(x_i, x_j)$ corresponds to a dual optimal solution in only one step, when applying the complementary slackness conditions for the edge variables. Thus, Theorem 4.1 holds for any dual decomposition for MAP which is at least as tight as the pairwise LP relaxation. In particular, adding cycle constraints does not change the premise of the theorem.

One conclusion that is immediate given Theorem 4.1 is that (for binary MRFs) the cycle inequalities give at least as tight of a relaxation as the cycle relaxation. In fact, for a single cycle, just one cycle inequality suffices to make the LP relaxation tight for a given instance. This is precisely what we observed in Example 1.

4.1 NP-Hardness Results

It is often possible to obtain much better results by tightening the relaxation even before the dual is solved to optimality [21]. Unfortunately, although we showed in Section 3 that for k-ary cycle inequalities $\max_{C,F,\pi} d(C,F,\pi)$ can be computed efficiently, the corresponding problem for cycle consistency constraints is significantly more difficult:

[4]This result is for binary variables only, so we let the projection be $\pi_i(x_i) = x_i$ and omit the π notation.

Theorem 4.2. *The optimization problem $\max_{C \in \mathcal{C}_{cycles}(G)} d(C)$ is NP-hard for $k = 2$ and beliefs $b_{ij}(x_i, x_j)$ arising from a non-optimal dual feasible point.*

We next show that, for $k > 2$, not even dual optimality helps:

Theorem 4.3. *The optimization problem $\max_{C \in \mathcal{C}_{cycles}(G)} d(C)$ is NP-hard for $k \geq 3$ even for beliefs $b_{ij}(x_i, x_j)$ corresponding to a dual optimal solution of the pairwise relaxation.*

Both proofs use a reduction from the Hamiltonian cycle problem. Full proofs can be found in the supplementary material.

5 Related Work

Our new algorithm is closely related to two earlier approaches for tightening the dual using cycle constraints. First, Komodakis et al. proposed to tighten the pairwise LP relaxation by a sequence of cycle repairing operations [12]. Their algorithm is applicable to graphical models with non-binary variables. For binary graphical models, when the dual is at optimality, two cycle repairs – corresponding to the two anchors of any variable (using their terminology) – can be seen to be equivalent to one coordinate descent step on a new cycle inequality for this cycle. We solve the open problem of how to *find* the cycles where cycle repairs are necessary. In their experiments, [12] explicitly enumerated over short cycles.

Second, Johnson proposed an algorithm to find *inconsistent* cycles in the dual [9]. His approach applies only to binary-valued graphical models, and only when the dual is close to optimality. In these cases, his algorithm can be shown to find a cycle C such that $d(C,F) > 0$ for some $F \subseteq C$, $|F|$ odd. His algorithm, which inspired our approach, constructs $s_{ij} \in \{+1, -1\}$ and looks for inconsistent cycles using the linear time method described in Section 3.1. Because of numerical difficulties, Johnson needed to use an edge-wise correlation measure, computed using the primal solution obtained from the smoothed dual [9, p.134]. By drawing the connection to cycle inequalities, we obtain a *weighted* approach whereas his was *unweighted*. As a result, there are no numerical difficulties, and our algorithm can be applied long before solving the dual to optimality.

It may seem surprising that the dual separation algorithm is so much faster than the primal separation algorithm for k-ary cycle inequalities [20]. However, this is because the dual searches over a smaller class

of cycle inequalities. Consider the case where we have solved the dual to optimality for the current relaxation. Then, using the complementary slackness conditions one can show that, for any cycle inequality C, F, π such that $d(C, F, \pi) > 0$, and for any primal solution μ,

$$\sum_{mn \in C \setminus F} \left(\mu^{\pi}_{mn}(0,1) + \mu^{\pi}_{mn}(1,0) \right) + \sum_{mn \in F} \left(\mu^{\pi}_{mn}(0,0) + \mu^{\pi}_{mn}(1,1) \right) = 0. \quad (13)$$

The right hand side could be anything less than 1 for us to obtain a violated cycle inequality, and it is always non-negative because $\mu_{ij}(x_i, x_j) \geq 0$. But, since the right hand side of Eq. 13 is 0, we conclude that the dual separation algorithm is only able to find cycle inequalities to add to the relaxation that are *very violated*. By Theorem 4.1, the same conclusion holds for binary graphical models for the cluster-pursuit algorithm given in [21], when applied to a dual optimal solution – if a triplet cluster C is found such that $d(C) > 0$, then there exists a cycle inequality C, F that is very violated by all primal solutions. It is also possible to give a $O(|E_\pi|)$ time separation algorithm in the primal that would separate this smaller class of k-ary cycle inequalities.

6 Experiments

In this section we report experimental results for the new cycle search algorithm (we call this the "cycle" method) applied to MAP inference problems arising from predicting protein-protein interactions [5, 8], protein side-chain placement [25], and stereo vision [25]. We compare the cycle method to cluster-pursuit using dictionary enumeration with triplet clusters [21], which we call the "triplet" method. Both algorithms were implemented using C++, and differ only in the mechanism used for cycle search. All experiments were performed on a 2.4 GHz AMD Opteron(tm) machine with 128 GB of memory.

We use the Max-Product Linear Programming (MPLP) algorithm to minimize the dual [6]. On all problems, we start by running MPLP for 1000 iterations. If the integrality gap is less than 10^{-4}, the algorithm terminates. Otherwise, we alternate between further tightening the relaxation (using either the cycle or triplet method) and running another 20 MPLP iterations, until the problem is solved optimally or a time limit is reached. For the triplet algorithm, we add between 5 and 20 triplets per outer iteration, and for the cycle algorithm, we add from 1 to 5 cycles per outer iteration (we required at least 5 new triplet clusters).

In our experiments we also consider a combination of the two approaches, which we call the "triplet+cycle" method, where we add the clusters found by *both* cycle search algorithms.

Biasing toward short cycles. Whereas previous cluster-pursuit approaches considered clusters of only three or four variables, our algorithm could potentially choose to add a cycle involving a large number of variables. Consequently, the *length* of the cycle added can significantly affect the per-iteration running time. Our algorithm must balance between (a) choosing cycles which most improve the dual objective and (b) keeping the per-iteration running time reasonable.

The length of the cycles found depends both on the initial *choice of the spanning tree* (line 1 of algorithm FindOddCycle, given in Figure 1) and on *which edge is chosen* to create the cycle (lines 5–7). Notice that the length of any cycle returned by FindOddCycle is at most twice the depth of the spanning tree T. We found that using breadth-first search to create the spanning tree results in much more shallow trees, and as a result significantly shorter cycles compared to depth-first search.

After creating the spanning tree and propagating the signs, any edge that has opposite signs on its endpoints could be chosen to create the cycle (lines 5–7). The cycle corresponds to the union of the edge and the paths from each endpoint to their least common ancestor (LCA) in T. We find the lengths of each of these cycles by running a LCA algorithm (we note that this can be done in amortized constant time using the algorithm of [17]). Then, we sort the edges in increasing order according to the length of the corresponding cycles, and return the shortest few.

We also experimented with an algorithm which is guaranteed to find the shortest cycles, but found that its running time was too long to be practical.

6.1 Protein-Protein Interaction

We consider 8 inference problems arising from the relational classification task of protein-protein interaction prediction [5, 8]. This inference problem aims at predicting protein-protein interactions (PPIs) given high-throughput protein-protein interaction and other cellular experimental data. The PPI problems are Markov networks with over 14,000 binary variables denoting the cellular localization of the proteins and whether any particular pair of pro-

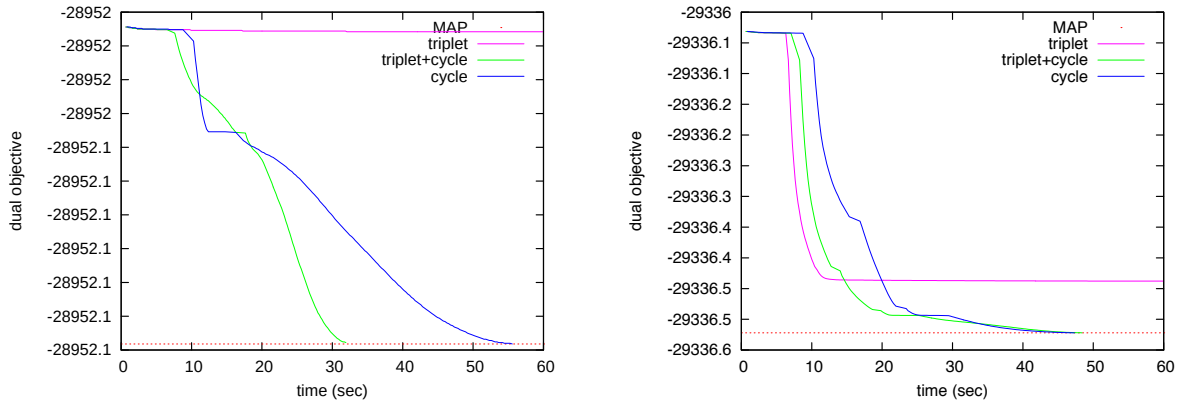

Figure 2: Comparison of the cycle search algorithms on a MAP inference problem from protein-protein interaction prediction. The time shown is for the tightening stage, *after* the initial 1000 iterations of ADLP.

teins interact. The Markov network has over 30,000 node and triad potentials. These inference problems are difficult to solve because the triad potentials induce many frustrated cycles. Each of the 8 inference problems corresponds to the parameters found at some iteration during learning, and the difficulty of inference varies substantially among them.

For 2 of the PPI problems, the cycle method finds the MAP assignment in less than a minute after solving the initial dual to optimality (see Figure 2).[5] For the other 6 problems, the cycle method obtains a slightly better dual objective value than the triplet method when we terminated at half an hour.

In contrast, the triplet method is unable to exactly solve any of the PPI problems. We noticed that the bound criterion [21] for most triplets found in these problems is close to 0, which explains the considerable difficulty for the triplet algorithm to quickly choose the best clusters to add to the relaxation.

These results indicate that the cycle algorithm has a significant advantage over the triplet algorithm on inference problems on sparse graphs.

6.2 Side-Chain Prediction

We next considered 30 protein side-chain placement inference problems, corresponding to the 30 proteins from [25] for which the pairwise LP relaxation is not tight. Previous work has shown that the triplet method exactly solves these [21]. The triplet algorithm's running time ranges from 1.12 to 182.18 seconds with a median of 20.42 seconds.

[5]For the PPI problems MPLP converges very slowly, so we instead use the ADLP algorithm [16] to solve the initial dual, before tightening.

The cycle method also finds the MAP assignment for all 30 proteins. The cycle algorithm's running time is between 2.92 and 3788 seconds, with a median of 24.83 seconds. The outlier which took 3788 seconds to solve was '1kmo'. The cycle method performs significantly worse on this example than the triplet method because the former needs 94 tightening iterations to find the single cluster that solves MAP exactly, whereas the latter finds it immediately.

The cycle algorithm using *only* the k-projection graph does not exactly solve '1qb7' and '1rl6'.[6] We show in Figure 3 the dual objective for '1qb7'. At around 50 seconds the cycle method, not finding any useful cycle with the k-projection graph, runs the partition finding algorithm explained in the supplementary section, finds the necessary cluster, and solves the protein to optimality.

The "triplet+cycle" method solves all of the side-chain placement problems quickly. As seen in Figure 3, it is slightly slower than the triplet method because of the additional time for running the cycle search method. From these results, we conclude that it is best to use both search methods, when feasible.

6.3 Importance of bound criterion

As we mentioned in the related work, for graphical models with binary variables, our cycle search method is similar to the algorithm earlier proposed by Johnson [9]. The key difference is that our approach has a bound criterion which is used to select *which* frustrated cycle to include, whereas Johnson's approach was unweighted (finding *any* odd-signed cycle). In this section we illustrate the importance of having the weighted bound criterion. In addition

[6][20] also needed the full projection graph for '1rl6'.

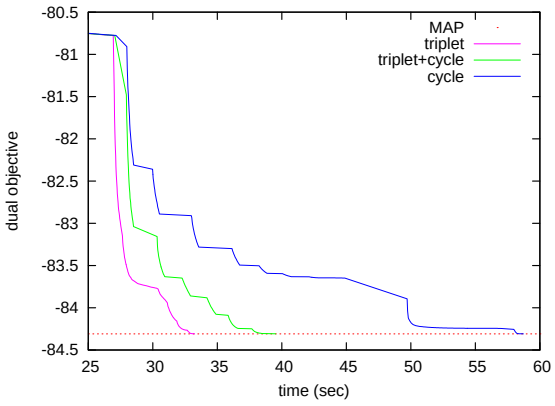

Figure 3: Comparison of all 3 methods on the protein-side chain placement problem '1qb7'.

to the 30 protein side-chain placement problems that we solved exactly, we also consider 4 inference problems arising from stereo vision (all variants of the "Tsukuba" image sequence), which were previously studied by [21, 25].

After finding the optimal value of the bound criterion, R (the threshold used in the binary search, described in Section 3.1), we prune the projection graph to consider only those edges with $|s_{mn}| \geq R/c$ for $c = 1, 4$, and 128. $c = 1$ corresponds to the usual cycle method, whereas $c = 128$ is more similar to an unweighted bound criterion (analogous to [9]).

We considered a protein failed if we could not obtain a certificate within 15 minutes. On the protein side-chain problems, we found that $c = 4$ worked best, solving all proteins but '1kmo' within 3.2 minutes. With $c = 1$, the cycle method additionally failed to solve '1ug6'. With $c = 128$, the cycle method additionally failed to solve '1a8i', '1et9' and '1gsk' (5 failures in total). One reason why $c = 4$ may be preferable over $c = 1$ for non-binary problems is because – since more edges are considered – the cycle method is more likely to find a shorter length cycle which uses each variable only once, rather than multiple times with different partitions.

When testing on stereo vision data, we found that the cycle algorithm was able to solve all 4 problems exactly within 1 hour with $c = 1$, but could not solve any of them within 3 hours for $c = 128$. We conclude that the bound criterion is essential for the cycle method to quickly solve MAP inference problems.

After observing that varying the number of MPLP iterations in each of the outer loops (i.e., after adding cycles) had a very minor effect on the overall running times, we also conclude that the cycle method is robust to the dual not being solved to optimality.

6.4 Summary of results

Using the "triplet+cycle" method, we exactly and quickly solved all 30 protein side-chain problems and 2 protein-protein interaction problems.

The cycle algorithm solved all 4 stereo problems exactly within 24–48 minutes using only 9–33 tightening iterations. The number of clusters added by the algorithm were between 227 and 1217.

7 Discussion

We believe that our algorithm for finding frustrated cycles may also be useful in graphical models that are not sparse. In these settings, dictionary enumeration methods which tighten the relaxation one triplet cluster at a time can eventually succeed at making all cycles consistent. However, the cycle method has several theoretical advantages. First, the dual bound criterion can be zero for some triplet clusters, but non-zero for a larger cycle involving the same variables; we give a concrete example of this in the supplementary material. In these cases, the cycle method would succeed at improving the dual objective, whereas the triplet method would obtain no guidance from the bound criterion and as a result would randomly choose a triplet to use in tightening the relaxation. Second, if a frustrated cycle is long, the triplet method – which adds clusters one at a time – would take several iterations before eventually adding all triplet clusters which triangulate the cycle, thus enforcing cycle consistency. In contrast, the cycle method would take a single iteration.

In this paper, we used the dual variables corresponding to the cycle inequalities only as a means for finding a frustrated cycle, after which we fully enforce cycle consistency. When the variables have a large number of states, enforcing even one cycle consistency constraint can significantly increase the computation time [18]. In these situations, it may be preferable to instead directly do coordinate descent with respect to the cycle inequality dual variables.

Finally, although in this paper we used the dual algorithm as a stand-alone MAP solver, for some problems it may be more effective to use within branch-and-bound, giving a branch-and-cut approach. The efficient cycle search algorithm can also be used together with any method for solving the dual decomposition, such as ADLP [16].

Abstract

Stochastic domains often involve risk-averse decision makers. While recent work has focused on how to model risk in Markov decision processes using risk measures, it has not addressed the problem of solving large risk-averse formulations. In this paper, we propose and analyze a new method for solving large risk-averse MDPs with hybrid continuous-discrete state spaces and continuous action spaces. The proposed method iteratively improves a bound on the value function using a linearity structure of the MDP. We demonstrate the utility and properties of the method on a portfolio optimization problem.

1 Introduction

It is common for decision makers to be risk-averse when uncertainty is involved. For example, risk-averse financial portfolio managers prefer an investment portfolio that mitigates the worst-case plausible losses even if the corresponding expected return is suboptimal. Since the worst-case losses corresponding to solutions that optimize the expected returns can be unacceptable to such decision-makers, there is a need to explicitly model risk-averse objectives. While it is common to use utility functions to capture the decision maker's tolerance of risk, this approach cannot capture many empirically observed risk-averse preferences (e.g. [13]). In addition, decision makers are often unable to provide appropriate utility functions, and non-linear utility functions can complicate the application of dynamic programming [12]. In this paper, we focus on *coherent risk measures*—an alternative model of risk-aversion.

Coherent measures of risk were developed in the field of finance and represent an alternative model of risk-avoidance to utility functions [2, 5]. A coherent risk measure ϱ is a generalization of the risk-neutral expectation operator that maps a random variable X to a real number. Informally, while the risk-neutral expectation computes the average corresponding to a given reference probability distribution, a coherent risk measure takes the worst average assessed over a suitably defined neighborhood around the reference distribution. As such, a coherent risk measure is also interpretable as a conservative way to account for ambiguity in the precise knowledge of the reference distribution. To be a coherent risk measure, the function ϱ must satisfy properties that include convexity and monotonicity, which we describe in detail later.

The properties of coherent risk measures in static settings have been studied extensively and are very well understood [5]. Their application to dynamic settings, in which decisions are taken sequentially as additional stochastic information arrives, is more complicated. Dynamic risk measures have been usually studied in stochastic programming settings which we discuss in Section 6. Recently, dynamic risk measures have been used to formulate risk-averse Markov decision processes [21, 13]. Unfortunately, the methods proposed in these papers only solve small MDPs in which both the states and actions can enumerated. In this paper, we extend the modeling methodology of [21] and [13] to solve structured MDPs with continuous state and action spaces.

To illustrate an MDP with continuous state and action spaces, consider the problem of managing a stock portfolio [11]. In this problem, the decision maker must allocate the investment among a portfolio of stocks in order to maximize the financial gain. The one-step gain of each stock is stochastic, but depends on the current market state; i.e. the distribution of returns is different for volatile and calm markets. The objective is to maximize the expected returns while minimizing the risk of significant losses.

The main components of a Markov decision process are the state and action spaces. For example, the state in

the portfolio management problem is represented by the current position in the stocks and cash, and the state of the market. While the current position may be modeled as a continuous vector, it is common to model the market in terms of a finite set of possible market states [11]. The resulting state space is naturally a hybrid discrete-continuous state space. The actions represent the change in the investments in every period and are also continuous. Because of the continuous aspects of the state and action sets, this problem cannot be solved using the methods proposed in [13]. Large MDPs such as this one are typically solved using approximate dynamic programming, a reinforcement learning method [18]. The method that we propose is related to approximate dynamic programming, but it also exploits the linearity of the domain and the coherent risk measure.

The remainder of the paper is organized as follows. First, Section 2 introduces coherent risk measures and describes their properties in multi-stage optimization. Section 3 then defines risk-averse hybrid linearly controlled MDPs. These problems have both continuous and discrete states, continuous actions, linear transitions, and their objective is formulated in terms of a coherent risk measure. In Section 4, we propose Risk-averse Dual Dynamic Programming (RDDP)—a method to solve hybrid risk-averse MDPs. Our method is related to stochastic dual dynamic programming and point-based methods for solving POMDPs [16]. In Section 5, we evaluate the algorithm on the portfolio management problem and analyze the solution properties. Finally, Section 6 discusses the connections to relevant work on risk-averse objectives in multi-stage stochastic programs.

2 Risk Measures in Markov Decision Processes

In this section, we briefly overview the state of the art in applying risk measures in dynamic settings. We formally define risk-averse Markov decision processes and other necessary notation. We omit some minor technical assumptions needed for continuous state and action sets; refer for example to Sections 4.3 and 4.4 of [19] for the technical details.

A *Markov decision process* is a tuple $(\mathcal{S}, \mathcal{A}, W, P, c)$ defined for time steps $\mathcal{T} = \{0 \dots T\}$ as follows. Let $\mathcal{S}$ be a *compact* state space and $\mathcal{A} \subseteq \mathbb{R}^m$ be a *compact* continuous action space. Let $W : \mathcal{S} \rightrightarrows \mathcal{A}$ denote a measurable set-valued function (or a multimap) that maps each state to the *compact* set of permissible actions and let $P : \mathcal{S} \times \mathcal{A} \to \mathcal{P}(\mathcal{S})$ denote the transition probabilities where $\mathcal{P}(\mathcal{S})$ is the set of all probability measures on $\mathcal{S}$; $P(s, a)$ represents the next-state probability measure for any $s \in \mathcal{S}$ and $a \in \mathcal{A}$. Let $c : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \mapsto \mathbb{R}$ represent the transition cost; $c(s_t, a_t, s_{t+1})$ represents the cost incurred when transiting from s_t to s_{t+1} upon taking action a_t. Finally, let s_0 denote a deterministic initial state. In the final time-step $T + 1$, we assume that there is no action taken and the problem terminates.

The focus of this paper is on *finite*-horizon total return models. The solution of a finite-horizon MDP is a policy which is composed of decision rules. A *decision rule* $d_t : \mathcal{S} \to \mathcal{A}$ at time t determines the action to be taken in each state. A collection of decision rules, one per each time step, is a deterministic Markov *policy* $\pi : \mathcal{T} \times \mathcal{S} \mapsto \mathcal{A}$. The set of all policies is denoted as Π.

The objective in solving risk-neutral MDPs is to minimize the total cost, or *return*, which is defined for $\pi = (d_1, \dots, d_t)$ as:

$$\varsigma(\pi) = \mathbf{E}_{P_\pi}\left[\sum_{t \in \mathcal{T}} c(S_t, d_t(S_t), S_{t+1})\right], \qquad (1)$$

where S_t is a random variable that represents the state at time t, distributed according to the probability distribution P_π induced by the policy π. The optimal return is $\varsigma^\star = \min_{\pi \in \Pi} \varsigma(\pi)$. It is well-known that there exists an optimal Markov deterministic policy, so it suffices to restrict our attention to this class of policies.

Risk averse MDPs have been formalized recently in [21] and [13]. Informally, given a reference probability distribution for each transition, these formulations modify the objective Eq. (1) by specifically penalizing a subset of the most adverse realizations of the induced cost distribution. In particular, the expectation is replaced by a *dynamically consistent* risk measure ϱ. Risk measures that are dynamically consistent can be applied to multistage optimization problems without violating the dynamic programming principle [22].

Assume that the one-step random MDP costs corresponding to action a_t taken at time step t are represented by $\{Z_{t+1}\}_{t \in \mathcal{T}}$ where $Z_{t+1} \in \mathcal{Z}_{t+1}$, and $\mathcal{Z}_{t+1}$ is the space of random variables adapted to the information filtration at time $t+1$, i.e. the history of the underlying stochastic process at time $t+1$. An ordinary risk measure would assign the objective based on the total sum of the costs $\varrho(\{Z_{t+1}\}_{t \in \mathcal{T}}) = \rho(\sum_{t \in \mathcal{T}} Z_{t+1})$. A dynamically consistent risk measure, on the other hand, is defined as a composition of one-step risk mappings:

$$\varrho(Z_1, \dots, Z_{T+1}) = \rho_0\left(Z_1 + \rho_1\left(Z_2 + \dots + \rho_T\left(Z_{T+1}\right)\right)\right).$$

The one-step conditional risk mappings $\rho_t : \mathcal{Z}_{t+1} \to \mathcal{Z}_t$ must satisfy the following properties:

(A1) *Convexity:* $\rho_{t+1}(\alpha \cdot Z + (1-\alpha) \cdot Z') \leq \alpha \cdot \rho_{t+1}(Z) + (1-\alpha) \cdot \rho_{t+1}(Z')$ for all $Z, Z' \in \mathcal{Z}_{t+1}$ and $\alpha \in [0, 1]$.

(A2) *Monotonicity:* If $Z \preceq Z'$ then $\rho_{t+1}(Z) \preceq \rho_{t+1}(Z')$.

(A3) *Translation equivariance:* If $a \in \mathcal{Z}_t$, then $\rho_{t+1}(Z + a) = \rho_{t+1}(Z) + a$.

(A4) *Positive homogeneity:* If $t > 0$, then $\rho_{t+1}(t \cdot Z) = t \cdot \rho_{t+1}(Z)$.

Note that the value $\rho_t(Z)$ is a random variable in $\mathcal{Z}_t$ and the inequalities between random variables are assumed to hold almost surely.

A general dynamically consistent risk measure may be cumbersome to use due to two reasons. The parameters that specify the particular choice of the mapping ρ_t could in general depend on the entire history until time t, and further, the argument on which the mapping applies, namely, Z_{t+1} could in general depend on the entire history until time $t+1$, therefore requiring non-Markov optimal policies. We, therefore, further restrict our treatment to *Markov risk measures* [21].

Markov risk measures require that the parameters that specify the particular choice of the conditional risk mappings ρ_t are independent of the history, given the current state, and further that the mapping operation is also independent of the history, given the current state. This is a natural choice for MDPs because the source of uncertainty is the stochastic transition corresponding to any given state-action pair (s_t, a_t), and the reference probability distribution for this stochastic transition is independent of the history, given the current state. Intuitively, an input to a conditional risk mapping of a Markov risk measure ρ_t is the random variable of the costs incurred during a transition from a state $s_t \in \mathcal{S}$ and the output of the risk mapping is a single number for each s_t.

The simplest example of a conditional risk mapping is the expectation in which case the objective becomes risk-neutral. The risk neutral objective would be:

$$\varrho(Z_1, \ldots, Z_{T+1}) = \mathbf{E}\left[Z_1 + \mathbf{E}\left[\ldots + \mathbf{E}\left[Z_{T+1}\right]\right]\right].$$

A more general risk measure that allows a convenient specification of the appropriate level of risk tolerance is the Average Value at Risk (AV@R$_\alpha$) parameterized at a chosen level $\alpha > 0$ which is defined as [5]:

$$\text{AV@R}_\alpha(Z) = \max_{q \in \mathcal{Q}_\alpha} \mathbf{E}_q[Z] \ , \tag{2}$$

$$\mathcal{Q}_\alpha = \left\{ q : q(\omega) \leq \frac{p(\omega)}{\alpha}, 0 \leq q(\omega) \leq 1, \omega \in \Omega \right\}.$$

Here, Ω is the *finite* sample space and p is a reference distribution which, in our case, is the distribution induced by the transition probabilities. It is easy to see that AV@R$_1(Z) = \mathbf{E}[Z]$ and AV@R$_0(Z)$ is the worst-case (or robust) realization. In plain words, average value at risk is the conditional expectation beyond the α quantile. Average value at risk, therefore, will assign a higher overall cost to a scenario with heavier tails even if the expected value stays the same. Fig. 1 illustrates how a AV@R is computed in comparison with a plain expectation.

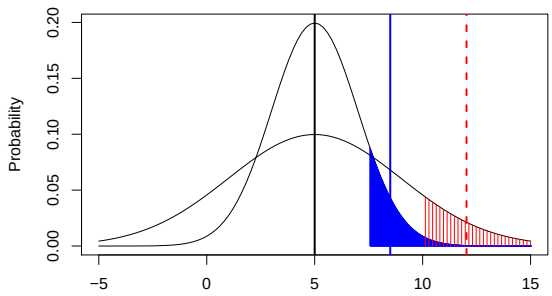

Figure 1: Comparison of two distributions with identical expectations and different AV@R$_{0.1}$ values. The filled-in regions illustrate the quantiles, while the vertical lines indicate the expectations and values at risk.

In the interest of clarity, we concentrate in the remainder of the paper on conditional risk mappings that are a convex combination of average value at risk and expectation and defined as follows:

$$\rho_t(X) = (1-\lambda)\mathbf{E}_p[X] + \lambda\,\text{AV@R}_\alpha(X) \tag{3}$$

We will use the fact that the set $\mathcal{Q}_\alpha$ is polyhedral to derive the algorithms. However, it is well known that any conditional risk mapping that satisfies the assumptions (A1)-(A4) can be represented as:

$$\rho_t(Z) = \sup_{Q \in \mathcal{Q}(s_t, a_t)} \mathbf{E}_Q[Z]$$

where $\mathcal{Q}(s_t, a_t) \subseteq \mathcal{P}(\mathcal{S})$ is a closed bounded convex set of probability measures on $\mathcal{S}$. In addition, when the conditional risk mapping satisfies the *comonotonicity* assumption [5], the set $\mathcal{Q}$ is polyhedral. The proposed algorithm can be, therefore, applied to any dynamically consistent risk measure in which the conditional risk mappings satisfy the comonotonicity assumption.

To derive RDDP, we need yet another representation of AV@R as a minimization linear program. Because the set $\mathcal{Q}_\alpha$ is a polytope, the optimization in Eq. (3) can be written as a linear program. The dual of this linear program yields the following representation:

$$\rho_t(Z) = (1-\lambda)\mathbf{E}_p[Z] + \lambda \begin{bmatrix} \min\limits_{\mu,\xi} & \mu + \dfrac{1}{\alpha} p^\intercal \xi \\ \text{s.t.} & \xi + \mathbf{1}\mu \geq Z \\ & \xi \geq \mathbf{0} \end{bmatrix} \tag{4}$$

The duality we used above for finite spaces can be generalized to more general sample spaces under reasonable technical assumptions [20]. The optimal value of μ corresponds to the quantile of Z at level α.

One attractive property of dynamically consistent risk measures is that they not only model risk aversion, but also preserve most of the structure of MDPs that makes them easy to solve. In particular, there exists an optimal deterministic Markov policy in risk-averse MDPs with Markov risk measures [21], under some mild additional technical assumptions. The additional technical conditions that are needed are the continuity of $P(s_t, \cdot)$ and lower semicontinuity of W and $c(s_t, a_t, s_{t+1})$ with respect to a_t.

It is also possible to define the *value function* in risk-averse MDPs with Markov risk measures. The finite-horizon value function $v_t : \mathcal{S} \to \mathbb{R}$ is defined identically as for the risk neutral case, except the expectations are replaced by a risk measure; that is for some policy π the value function represents the return obtained when starting in a given state. The action-value function $q_\pi : \mathcal{T} \times \mathcal{S} \times \mathcal{A} \mapsto \mathbb{R}$ for a policy π, also known as Q-function [1, 18], represents the value function in a state s *after* taking an action a. The optimal value function is a value function that corresponds to an optimal policy.

The optimal value function in risk-averse MDPs must satisfy the Bellman optimality conditions, which are stated in the following theorem.

Theorem 1 ([21])**.** *A finite-horizon value function $v^\star(t)$ is optimal if and only if it satisfies for all $s \in \mathcal{S}$ and $t \in \mathcal{T}$ the following equality:*

$$v_t^\star(s_t) = \min_{a \in \mathcal{A}} q_t^\star(s_t, a)$$
$$q_t^\star(s_t, a) = \rho_t \left(c_t(s_t, a, S_{t+1}) + v_{t+1}^\star(S_{t+1}) \right).$$

Here, S_{t+1} is a random variable representing the state at $t+1$ distributed according to the transition probability $P(s_t, a)$ and $v_{T+1}(s) = 0$.

We will use RDDP to compute an approximately optimal value function for a risk averse MDP. The actual solution is the greedy policy with respect to this value function. A policy π is *greedy* with respect to a value function q when it is defined for any $s_t \in \mathcal{S}$ at time t as:

$$\pi(s_t) \in \arg\min_{a \in \mathcal{A}} q_t(s_t, a) \ .$$

Using the greedy policy is the most common method of computing a policy from a value function.

This section introduced a very general model for risk-averse Markov decision processes. In the remainder of the paper, Section 3 defines a linear structure of the state and action spaces that is common in some domains, and Section 4 derives RDDP that exploits this structure to efficiently approximate the optimal value function.

3 Hybrid Linearly Controlled Problems

Standard MDP solution methods, such as value or policy iteration, do not scale easily to large or continuous Markov decision processes. Unfortunately, many practical applications involve MDPs with continuously many states and actions. In this section, we describe a specific class of risk averse MDPs with linear transitions and costs that can be solved more efficiently.

Informally, a hybrid linearly controlled problem is an MDP with a state set that has both a discrete and a continuous component. The actions are continuous. The transition probabilities are independent of continuous states and the transitions for continuous states can be described linearly in terms of the continuous states and actions. The following definition describes the problem formally.

Definition 1. *A* hybrid linearly controlled problem *is an MDP $(\mathcal{S}, \mathcal{A}, W, P, c)$ such that:*

- *States $\mathcal{S} = \mathcal{D} \times \mathcal{X}$ where $\mathcal{X} \subseteq \mathbb{R}^n$ is a closed polyhedral set of continuous states and $\mathcal{D}$ is a (small) finite set of discrete states.*
- *Actions $\mathcal{A} \subseteq \mathbb{R}^m$ is a closed convex polyhedral set for some m.*
- *Admissible actions for $(d, x) \in \mathcal{S}$ are restricted by the set-valued map $W : \mathcal{S} \rightrightarrows \mathcal{A}$ defined as:*

  $$W(d, x) = \{a \in \mathcal{A} \ : \ A_d a = b_d - X_d x, l_d \leq a \leq u_d\}.$$

- *Transitions $P : \mathcal{S} \times \mathcal{A} \to \mathcal{P}(\mathcal{S})$ are defined as follows. Assume a* finite *sample space Ω_d for each $d \in \mathcal{D}$ with a given reference probability distribution P_D. Ω_d can be seen as a $d-$specific, one-step finite sample space corresponding to the evolution of an underlying exogenous, stationary, stochastic process. Further, assume the following random variables are specified: $D : \Omega_d \to \mathcal{D}, T_x : \Omega_d \to \mathbb{R}^{n \times n}, T_a : \Omega_d \to \mathbb{R}^{n \times m}, U : \Omega_d \to \mathbb{R}^n$. The mapping D captures the action-independent transition from one discrete state to another in the set $\mathcal{D}$. Now define a random variable:*

  $$X = T_x x + T_a a + U \ .$$

  The mapping X captures the transition from one continuous state to another in the set $\mathcal{X}$ upon taking action a. Both the discrete and continuous state transitions are induced by P_D. In other words, $P((d, x), a)$ is the probability distribution induced by P_D over all (random) pairs (D, X).
- *Cost function $c : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \to \mathbb{R}$ is a linear function in terms of states and actions:*

  $$c(s, a, s') = c((d, x), a, (d', x')) = c_a^\mathsf{T} a + c_x^\mathsf{T} x + c_n^\mathsf{T} x'.$$

For sake of simplicity, we assume that there exists an admissible action for every state (W is non-empty). This is equivalent to the complete recourse assumption, which is common in stochastic programming.

Dynamic Portfolio Management

We now use a portfolio optimization problem—described in [11]—to illustrate the above model of a hybrid linearly controlled system; later we use this model to experimentally evaluate RDDP. The model assumes three risky assets, cash, and a market state. The one-step returns of the risky assets are denoted by a vector $r_t = (r_t^1, \ldots, r_t^3)$ for any time t. In addition, there is assumed to be a risk-free asset—cash—with a constant and known return r^f. All returns are inflation adjusted. The monetary holdings of the assets at time t are denoted by a vector $x_t = (x_t^1, \ldots, x_t^3)$ and the risk-free cash position is c_t. The decision maker decides on trades that are bought (positive) and sold (negative) on a daily basis, which are denoted by $a_t = (a_t^1, \ldots, a_t^3)$. The transaction costs $\kappa(a_t)$ for a trade are proportional and defined as:

$$\kappa(a_t) = \sum_{i=1}^{3} \delta_i^+ \left[a_t^i\right]_+ - \delta_i^- \left[a_t^i\right]_-$$

for some non-negative δ_i^+ and δ_i^-. The asset holdings x_t and cash position c_t evolve according to:

$$x_{t+1}^i = r_{t+1}^i \cdot (x_t^i + a_t^i) \quad \forall i$$
$$c_{t+1} = r^f \cdot (c_t - \mathbf{1}^\mathsf{T} a_t - \kappa(a_t)) \ .$$

The return rates evolve with the state of the market, as we describe below. The goal of the investor is to maximize a function of the total terminal wealth; it is necessary to not only maximize the expected wealth but also account for the associated risk.

The returns for risky assets evolve according to an exogenous stochastic process that is independent of the investor's position. In particular, the market state is a one-dimensional continuous real variable z_t which partially predicts the returns. The market state and the returns evolve linearly with a jointly normally distributed noise as:

$$\begin{pmatrix} \ln r_{t+1} \\ z_{t+1} \end{pmatrix} = \begin{pmatrix} a_r + b_r z_t \\ a_z + b_z z_t \end{pmatrix} + \begin{pmatrix} e_{t+1} \\ v_{t+1} \end{pmatrix} \ , \qquad (5)$$

where the stochastic variables (e_{t+1}, v_{t+1}) are distributed according to a multivariate normal with zero mean and variance Σ for all times. The values $a_r, b_r, a_z, b_z, \sigma$ were estimated from NYSE data for 1927-1996 [11]. Note that r_{t+1} depends only on z_t and is independent of r_t. We describe the values of these variables in more detail in Appendix A.

The one-dimensional market state variable and the market rates transitions are discretized [11, 3]. The market state variable is discretized uniformly to 19 points. The distributions for market rates are then estimated for the discrete grid using Gaussian quadrature methods with 3 points per each dimension (27 total) to precisely match the mean and the variance [10].

The dynamic portfolio optimization problem can then be naturally modeled as a hybrid linearly controlled problem. The state space $\mathcal{S} = (\mathcal{D}, \mathcal{X})$ is factored into discrete states $\mathcal{D} = \{1 \ldots 19\}$ that represent the market state z and continuous states $\mathcal{X} \subset \mathbb{R}^4$ that represent the asset investment and the monetary position. The first three elements of $x \in \mathcal{X}$ represent the asset positions and the last element represents the cash.

The set of actions $\mathcal{A}$ represents the feasible trades $a_t \in \mathbb{R}^3$ for each of the three assets. The cash position is adjusted accordingly, depending on the balance of the trades and transaction costs. The actions are constrained by $W(s)$ in order for the asset and cash positions to remain non-negative as follows:

$$W(d,x) = \left\{ a \quad : \quad \begin{array}{c} x(4) - \mathbf{1}^\mathsf{T} a - \kappa(a) \geq 0 \\ x(i) + a(i) \geq 0 \quad i = 1 \ldots 3 \end{array} \right\} \ .$$

The costs represent the total change in wealth, which is a function of the capital gains and the transaction costs. Formally, for any $(d,x) \in \mathcal{S}$, $a \in \mathcal{A}$, $(d',x') \in \mathcal{S}$ the cost is the reduction in total wealth:

$$c((d,x), a, (d',x')) = \mathbf{1}^\mathsf{T}(x - x') \ .$$

The evolution of the dynamic portfolio optimization is depicted in Fig. 2. The round nodes indicate states, while the square nodes indicate intermediate state-action positions. The solid arrows represent the optimization decisions to rebalance the portfolio and the dashed arrows represent stochastic transitions that determine the next market state and the returns. The figure also indicates at which point the risk mappings are applied.

4 Risk Averse Dual Dynamic Programming

In this section, we describe a new approximate algorithm to solve hybrid linearly controlled problems. This algorithm is loosely based on value iteration but uses the polyhedral structure of the MDP to simultaneously update value functions over a range of states. The method is approximate because it uses simulation to identify the relevant states.

The Bellman optimality equations, as described in Theorem 1, can be easily adapted for the hybrid linearly controlled problem as follows.

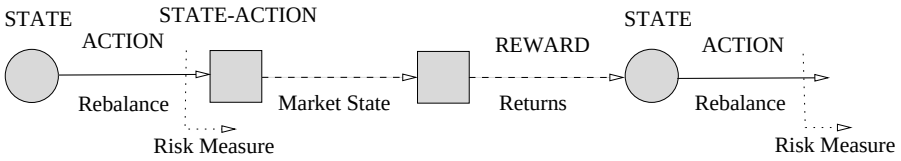

Figure 2: Transitions in the portfolio optimization problem.

Corollary 1 (Bellman optimality condition)**.** *A finite-horizon value function $v^\star(t)$ is optimal if and only if it satisfies for all $s \in \mathcal{S}$ and $t \in \mathcal{T}$ the following equality:*

$$v_t^\star(s_t) = \min_{a \in W(s_t)} q_t^\star(s_t, a) \tag{6}$$

$$q_t^\star(s_t, a) = \rho_t \left(c(s_t, a, S_{t+1}) + v_{t+1}^\star(S_{t+1}) \right) \tag{7}$$

Here, S_{t+1} is a random variable representing the state at time $t+1$ distributed according to the transition probability $P(s_t, a)$ and $v_{T+1}(s_{T+1}) = 0$.

Assume a state $s = (d, x)$ and consider D and X to be random variables representing the next state as in Definition 1. Then Eq. (7), which is in particular a composition of a risk measure with an affine map, can be written as:

$$\begin{aligned} q_t^\star(s,a) &= q_t^\star((d,x),a) \\ &= \rho_t \left(c_a^\mathsf{T} a + c_x^\mathsf{T} x + c_n^\mathsf{T} X + v_{t+1}(D, X) \right) \\ &= \rho_t \big(c_a^\mathsf{T} a + c_x^\mathsf{T} x + c_n^\mathsf{T} T_x x + c_n^\mathsf{T} T_a a + c_n^\mathsf{T} U + \\ &\quad + v_{t+1}(D, T_x x + T_a a + U) \big) \\ &= \rho_t \left(Z_{t+1}(d, x, a) \right) \ , \end{aligned}$$

for the finite vector-valued (random) variable $Z_{t+1}(d, x, a) = c_a^\mathsf{T} a + c_x^\mathsf{T} x + c_n^\mathsf{T} T_x x + c_n^\mathsf{T} T_a a + c_n^\mathsf{T} U + v_{t+1}(D, T_x x + T_a a + U)$, which has dimension $|\Omega_d|$.

To derive RDDP, we now show that the Bellman optimality conditions for linearly controlled hybrid problems can be formulated as a linear program. The optimization variables in the problem correspond to actions and the risk measure. The constraints are a function of the state. Using Eq. (4), it can be readily shown that Eq. (7) a linear program. This representation can then be coupled with the optimization over the action a in Eq. (6) to get the following linear program representation of the Bellman optimality conditions:

$$v_t^\star(d, x) = \left[\begin{array}{ll} \min\limits_{a,\mu,\xi} & (1-\lambda) p_d^\mathsf{T} Z_{t+1}(d, x, a) + \lambda \big(\mu + \frac{p_d^\mathsf{T} \xi}{\alpha} \big) \\ \text{s.t.} & A_d a = b_d - B_d x \\ & l_d \le a \le u_d \\ & \xi + \mathbf{1}\mu \ge Z_{t+1}(d, x, a) \\ & \xi \ge \mathbf{0} \end{array} \right], \tag{8}$$

where p_d is the measure P_D for $d \in \mathcal{D}$. The notation above assumes that random variables are represented as vectors as the following equality illustrates:

$$p_d^\mathsf{T} Z_{t+1}(d, x, a) = \sum_{\omega \in \Omega_d} p_d(\omega) Z_{t+1}(d, x, a, \omega) \ ,$$

where: Ω_d is the *finite* sample space and $Z_{t+1}(d, x, a, \omega) = c_a^\mathsf{T} a + c_x^\mathsf{T} x + c_n^\mathsf{T} T_x(\omega) x + c_n^\mathsf{T} T_a(\omega) a + c_n^\mathsf{T} U(\omega) + v_{t+1}^\star(D(\omega), T_x(\omega) x + T_a(\omega) a + U(\omega))$.

Now, using Eq. (8), it is easy to show the following proposition that describes the structure of value functions.

Proposition 1. *Assuming that $W(s)$ is non-empty for all $s \in \mathcal{S}$, the optimal value function is piecewise affine convex function of x for each $d \in \mathcal{D}$:*

$$v_t^\star(d, x) = \max_{i \in \mathcal{I}_t(d)} \ (q_{x,i}^\mathsf{T} x + q_{c,i}) \ , \tag{9}$$

where $\mathcal{I}_t(d)$ is a finite non-empty set. In addition, the state-action value function $q_t^\star(s, a)$ is piecewise affine convex in a for any $s \in \mathcal{S}$.

Proof. We prove the proposition by a backward induction on t. The proposition holds trivially for v_{T+1} (since $v_{T+1} = 0$). Consider $t = T$. The linear program in Eq. (8) may be simplified as,

$$v_T^\star(d, x) = \left[\begin{array}{ll} \min\limits_{a,\mu,\xi,z} & \lambda \cdot \mu + \sum\limits_{\omega \in \Omega_d} p_d(\omega) \Big((1-\lambda) \cdot z(\omega) + \\ & \quad + \frac{\lambda}{\alpha} \cdot \xi(\omega) \Big) \\ \text{s.t.} & \delta|_1 : \ A_d a = b_d - B_d x \\ & \delta|_2 : \ z(\omega) - (c_a^\mathsf{T} + c_n^\mathsf{T} T_a(\omega)) a = \\ & \quad = (c_x^\mathsf{T} + c_n^\mathsf{T} T_x(\omega)) x + c_n^\mathsf{T} U(\omega) \\ & \delta|_3 : \ l_d \le a, \quad \delta|_4 : \ a \le u_d \\ & \xi(\omega) + \mu - z(\omega) \ge 0, \quad \xi \ge \mathbf{0} \ . \end{array} \right] \tag{10}$$

Due to the assumption of a non-empty and bounded $W(s)$ for all $s \in \mathcal{S}$, the set of extreme points corresponding to the dual polytope of the above linear program is a non-empty, finite set that is independent of x, and depends only on d. Let $\mathcal{I}_t(d)$ denote this finite set. By duality, we have

$$\begin{aligned} v_T^\star(d, x) = \max_{i \in \mathcal{I}_t(d)} \ & \Big(\delta_i|_1^\mathsf{T} (b_d - B_d x) \\ & + \sum_{\omega \in \Omega_d} \delta_i|_2(\omega) \big((c_x^\mathsf{T} + c_n^\mathsf{T} T_x(\omega)) x + c_n^\mathsf{T} U(\omega) \big) . \\ & + \delta_i|_3^\mathsf{T} l_d + \delta_i|_4^\mathsf{T} u_d \Big) \end{aligned}$$

The above expression is indeed a piecewise affine convex function of x, where we may readily identify $q_{x,i}$ and $q_{c,i}$ by algebraically grouping terms that are linear in x and the additive constant, for each i. Thus the proposition is true for $t = T$. Assuming that it is true for any $t+1 \leq T$, we can show next that it is true for t as well.

Now, for any $t < T$, the mathematical optimization in Eq. (8) with the representation of $v^\star_{t+1}$ as in Eq. (9) is the following linear program.

$$
\begin{aligned}
& v^\star_t(d,x) = \\
& \left[\begin{array}{ll}
\min\limits_{\substack{a,\mu,\\ \xi,z,y}} & \lambda\cdot\mu + \sum\limits_{\omega\in\Omega_d} p_d(\omega)\Big((1-\lambda)\cdot z(\omega) + \\
& \qquad + \dfrac{\lambda}{\alpha}\cdot\xi(\omega)\Big) \\
\text{s.t.} & \delta|_1:\ A_d a = b_d - B_d x \\
& \delta|_2:\ z(\omega) - (c_a^\mathsf{T} + c_n^\mathsf{T} T_a(\omega))a = \\
& \quad = (c_x^\mathsf{T} + c_n^\mathsf{T} T_x(\omega))x + c_n^\mathsf{T} U(\omega) + y(\omega) \\
& \delta|_3:\ l_d \leq a, \quad \delta|_4:\ a \leq u_d \\
& \delta|_5:\ y(\omega) - q_{x,j}^\mathsf{T} T_a(\omega) a \geq q_{x,j}^\mathsf{T}\cdot \\
& \quad \cdot\big(T_x(\omega)x + U(\omega)\big) + q_{c,j} \\
& \qquad \forall j \in \mathcal{I}_{t+1}(D(\omega)) \\
& \xi(\omega) + \mu - z(\omega) \geq 0, \quad \xi \geq \mathbf{0}\ .
\end{array}\right]
\end{aligned}
\tag{11}
$$

The constraint family indexed by $\delta|_5$ is a consequence of the induction hypothesis, where $y(\omega)$ is an auxiliary variable that captures $v^\star_{t+1}(D(\omega), X(\omega))$. A similar argument using duality for Eq. (11) gives:

$$
\begin{aligned}
v^\star_t(d,x) = \max_{i\in\mathcal{I}_t(d)} \Big(& \delta_i|_1^\mathsf{T}(b_d - B_d x) + \\
& + \sum_{\omega\in\Omega_d} \delta_i|_2(\omega)\big((c_x^\mathsf{T} + c_n^\mathsf{T} T_x(\omega))x + c_n^\mathsf{T} U(\omega)\big) + \\
& + \delta_i|_3^\mathsf{T} l_d + \delta_i|_4^\mathsf{T} u_d + \\
& + \sum_{\substack{\omega\in\Omega_d,\\ j\in\mathcal{I}_{t+1}(D(\omega))}} \delta_i|_5(\omega,j)\cdot\big(q_{x,j}^\mathsf{T}(T_x(\omega)x + U(\omega)) + \\
& + q_{c,j}\big)\Big),
\end{aligned}
\tag{12}
$$

thereby giving a piecewise affine convex function of x for $v^\star_t(d,x)$. □

Note that the convex representation in Eq. (9) has an exponentially large number of pieces in general, and is not usable in its exact form. The algorithm we propose, RDDP, takes advantage of the piecewise linear representation of the optimal value function to approximate it efficiently. This method is related to value iteration; it iteratively grows an approximation of the large set $\mathcal{I}_t(d)$ by adding one element in each step. Fortunately, it is not necessary to compute the optimal value function to get a good policy—a good value function will suffice. We propose an algorithm that approximates the value function from below by using only a subset of $\mathcal{I}_t(d)$. The algorithm is summarized in Algorithm 1.

In particular, we identify the relevant linear pieces of each value function by successively refining *lower bounds* on the value function. Because the representation as shown in Eq. (9) is convex, a subgradient inequality of the function may be readily derived at any (d,x) which will serve as a lower bound. The following proposition summarizes this property.

Proposition 2. *Consider $v^\star_t(d,x)$ described as in Proposition 1, and let $\hat{x} \in \mathcal{X}$ be any fixed continuous component of the hybrid state. For any chosen value d, let $\delta_{\hat{i}}$ be the corresponding optimal dual solution of Eq. (11), where $\hat{i} \in \mathcal{I}_t(d)$, and $f^\star(\hat{x})$ be the corresponding optimal objective value. Then: $e_x^\mathsf{T} x + e_c \leq v^\star_t(d,x)$ where:*

$$
\begin{aligned}
e_x^\mathsf{T} &= -\delta_{\hat{i}}^\star|_1^\mathsf{T} X_d + \sum_{\omega\in\Omega_d}\big(\delta_{\hat{i}}^\star|_2(\omega) c_n^\mathsf{T} T_x(\omega)\big) \\
&\quad + \sum_{\substack{\omega\in\Omega_d,\\ j\in\mathcal{I}_{t+1}(D(\omega))}} \big(\delta_{\hat{i}}^\star|_5(\omega,j) q_{x,j}^\mathsf{T} T_x(\omega)\big) \\
e_c &= f^\star(\hat{x})\ .
\end{aligned}
$$

In addition, with such lower bounds added in Algorithm 1, we are guaranteed to converge to the optimal value function.

Proof. The lower bounding inequality for $v^\star_t(d,x)$ follows directly from the subgradient of the convex value function as established in Proposition 1. It is a direct consequence of Eq. (12), since $\hat{i} \in \mathcal{I}_t(d)$. In particular, starting with an empty set $\mathcal{J}_t(d)$ as our approximation for $\mathcal{I}_t(d)$, at each time step we iteratively improve $\mathcal{J}_t(d)$ by adding an additional element $\hat{i}$. The convergence to the optimal solution follows because the scenario tree that represents all T-step realizations of the uncertainty is finite. Then, using backward induction, finite termination of the algorithm can be readily shown. □

5 Empirical Results

In this section, we present numerical results of RDDP on the portfolio optimization domain described in Section 3. The results not only demonstrate the utility of RDDP in modeling and solving risk-averse MDPs but also illustrate the properties of risk-averse behavior in portfolio optimization. Please note that it is impractical to solve the portfolio optimization problem using discretization since the state-actions space is 8-dimensional. Even with a moderate discretization with 8 points per each dimension, computing the value of the risk measure Eq. (2) for all states and actions

involves a linear program with $8^8 * 19 * 27 \approx 9 \cdot 10^9$ variables; here 19 and 27 represent the number of transitions.

We start by evaluating RDDP convergence in a risk-neutral setting; it is easy to evaluate the quality of such a policy by simulation. The policy computed by RDDP for this objective is simple: it always invests the full wealth in the small-cap stock which has the highest expected value. As Proposition 2 shows, RDDP updates a guaranteed lower bound on the optimal value function in each iteration. Because this is a minimization problem, a lower bound on the value function corresponds to an upper bound on the total wealth. Fig. 3 shows the convergence of the lower bound for the consecutive iterations of RDDP. The figure compares the upper bound with simulated returns for 5 time steps and 3000 runs for each policy. The results show that the bound converges close to the optimal solution in 10 iterations. Each iteration involves solving 100 linear programs in Eq. (11).

The opposite of the risk-neutral formulation is the worst-case—or robust—formulation with $\lambda = 1$ and $\alpha = 0$. The robust formulation essentially corresponds to replacing the expectation over the outcomes by the worst case value. The optimal solution in this setting is to invest the entire wealth in cash, which has a constant return and RDDP converges to it in a single iteration. While the worst-case solution is easy to compute, it is hard to evaluate its value by simulation. This is because one needs to sample all realizations to find the worst one.

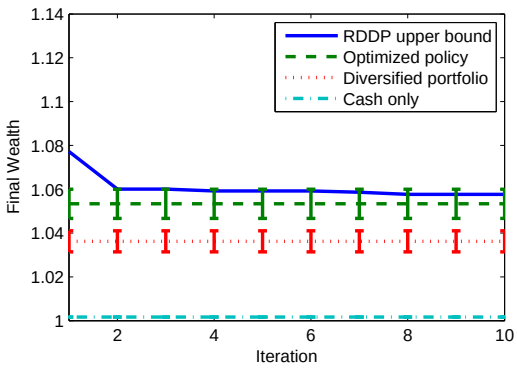

Figure 3: Simulated returns and an upper bound computed by RDDP. The confidence bounds correspond to 2 standard deviations.

Finally, we evaluate a mildly risk-averse solution with $\lambda = 0.2$ and $\alpha = 0.7$. Given this objective, the decision maker optimizes the expected return with a weight of 80% and the 70% tail expectation with a weight of 20%. The solution computed for this risk-averse objective invests in a mix of cash and the small-cap stock that depends on the market state. There is no investment in large or medium-cap stock.

Fig. 4 compares the investment value for risk neutral and averse solutions. The investment for the risk-averse solution is 90% in cash and 10% in small-cap stop; the fractions are reversed for the risk-neutral solution. The value of the risk-neutral solution increases with market state because the expected return of stocks increases with higher volatility. The value of the risk averse solution increases for calm market states (1-5) but decreases with higher market volatility as the portfolio mix becomes more biased towards cash. The value function the decreases sharply when the volatility is high because of trading fees charged when rebalancing towards cash.

The risk-averse solution achieves an average return of about 0.6%, which is much lower than 5.4% for the risk neutral solution. However, the variance of the risk-averse solution is close to 0 and the return is about 5 times greater than the return of pure cash investment 0.1%. RDDP also efficiently optimizes the dynamically consistent risk measure reducing the lower bound by a factor of 26.9 in the first three iterations.

It is interesting to compare the RDDP solution to existing methods for solving portfolio optimization problems. The risk aversion in previous work was modeled by a concave utility function and the solutions were heuristics based on frictionless models [11, 3].

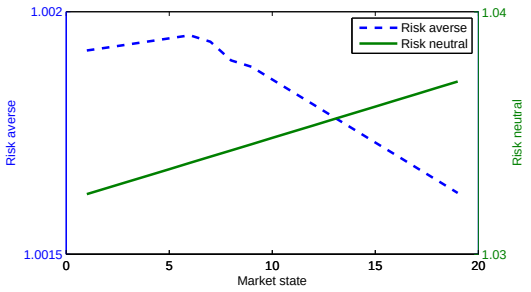

Figure 4: Value of investment as a function of the market state (negated value function). Market volatility increases with increasing state.

The utility-based risk aversion, coupled with the assumption of no transaction fees, led to diversification of the portfolio between middle and large capitalization stocks. On the other hand, the RDDP solution with the AV@R risk measure prefers diversification into cash to other stocks. Future work will need to address whether this difference is due to different risk objectives or different approximation techniques used to compute the solutions.

6 Related Work and Discussion

In this section, we discuss connections between RDDP and related work in both stochastic programming and artificial intelligence communities. Large or continuous risk-neutral MDPs, such as the hybrid linearly controlled problems, are often solved by approximate dynamic programming or reinforcement learning. Approximate dynamic programming overcomes the large size of these problems by restricting value functions to a small linear space [18]. We are not aware, however, of any approximate dynamic programming methods that optimize risk-averse objectives. RDDP is similar to approximate dynamic programming, except the features are constructed automatically using the special structure of the problem. As a result, RDDP is easier to apply to compatible problems, but is less general because it cannot be applied to non-linear problems.

RDDP is also related to stochastic dual dynamic programming (SDDP). SDDP is an approximate method for solving large multistage linear programs with certain independence assumptions [14, 15, 22].Some of these methods have been extended to risk averse objectives [9, 6, 17, 7]; although they typically assume a different independence structure from the proposed linearly controlled problems.

In a parallel stream of work on risk-averse optimization, models with polyhedral risk measures have been studied [4, 8]. Unlike the Markov risk measures, polyhedral risk measures are not dynamically consistent, but must satisfy other properties that make the resulting problems easy to solve.

7 Conclusion

The paper describes RDDP, a new algorithm for solving Markov decision processes with risk averse objectives and continuous states and actions. We model the risk-aversion using dynamically consistent convex risk measures, which is an established approach in stochastic finance. Our experimental results on a portfolio optimization problem indicate that RDDP can be converge quickly to a close-to-optimal solution for both risk-averse and risk-neutral objectives. Our risk averse solutions also provide new insights into the properties of risk-aversion in the portfolio optimization setting.

While the focus of this paper is on a financial application, there are numerous other domains that exhibit similar linear properties, such as stochastic inventory management, or hydrothermal energy management. The portfolio optimization problem represents a good benchmark, because it is relatively simple to describe and fit to real data, and a similar structure can be found in many domains that involve optimal utilization of finite resources.

One significant weakness of RDDP is that the convergence criterion is not well defined and risk-averse objectives may be hard to evaluate by simulation. It is not hard, however, to remedy both these issues. Using the convexity of the optimal value function and the lower bound computed by RDDP, it is also possible to compute an upper bound on the value function based on Jensen's inequality. The difference between the upper and lower bounds then provides a reliable stopping criterion and an empirical value of a policy.

A Numerical Values

The values $a_r, b_r, a_z, b_z, \sigma$ were estimated from NYSE data for 1927-1996 [11]. Table 1 summarizes the regression coefficients a_r, b_r, a_z, b_z and Table 2 summarizes the covariance of the noise σ. The risk-free return on cash is $r_f = 1.00042$. The initial market state is $z_0 = 0$.

Abstract

A market-maker-based prediction market lets forecasters aggregate information by editing a consensus probability distribution either directly or by trading securities that pay off contingent on an event of interest. Combinatorial prediction markets allow trading on any event that can be specified as a combination of a base set of events. However, explicitly representing the full joint distribution is infeasible for markets with more than a few base events. A factored representation such as a Bayesian network (BN) can achieve tractable computation for problems with many related variables. Standard BN inference algorithms, such as the junction tree algorithm, can be used to update a representation of the entire joint distribution given a change to any local conditional probability. However, in order to let traders reuse assets from prior trades while never allowing assets to become negative, a BN based prediction market also needs to update a representation of each user's assets and find the conditional state in which a user has minimum assets. Users also find it useful to see their expected assets given an edit outcome. We show how to generalize the junction tree algorithm to perform all these computations.

1 INTRODUCTION

Prediction is a fundamental task for AI systems. There is strong theoretical and empirical support for the superiority of ensemble forecasts over individual forecasts (Solomonoff, 1978). While weighted forecasts are theoretically optimal, it has been surprisingly difficult to beat a simple unweighted average. Prediction markets have emerged as a simple and robust way to give high-performing forecasters more influence on the aggregated forecast. Not only do prediction markets typically out-perform both individual human forecasters and naïve unweighted averages (c.f., Chen and Pennock 2010), they show promise as an information combination method for machine aggregation as well. Barbu and Lay (2011) show that combining machine learners with prediction markets often outperforms top ensemble predictors like Random Forest on UCI datasets. A key advantage is that "the market mechanism allows the aggregation of specialized classifiers that participate only on specific instances." That is, learners can opt to bid only on cases they understand. So while most prediction markets use only human traders, they need not. Indeed, smart traders use algorithms, and Nagar and Malone (2011) provide strong evidence that human-machine combinations outperform either: machines do well when the rules hold, while humans recognize "broken leg" situations where they don't.

We focus on market-scoring-rule systems which create prediction markets from the sequential application of proper scoring rules, sidestepping impossibility theorems that apply to simultaneous aggregation of forecasts (Hanson, 2003; Chen and Pennock, 2010). Independent of whether traders are human and/or machine, we address the question of how to make the market itself more expressive by allowing combinatorial trades. While traditional prediction markets ignore dependencies among events, combinatorial prediction markets explicitly consider and exploit dependencies among base events. As Chen and Pennock (2010) argue:

> Why do we need or want combinatorial-outcome markets? Simply put, they allow for the collection of more information. Combinatorial outcomes allow traders to assess the correlations among base objects, not just their independent likelihoods, for example the correlation between Democrats winning

in Ohio and Pennsylvania.

We prove some new results regarding combinatorial prediction markets and report on an implementation using Bayesian networks.

1.1 PREDICTION MARKETS

Prediction markets make probabilistic forecasts by allowing participants to trade contingent assets. Prices in such a market can be interpreted as probabilities: if an asset paying \$1 contingent on event E is currently selling for \$0.75, then the current market probability of E is 75%. Prediction markets are an increasingly popular way to aggregate information and judgments from groups (Tziralis and Tatsiopoulos, 2007). Traders self-select to speak on the topics they think they know best. Those with more knowledge achieve greater influence by acquiring more assets, and market prices inform everyone of trader information.

In a market-maker-based prediction market, an automated trader stands ready to buy or sell assets on any relevant event. The prices it offers can be seen as a current trader consensus on the probabilities of those events, and trades can be seen as edits of consensus probabilities. In a logarithmic market scoring rule based (LMSR-based) prediction market, the market maker varies its price exponentially with the quantity of assets it sells. Tiny trades are fair bets at the consensus probabilities (Hanson, 2003). Larger trades change the consensus probabilities; we call such trades "edits." Users make edits in an attempt to maximize assets, thereby forming a consensus distribution that aggregates information from all market participants.

1.2 COMBINATORIAL PREDICTION MARKETS

In a combinatorial prediction market, one can trade on any event that can be specified as a combination (e.g. 'and' or 'or') of a base set of events. A market-maker-based combinatorial prediction market, therefore, declares a complete consistent probability distribution over a combinatorial space of events, and lets participants edit any part of that distribution. In a combinatorial LMSR-based market, users can make conditional bets that satisfy intuitive independence properties. For example, letting "$\neg$" denote "not", a trader who increases the value of $p(A|B)$ gains if B and A occur and loses if B and $\neg A$ occur. Such an edit changes neither $p(B)$ nor $p(A|\neg B)$ and the trader neither gains nor loses if $\neg B$ occurs (Hanson, 2007).

With a large set of base events, the number of event combinations becomes astronomical, making it intractable in general to compute market prices and trades. In particular, it is in general NP-hard to maintain correct LMSR prices across an exponentially large outcome space (Chen et al., 2008a).

One way to achieve tractability is to limit the complexity of the consensus probability distribution by using a factored representation of the joint distribution. Examples include Bayesian networks (BNs) and Markov networks, which admit standard algorithms to efficiently compute conditional marginals and perform evidential updating (e.g. Pearl 1988; Jensen 1996; Shachter et al., 1990). Graphical models are widely used in many applications, often achieving tractable inference in networks with thousands of variables.

Bayesian networks have been used to represent joint distributions in prediction markets. Chen et al. (2008b) used a BN to represent prices in a tournament, and Pennock and Xia (2011) used a BN to represent probabilities in a LMSR-based combinatorial prediction market.

Pennock and Xia (2011) proved that probabilities can be updated in polynomial time for edits which do not violate the conditional independence assumptions of a decomposable BN of fixed treewidth. However, they do not show how to accomplish two other tasks that are important in practical prediction markets. They do not show how to let traders reuse assets purchased in previous trades to pay for new trades. They also do not show how to calculate a trader's expected assets to see if the trader is already 'long' or 'short' on an issue before making an edit.

1.3 REUSING ASSETS

In the LMSR framework of Pennock and Xia (2011), each edit takes the form of a participant paying cash to a market maker to obtain an event contingent asset, which pays cash if a certain event happens. A trader who has run out of cash is not permitted to make any more trades. Yet the assets one has obtained from prior trades are often sufficient to guarantee many more trades. For example, suppose a user buys an asset "Pays \$10 if A," and then later buys an asset "Pays \$10 if $\neg A$." Because one of these assets is guaranteed to pay off, the two assets are together worth \$10 in cash, and could be used to support future purchases. However, in a naïve implementation, this \$10 is unnecessarily tied up until the truth-value of A is resolved. While we might imagine that a system could easily notice the guaranteed payoff and trade those assets in for cash, it would be difficult to notice more complex combinations of trades worth a guaranteed amount of cash.

In a market that allows conditional trades, a consensus probability $p(A|B) = x$ corresponds to a market

price of $\$x$ for a trade that pays \$1 if events B and A both occur, pays nothing if B and $\neg A$ both occur, and is called off (returning the purchase price to the user) if $\neg B$ occurs. Although Pennock and Xia (2011) do not use conditional securities, conditional probabilities are established by trading securities that depend on joint states. A consensus probability $p(A|B) = x$ corresponds to a market price of $\$x$ to purchase two separate securities, one paying \$1 if B and A both occur and the other paying $\$x$ if $\neg B$ occurs.

Now, suppose a user wants to trade on event A given N mutually exclusive conditions B_i, where the current market probabilities are $p(A|B_i) = x_i, i = 1 \ldots N$. Without asset reuse, such a user would have to purchase N separate pairs of assets, where the i^{th} pair costs $\$x_i$ and pays \$1 if A and B_i occur, 0 if $\neg A$ and B_i occur, and x_i if $\neg B_i$ occurs. The total purchase price of $\sum x_i$ would be tied up until one of the B_i occurred, although the collection of assets is guaranteed to pay off at least $\sum \$x_i - \max\{\$x_i\}$. If N is large and the probabilities are non-negligible, a considerable sum could be unnecessarily tied up.

1.4 OUR CONTRIBUTIONS

In order to be able to reuse assets, we first need to represent the user's assets in a form that allows efficient computation to find the minimum asset state after the user's edits. Further, a factored representation of assets will provide significant savings in space and improve efficiency of asset management. In this paper, we show how to exploit the junction tree to efficiently maintain a representation of a trader's state-dependent assets, i.e., for each state the final cash this trader would hold if this state were revealed in the end to be the actual state. We also show how to use these data structures to efficiently find the largest amount by which the user could raise or lower the probability of an event of interest, before the change might result in the trader holding negative assets in some state. Keeping edits within these limits ensures that traders can reuse assets while never 'going broke.' Asset reuse enables more efficient information aggregation (i.e., users can make more trades before running out of assets) for a given amount of assets.

A trader about to make an edit also usually finds it useful to know whether she is 'long' or 'short' on the issue she is about to trade. For example, a user editing the value of $p(A|B)$ might like to know whether she should currently expect to gain more if B and A happens, or if B and $\neg A$ happens. Learning that she already stands to gain more if A and B happens should make a risk-averse trader more reluctant to raise the value of $p(A|B)$, thereby acquiring more such assets. In this paper we show how to efficiently maintain a representation of each trader's expected assets, where the expectation is with respect to the market consensus probabilities. We also show how to efficiently calculate the conditional expectations relevant for being 'long' or 'short' on a given edit.

The key word here is "efficiently". Existing combinatorial implementations follow the naïve joint-state enumeration described by Hanson (2007), and are therefore limited to at most about 20 related binary variables. Pennock and Xia (2011) proved that one can use Bayesian networks for combinatorial prediction markets. However, they treat an inverse system where assets are easy to calculate and prices are the bottleneck. Further, they did not have an implementation of their method. We use a single Bayesian (or Markov) network for representing the market probability distributions, stored as clique potentials in the associated junction tree. Further, we prove that assets can be represented using the same factorization as the joint distribution. Thus, our method maintains a parallel junction tree data structure for each user's assets. We describe algorithms for updating these asset junction trees when users make edits. Asset factorization is an important advance in space and computational efficiency. We have developed a complete MATLAB implementation and a partial Java implementation of our algorithms. To our knowledge, ours is the first published implementation of BN-based combinatorial prediction markets.

Although arbitrary graphical probability models are of course intractable, in this paper we show how to adapt the junction tree algorithm to perform the desired computations in models whose treewidth is not too large. It follows trivially that for a fixed treewidth, complexity is polynomial in the number of variables and linear in the number of simultaneous edits. This is a major improvement over existing naïve implementations, which are equivalent to a fully-connected graph and therefore exponential in the number of variables. We describe numerical experiments that demonstrate the anticipated exponential savings in space and time for given bounds on treewidth.

Organization of this paper: The next section states our definitions and notation. Section 3 briefly describes relevant work on Bayesian networks and the junction tree algorithm. Section 4.3 presents our probability and asset updating algorithm. In Section 5, we first walk through the algorithm using a simple 3-node BN model. We then examine the scalability of our algorithm in a simulation study. Sections 6 and 7 provide discussion and conclusion.

2 DEFINITIONS AND NOTATION

Capital letters such as A, B_i, X denote random variables. Bold capital letters (e.g., $\mathbf{A}, \mathbf{B}_i, \mathbf{X}$) denote vectors of random variables. Corresponding lowercase letters (e.g., $a, b_i, x, \mathbf{a}, \mathbf{b}_i, \mathbf{x}$) denote particular instantiations of the random variables. Unless stated otherwise, symbols p and ϕ denote probability distributions and likelihoods respectively. $\mathcal{B}$ represents a BN, $\mathcal{T}$ the corresponding clique tree, and $\mathbb{C}, \mathbb{S}$ the set of cliques and set of separators, respectively. The conditional probability distribution of X given Y is denoted by $p(X|Y)$. For a Bayesian network on random variables $\mathbf{X} = \langle X_1, X_2, \ldots, X_n \rangle$, we use $Pa(X_i)$ to denote the parents of X_i in the directed acyclic graph corresponding to the BN. Thus, the conditional probability distribution (CPD) of the random variable X_i is denoted by $p(X_i|Pa(X_i))$. We denote negation with "$\neg$", so $(X = \neg x) \equiv (X \neq x)$.

Each user u has an asset value $S_{\mathbf{x}}$ associated with each joint outcome $\mathbf{x}$. When necessary to index assets by user, we add a superscript, $S^u_{\mathbf{x}}$. The expected assets $\bar{S}$ for user u is the user's net worth:

$$\bar{S}^u = \sum_{\mathbf{x} \in \Omega} p(\mathbf{x}) S^u_{\mathbf{x}} \tag{1}$$

where Ω is the Cartesian product of the state spaces of all random variables. We denote the cardinality of the joint state space by $L = |\Omega|$.

3 PRELIMINARIES

If we represent the prediction market's probability distribution as a Bayesian network, then edits in the prediction market correspond to soft evidence on variables in the Bayesian network (see Section 3.1 below), and probability updating can be done using standard algorithms. Allowable edits are determined by the user's assets, and in particular that state which has the fewest assets for the edit being considered. We show below that the same junction tree can be used to represent a factorization of both probabilities and assets. The minimum asset state can be found by using min-propagation in the asset junction tree. That can be done is a consequence of a theorem by Dawid (1992) showing that min-propagation works for any function of the probabilities in a junction tree. We use this fact in Section 4.3.

A Bayesian network $\mathcal{B}$ factors the joint distribution for the random vector $\mathbf{X}$ into a product of local distributions:

$$p(\mathbf{x}) = \prod_{1 \leq k \leq n} p(X_k = x_k | \mathbf{X}_{Pa(X_k)} = \mathbf{x}_{Pa(X_k)})$$

This factorization in turn can be compiled into an undirected tree structure called a junction tree. The junction tree is composed of cliques and separators, such that p is the product of all clique marginal distributions divided by the product of all separator marginal distributions:

$$p(\mathbf{x}) = \frac{\prod_{c \in \mathbb{C}} p_c(\mathbf{x}_c)}{\prod_{s \in \mathbb{S}} p_s(\mathbf{x}_s)}. \tag{2}$$

Here, $\mathbf{x}_c$ and $\mathbf{x}_s$ denote the states of the variables in clique c and separator s, respectively, and p_c and p_s are the marginal distributions for the clique and separator variables, respectively. The junction tree algorithm (Lauritzen and Spiegelhalter, 1988) uses this transformation to perform exact inference on the BN. We note that although we focus on BNs, our algorithms apply equally well to any representation that can be compiled into a junction tree.

3.1 SOFT EVIDENCE & BELIEF UPDATING

General BN inference computes the posterior distribution given observations, also known as hard evidence. In prediction markets, we need to update market distributions given user edits that revise some non-extreme p to another non-extreme p' on variables. That is, evidence from user edits is in general uncertain. The literature considers two kinds of uncertain evidence. *Soft* evidence specifies a new probability distribution of the variable regardless of its previous distribution (Koski and Noble, 2009; Langevin and Valtorta, 2008; Valtorta et al., 2002), whereas *virtual* evidence, also known as *likelihood* evidence, represents the relative likelihood of the evidence given the true state. These likelihood values do not necessarily sum to 1 over all states. Virtual evidence is often implemented as observations on a hidden "dummy" node as the child node of the node on which virtual evidence is specified. In our case, we implement user edits as soft evidence. We use $\phi(X)$ to denote soft evidence on variable X. Usually, soft evidence on a single variable can be implemented as virtual evidence (Pearl, 1990), allowing standard junction tree inference algorithms to apply.

In our prediction market, a user edits the probability that the target variable T is in one of its states t, for example, changing $p(T = t) = a$ into $p(T = t) = b$. We then assign $1 - b$ to T's other states in proportion to their previous probabilities, and represent this edit

as soft evidence on T. Similarly, if the user would like to edit $p(T = t|\mathbf{A} = \mathbf{a})$ conditional on the values of other variables $\mathbf{A} = \mathbf{a}$, we represent this conditional edit as conditional soft evidence. An unconditional edit corresponds to an empty assumption set $\mathbf{A} = \emptyset$.

3.2 MIN-CALIBRATION OF JUNCTION TREE

In the standard junction tree algorithm for discrete BNs, marginalization is done by summing out variables. When we replace summation with maximization in the propagation algorithm, a max-calibrated junction tree with max potentials for all cliques will be returned. It is then straightforward to find the configurations over all states with maximum joint probability based on these max-potentials. Similarly, min-calibration of the junction tree can be performed by replacing summation with minimization, and the minimum probability configuration can be found accordingly. Further, Dawid (1992) proved that min/max-calibrations are valid for functions on the potentials. We will use this fact to find the boundary conditions for a user's assets, thus allowing asset reuse while preventing the possibility of assets going negative.

4 PROBABILITY AND ASSET UPDATING ALGORITHM

Once again, any edit in the prediction market is implemented by asserting soft evidence in the corresponding BN. We use the junction tree inference algorithm to update the consensus joint probability distribution after each edit. Then we use LMSR as the market maker to update the user's assets accordingly. We assume a market trading on purely discrete variables and so the representing BN is a purely discrete network. After updating, each clique in the junction tree maintains the correct joint distribution of variables in the clique.

A given user has assets $S_{\mathbf{x}}$ associated with every joint state $\mathbf{x}$ of the domain variables. LMSR dictates that assets change in proportion to the log of the ratio of probabilities:

$$\Delta S_{\mathbf{x}} = b \ln \frac{p'(\mathbf{x})}{p(\mathbf{x})},$$

where $p'(\mathbf{x})$ is the new probability for the joint state $\mathbf{x}$ arising from the user's edit, $p(\mathbf{x})$ is the previous probability, and b is a constant defining the unit of currency. Allowed changes must respect the rule that the minimum across all states of the user's assets must not be allowed to drop below zero, i.e., $\min_x S_x \geq 0$. After an edit to the consensus distribution, the asset data structure changes for the user making the edit; the asset data structures for all other users remain unchanged.

4.1 ASSET FACTORIZATION

It is convenient to define a transformation $q(\mathbf{x})$ of the assets $S_{\mathbf{x}}$, such that

$$S_{\mathbf{x}} = b \ln(q(\mathbf{x})). \tag{3}$$

We then have

$$\frac{q'(\mathbf{x})}{q(\mathbf{x})} = \frac{p'(\mathbf{x})}{p(\mathbf{x})}, \tag{4}$$

where $q(\mathbf{x})'$ is the updated asset for joint state $\mathbf{x}$, corresponding to the probability change $p'(\mathbf{x})$. The derivation is:

$$\begin{aligned} S'_{\mathbf{x}} &= S_{\mathbf{x}} + \Delta S_{\mathbf{x}} \\ &= S_{\mathbf{x}} + b \ln \frac{p'(\mathbf{x})}{p(\mathbf{x})} \\ &= b \ln(q(\mathbf{x})) + b \ln \frac{p'(\mathbf{x})}{p(\mathbf{x})} \\ &= b \ln(q'(\mathbf{x})) \end{aligned}$$

$$\Rightarrow b \ln(q'(\mathbf{x})) = b \ln(q(\mathbf{x})) + b \ln \frac{p'(\mathbf{x})}{p(\mathbf{x})}$$

$$\Rightarrow \ln(q'(\mathbf{x})) - \ln q(\mathbf{x}) = \ln \frac{p'(\mathbf{x})}{p(\mathbf{x})}.$$

Therefore, the identity $\ln a - \ln b = \ln a/b$ establishes Equation (4).

To interpret b, note that if the user changes the probability at state $\mathbf{x}$ from $p(\mathbf{x})$ to $p'(\mathbf{x}) = 1$ and $\mathbf{x}$ turns out to be true, the user gains $\Delta S_{\mathbf{x}} = -b \ln p(\mathbf{x})$. The maximum possible gain is therefore $-b \ln p(\mathbf{x}_*)$, where $\mathbf{x}_*$ is the minimum probability state. If all states start out equally likely, i.e., $p(\mathbf{x}) = 1/L$ for all $\mathbf{x}$, then the maximum gain to users, and the maximum loss to the market maker, is $b \ln L$, where L is the total number of states. Therefore to bound losses to be no more than M, we usually initialize all market states to be equally likely at the start of trading and set $b = M/\ln L$.

Because q starts out independent of the state and changes in proportion to changes in p, we can decompose q in a similar manner to the decomposition of p, shown in Equation (2). Specifically,

$$q(\mathbf{x}) = \frac{\prod_{c \in \mathbb{C}} q_c(\mathbf{x}_c)}{\prod_{s \in \mathbb{S}} q_s(\mathbf{x}_s)}, \tag{5}$$

where q_c and q_s are local asset components defined on the clique and separator variables, respectively. Notice the similarity to (2). This factored representation for assets is preserved long as edits are confined to variables in the same clique, i.e., trades are *structure preserving* (Pennock and Xia, 2011). This allows us to do all calculations locally in every clique and separator, because Equation (4) is valid for the joint space of

each clique and separator. Namely, we can establish the same junction tree structure for the assets q and make local updates when edits occur. When there is a probability edit, we propagate the soft evidence in the junction tree to obtain the correct probability update for every clique and separator. For structure preserving trades, assets can be updated simply by choosing a clique c containing the variables being traded and multiplying $q_c(\mathbf{x}_c)$ by the probability ratio:

$$q'_c(\mathbf{x}_c) = q_c(\mathbf{x}_c)\frac{p'_c(\mathbf{x}_c)}{p_c(\mathbf{x}_c)}. \quad (6)$$

Combining this with Equation (5) gives the same result as Equation (4). However, we usually do not need to compute global assets q for each possible joint state. For space and computational efficiency, a representation of the user's assets is stored locally in cliques of the asset junction tree. This asset junction tree is used to compute the minimum asset value and its associated state, as well as the expected value user's expected assets.

To ensure that the user's assets remain non-negative in all states, we must place limits on the edits a user is allowed to make. Equivalently, no edit may allow the transformed assets q as defined in Equation (3) to become less than 1. We must find the limits on edits beyond which the probability change will result in negative assets in some state. Let us assume that the user is editing $p(T = t|\mathbf{A} = \mathbf{a})$, denoted as p^t, to $p^\#$. Let m_t denote her current minimum q given $(\mathbf{A} = \mathbf{a}, T = t)$. Let $m_{\neg t}$ denote her current minimum q given $(\mathbf{A} = \mathbf{a}, T \neq t)$. If $(\mathbf{A} = \mathbf{a}, T = t)$ occur after the edit, we have to ensure that the updated minimum $q^\#$ remains greater than 1. That is:

$$q^\# = m_t\frac{p^\#}{p^t} \geq 1.$$

Then

$$p^\# \geq \frac{p^t}{m_t}.$$

Similarly, if $(\mathbf{A} = \mathbf{a}, T \neq t)$ occurs after the edit, the updated minimum assets q^u must remain greater than 1. That is:

$$q^u = m_{\neg t}\frac{1-p^\#}{1-p^t} \geq 1.$$

It follows that

$$p^\# \leq 1 - \frac{1-p^t}{m_{\neg t}}.$$

Summarizing the above results, the allowable edit range for $p(T = t|\mathbf{A} = \mathbf{a})$ is:

$$\left[\frac{p(T = t|\mathbf{A} = \mathbf{a})}{m_t}, 1 - \frac{1 - p(T = t|\mathbf{A} = \mathbf{a})}{m_{\neg t}}\right]. \quad (7)$$

Note that the minimum assets can be found by min-calibration over the asset junction tree, as mentioned in Section (3.2).

For every user, we maintain a separate asset junction tree in which the affected clique is updated only after this particular user makes an edit. Edits made by a given user will have no effect other users' assets. But because every edit changes the market probability, we update market distribution after each edit accordingly (where the updates are stored as clique potentials of the junction tree).

4.2 EXPECTED VALUE / SCORE

A user typically wants to know the expected value of her assets given the current market consensus prices. If she is contemplating an edit to event A, she would want to know what her expected assets will be if A happens and if $\neg A$ happens. These expectations can be calculated efficiently given the factorization represented in the junction tree. The expected score is obtained as follows (recall that c indexes cliques and s indexes separators).

$$\bar{S} = \sum_c \sum_{x_c} S_c(\mathbf{x}_c)p_c(\mathbf{x}_c) - \sum_s \sum_{x_s} S_s(\mathbf{x}_s)p_s(\mathbf{x}_s), \quad (8)$$

where

$$S_c(\mathbf{x}_c) = b\ln(q_c(\mathbf{x}_c)), \quad (9)$$

and

$$S_s(\mathbf{x}_s) = b\ln(q_s(\mathbf{x}_s)). \quad (10)$$

This result is derived as follows. First, we substitute (5) into (3) and then substitute (9) and (10) into the result to obtain the following expression for $S_\mathbf{x}$:

$$S_\mathbf{x} = \left[\sum_c S_c(\mathbf{x}_c) - \sum_s S_s(\mathbf{x}_s)\right]. \quad (11)$$

Next, we substitute (11) into (1), suppressing the superscript u, to obtain:

$$\begin{aligned}\bar{S} &= \sum_x p(\mathbf{x})\left[\sum_c S_c(\mathbf{x}_c) - \sum_s S_s(\mathbf{x}_s)\right] \\ &= \sum_c \sum_x S_c(\mathbf{x}_c)p(\mathbf{x}) - \sum_s \sum_x S_s(\mathbf{x}_s)p(\mathbf{x}).\end{aligned}$$

Letting $\mathbf{x}_{\neg c}$ and $\mathbf{x}_{\neg s}$ denote the states of the variables not in clique c and separator s, respectively, we obtain:

$$\begin{aligned}\bar{S} &= \sum_c \sum_{\mathbf{x}_c} S_c(\mathbf{x}_c) \sum_{\mathbf{x}_{\neg c}} p(\mathbf{x}) - \sum_s \sum_{\mathbf{x}_s} S_s(\mathbf{x}_s) \sum_{\mathbf{x}_{\neg s}} p(\mathbf{x}) \\ &= \sum_c \sum_{x_c} S_c(\mathbf{x}_c)p_c(\mathbf{x}_c) - \sum_s \sum_{x_s} S_s(\mathbf{x}_s)p_s(\mathbf{x}_s),\end{aligned}$$

which establishes (8). Further, let

$$\bar{S}_c = \sum_{x_c} S_c(\mathbf{x}_c) p_c(\mathbf{x}_c),$$

and

$$\bar{S}_s = \sum_{x_s} S_s(\mathbf{x}_s) p_s(\mathbf{x}_s).$$

Then for brevity, we can write

$$\bar{S} = \sum_c \bar{S}_c - \sum_s \bar{S}_s.$$

Clearly, the values $\bar{S}_c$ and $\bar{S}_s$ represent local expected scores for cliques and separators, respectively. This local score decomposition demonstrates once again the beauty of factorization.

4.3 PROBABILITY AND ASSET UPDATING ALGORITHM

To summarize our procedure for updating probabilities and assets, please see Algorithm 1. The algorithm maintains a consensus probability distribution and an asset structure for each user. The probability distribution and the asset structures factor according to the same junction tree. After each edit, the assets of the user making the edit and the consensus distribution are updated.

Algorithm 1 Update probability and user assets for a BN representing a combinatorial prediction market

Require: a BN model $\mathcal{B}$ over a set of domain variables $\mathbf{X}$ that represents the combinatorial prediction market joint distribution, the clique tree $\mathcal{T}$ corresponding to $\mathcal{B}$, consisting of cliques $\mathbb{C}$ and separators $\mathbb{S}$.

Require: The current market probability distribution p represented by a probability junction tree.

Require: The current assets q for user u represented by an assets junction tree.

for each conditional edit p' on the target variable $T = t$ with assumptions $\mathbf{A} = \mathbf{a}$ by user u: **do**

- Tell the user the expected scores $\bar{S}(T = t, \mathbf{A} = \mathbf{a})$ and $\bar{S}(T \neq t, \mathbf{A} = \mathbf{a})$ indicating the user's long/short status.
- Calculate the edit limits for $p(T = t|\mathbf{A} = \mathbf{a})$ using Equation (7).
- Allow user to trade $p'(T = t|\mathbf{A} = \mathbf{a})$ within the edit limits. And apply $p'(T = t|\mathbf{A} = \mathbf{a})$ as soft evidence to the junction tree.
- Update probability distributions of cliques and separators to be $p'_c,\ p'_s,\ c \in \mathbb{C}, s \in \mathbb{S}$ by calling the junction tree inference algorithm.
- Find the clique c containing target variable T and assumed variables $\mathbf{A}$, and update the assets clique corresponding to c using Equation (6).

end for

return User's expected assets after the edit; user's min-q value and its associated min-q states.

5 NUMERICAL EVALUATION

5.1 TEST CASES FOR *BN-DEF*

We developed a complete MATLAB implementation for our algorithm using BNT (Murphy, 2001) and currently we are developing a Java implementation in UnBBayes (Matsumoto et al., 2011). Our implementation requires the target variable and all assumed (conditioning) variables to belong to the same clique. Cross-clique conditioning is possible, but requires approximations (see Section 6).

In this section, we illustrate how the algorithm works using the simple 3-node BN model *BN-DEF*, shown in Figure 1. The CPDs for nodes in *BN-DEF* are shown in the picture next to the corresponding nodes. This network has only two cliques $\{D, E\}$ and $\{D, F\}$. We work through the algorithm, showing intermediate results.

We begin by initializing q to be 100 for every cell in the asset tables. The scale parameter b is specified as $10/\ln(100)$, making the initial asset score 10 for every state for all users. We imagine two users, Joe and Amy, making successive edits.

Joe's first edit - Suppose Joe thinks the current market probability of $E = e1$ (0.65) is not reasonable, and wants to increase it. Since this will be his first trade, his initial uniform q makes his current position neutral because both min-q values given $E = e1$ and $E \neq e1$ are equal to 100. Using Equation (7), we calculate his edit limits on $E = e1$ to be $[0.0065, 0.9965]$. Based on his private information, Joe chooses 0.8 as the new $p(E = e1)$. The market distribution is then updated such that marginal probabilities of D, E, F are now $[0.58, 0.42], [0.8, 0.2]$, and $[0.22, 0.78]$ respectively. Joe's expected assets are $\bar{S} = 10.12$, and his min-q is 57.14 at two min-states - $\{d2, e2, f1\}$, and $\{d2, e2, f2\}$.

Amy's first edit - Now Amy is interested in changing $p(D = d1|F = f2)$, which due to Joe's edit is currently 0.52. Again, since this will be Amy's first trade, she has neutral positions. Using Equation (7), we find her edit limits on $D = d1$ given $F = f2$ to be $[0.0052, 0.9952]$. Suppose Amy wants to move the probability to 0.7. Now, the market distribution is updated such that the marginal probabilities of D, E, F are now $[0.72, 0.28]$, $[0.85, 0.15]$, and $[0.22, 0.78]$ respectively. Note that F is unaffected – it was assumed. Amy's expected assets are $\bar{S} = 10.11$, and her min-q is 62.54 at two min-states - $\{d2, e1, f2\}$, and $\{d2, e2, f2\}$. Note that Amy's edit does not affect any other users' asset data.

Joe's second edit - Let us now consider an extreme edit example. Joe comes back and wants to see what will happen if he makes a big move on $p(E = e1|D = d2)$ (currently equal to 0.59). First of all, Joe finds that he has a long position for this trade since his $\bar{S}(E = e1, D = d2) = 10.45$, and $\bar{S}(E \neq e1, D = d2) = 8.79$. Second, his edit limits returned by the algorithm are $[0.0048, 0.9928]$. If he decides to move $p(E = e1|D = d2)$ to 0.99, then the marginal probabilities of D, E, F can be updated to $[0.72, 0.28]$, $[0.96, 0.04]$ and $[0.22, 0.78]$, respectively. Joe's expected assets after this trade are $\bar{S} = 10.67$, and his min-q is 1.39 at two min-states - $\{d2, e2, f1\}$, and $\{d2, e2, f2\}$. Note that in this case, Joe's min-q is very close to the threshold.

5.2 SCALABILITY STUDY

To investigate scalability, we first tested our algorithms on randomly generated networks of varying sizes. Our random networks were generated using BN-Generator 0.3 (Ide et al., 2004). We varied the number of variables from 30 to 960 and the treewidth bound from 5 to 20. For each combination of number of variables and the treewidth, three random BNs were generated. All random variables were binary. For each randomly generated network, we calculated the system lock time, defined as the CPU time required to update the probability distribution after an edit is confirmed by the user. While the system is locked, new edits have to be rejected or queued; thus lock time is a key performance metric. We ran this test on our Java implementation. Although not fully complete, the Java implementation performs probability updating, the part of the calculation required to determine the system lock time.

Figure 2 shows the results of our scalability study. As is well known, the complexity of the junction tree algorithm – and therefore the maximum lock time – is polynomial in the treewidth. We can see from the figure that the system can easily handle binary networks

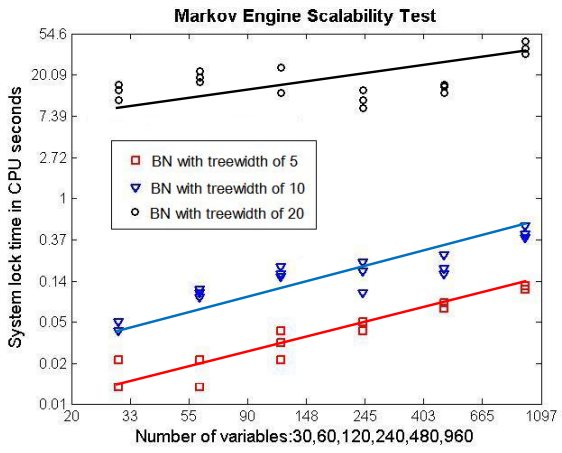

Figure 2: Edit Lock Time versus Network Size

of treewidth 10, but performance begins to degrade noticeably with treewidth 20. The algorithm is not very sensitive to increases in the number of variables when the treewidth is held constant.

We also investigated another key performance parameter, the potential rejection rate under different market environments, modeled by frequency of edits. As noted above, edits attempted while the system is locked may have to be rejected. For this study, we used ALARM (Beinlich et al., 1989), a 37-node BN with treewidth of 4 often used as a benchmark for graphical model algorithms. We chose ALARM because its size and treewidth are at the upper end of the range we expect for our live combinatorial prediction market. The objective of this test is to investigate how our approach performs with frequent edits by multiple users.

We simulated a market with 100 participants, and expected edits of 2/minute, 8/minute, and 30/minute, assuming a Poisson distribution for edit arrivals. For comparison, on Super Tuesday, InTrade had 18,629 trades from 780 unique users, for an average of 13 trades per minute. Prediction market trades are quite lumpy in both questions and time; we think our figures span a plausible range. The system lock time for ALARM is 0.3 seconds in our MATLAB implementation. We did not implement enhancements such as lazy propagation (Madsen and Jensen, 1998) that would give further edit-dependent reductions in lock time. 1000 edits were simulated by randomly chosen users from 100 market participants, given randomly chosen assumed variables and betting on randomly chosen target variable from randomly chosen cliques among the 27 cliques of ALARM's junction tree. If the randomly chosen clique had more than 3 variables, we then randomly chose two variables with their randomly chosen

states to be assumed values on which the edit was conditioned. Inter-arrival times between edits were modeled by exponentially distributed variables with means of 2, 7.5 and 30 seconds respectively, representing market intensities of 30, 8 and 2 edits per minute, correspondingly. Table 1 presents the average number of rejects and the rejection rates for our experiments.

Table 1: ALARM: Simulation Results for 1000 Edits

Market Intensity	Average rejects	Average rejection rate
2 edits/minute	11.3	1.2%
8 edits/minute	39.2	4%
30 edits/minute	142.6	14.3%

In this network, the system could sustain an arrival rate of 8 edits/minute (11,520/day) with less than a 5% rejection rate. By queuing edits and rejecting only those whose terms have become worse for the user, this can be at least halved. A compiled language would be much faster for all the non-matrix operations, and with a good choice of library, not much slower at matrix operations.

6 NON STRUCTURE-PRESERVING EDITS

When we have conditional edits such that the target variable and the assumed variables are not in the same clique, then the edits are not structure preserving. In that case, if we keep our sparser structure, then the minimum KL-distance approximation to the true posterior distribution will be the one that has the same marginal distributions for all the cliques (Darwiche, 2009).

7 CONCLUSION AND FUTURE WORK

In this paper, we describe a method to update both the probabilities and assets in a combinatorial prediction market. The approach uses a junction tree compiled from the associated Bayesian network to represent the consensus probability distribution, and a structurally identical junction tree to represent each participant's assets. Allowable edits are calculated using min-propagation in the assets junction tree, and an allowable edit is chosen. The probability distribution is updated by applying soft evidence to the (shared) probability junction tree, and propagating. Assets are updated by simple multiplication in a single clique, without requiring a separate propagation. We developed a complete implementation of our algorithm and demonstrated its scalability by performing computational experiments on randomly generated BNs with varying sizes from 30 to 960 variables, and treewidth of 5 to 20. Further, we conducted a simulation study to illustrate the robustness of our method under varying market environments. Test results show that the system performs well for networks with treewidth of up to 10, and can sustain a simulated market with expected arrival rate of 8 edits/minute with less than 5% rejection rate.

Future work will measure the computational savings (or increase in network size) compared to a more straightforward combinatorial prediction market algorithm. We also plan use this technique in an online forecasting system, and to examine the tradeoff between a minimum-KL approximation (which may confuse users) and a less accurate but simpler set of assumptions.

Abstract

Cardinality potentials are a generally useful class of high order potential that affect probabilities based on how many of D binary variables are active. Maximum a posteriori (MAP) inference for cardinality potential models is well-understood, with efficient computations taking $\mathcal{O}(D \log D)$ time. Yet efficient marginalization and sampling have not been addressed as thoroughly in the machine learning community. We show that there exists a simple algorithm for computing marginal probabilities and drawing exact joint samples that runs in $\mathcal{O}(D \log^2 D)$ time, and we show how to frame the algorithm as efficient belief propagation in a low order tree-structured model that includes additional auxiliary variables. We then develop a new, more general class of models, termed *Recursive Cardinality models*, which take advantage of this efficiency. Finally, we show how to do efficient exact inference in models composed of a tree structure *and* a cardinality potential. We explore the expressive power of Recursive Cardinality models and empirically demonstrate their utility.

1 Introduction

Probabilistic graphical models are widely used in machine learning due to their representational power and the existence of efficient algorithms for inference and learning. Typically, however, the model structure must be restricted to ensure tractability. To enable efficient *exact* inference, the most common restriction is that the model have low tree-width.

A natural question to ask is if there are other, different restrictions that we can place on models to ensure tractable exact or approximate inference. Indeed, a celebrated result is the ability of the "graph cuts" algorithm to exactly find the maximum a posteriori (MAP) assignment in any pairwise graphical model with binary variables, where the internal potential structure is restricted to be submodular. Along similar lines, polynomial-time algorithms can exactly compute the partition function in an Ising model if the underlying graph is planar (Fisher, 1961).

Extensions of these results have been a topic of much recent interest, particularly for the case of MAP inference. Gould (2011) shows how to do exact MAP inference in models with certain higher order terms via graph cut-like algorithms, and Ramalingham et al. (2008) give results for multilabel submodular models. Tarlow et al. (2010) provide efficient algorithms for a number of other high-order potentials.

Despite these successes in finding the optimal configuration, there has been relatively less progress in efficient high order marginalization and sampling. This partially stems from the difficulty of some of the computations associated with summation in these models. For example, computing the partition function for binary pairwise submodular models (where graph cuts can find the MAP) is #P-complete, so we do not expect to find an efficient exact algorithm.

One important high-order potential where such hardness results do not exist is the cardinality potential, which expresses constraints over the number of variables that take on a particular value. Such potentials come up in natural language processing, where they may express a constraint on the number of occurrences of a part-of-speech, e.g., that each sentence contains at least one verb. In computer vision, a cardinality potential might encode a prior distribution over the relationships between size of an object in an image and distance from camera. In a conference paper matching system, cardinality potentials could enforce a requirement that e.g. each paper have 3-4 reviews and each reviewer receive 8-10 papers.

A simple form of model containing a cardinality potential is a model over binary variables, where the model probability is a Gibbs distribution based on an energy function consisting of unary potentials θ_d and one cardinality potential $f(\cdot)$:

$$-E(\boldsymbol{y}) = \sum_d \theta_d y_d + f(\sum_d y_d) \quad (1)$$

$$p(\boldsymbol{y}) = \frac{\exp\{-E(\boldsymbol{y})\}}{\sum_{\boldsymbol{y}'} \exp\{-E(\boldsymbol{y}')\}}, \quad (2)$$

where no restrictions are placed on $f(\cdot)$. We call this the *standard cardinality potential model*. Perhaps the best-known algorithm in machine learning for computing marginal probabilities is due to Potetz and Lee (2008); however, the runtime is $\mathcal{O}(D^3 \log D)$, which is impractical for larger problems.

We observe in this paper that there are lesser-known algorithms from the statistics and reliability engineering literature that are applicable to this task. Though these earlier algorithms were not presented in terms of a graphical modeling framework, we will present them as such, introducing an interpretation as a two step procedure: (i) create auxiliary variables so that the high order cardinality terms can be re-expressed as unary potentials on auxiliary variables, then (ii) pass messages on a tree-structured model that includes original and auxiliary variables, using a known efficient message computation procedure to compute individual messages. The runtime for computing marginal probabilities with this procedure will be $\mathcal{O}(D \log^2 D)$. This significant efficiency improvement over the Potetz and Lee (2008) approach makes the application of cardinality potentials practical in many cases where it otherwise would not be. For example, exact maximum likelihood learning can be done efficiently in the standard cardinality potential model using this formulation.

We then go further and introduce a new high order class of potential that generalizes cardinality potentials, termed Recursive Cardinality (RC) potentials, and show that for balanced RC structures, exact marginal computations can be done in the same $\mathcal{O}(D \log^2 D)$ time. Additionally, we show how the algorithm can be slightly modified to draw an exact sample with the same runtime. We follow this up by developing several new application formulations that use cardinality and RC potentials, and we demonstrate their empirical utility. The algorithms are equally applicable within an approximate inference algorithm, like loopy BP, variational message passing, or tree-based schemes. This also allows fast approximate inference in multi-label models that contain cardinality potentials separately over each label.

Finally, we show that cardinality models can be combined with a tree-structured model, and again assuming a balanced tree, exact inference can be done in the same $\mathcal{O}(D \log^2 D)$ time (for non-balanced trees, the runtime is $\mathcal{O}(D^2)$). This leads to a model class that strictly generalizes standard tree structures, which is also able to model high order cardinality structure.

2 Related Work

2.1 Applications of Cardinality Potentials

Cardinality potentials have seen many applications, in diverse areas. For example, in worker scheduling programs in the constraint programming literature, they have been used to express regulations such "each sequence of 7 days must contain at least 2 days off" and "a worker cannot work more than 3 night shifts every 8 days" (Régin, 1996). Milch et al. (2008) develop cardinality terms in a relational modeling framework, using a motivating example of modeling how many people will attend a workshop. In error correcting codes, message passing-based decoders often use constraints on a sum of binary variables modulus 2 (Gallager, 1963). Another application is in graph problems, such as finding the maximum-weight b-matching, in which the cardinality parameter b constrains the degree of each node in the matching (Huang & Jebara, 2007), or to encode priors over sizes of partitions in graph partitioning problems (Mezuman & Weiss, 2012).

More recently, cardinality potentials have become popular in language and vision applications. In part-of-speech tagging, cardinalities can encode the constraint that each sentence contains at least one verb and noun (Ganchev et al., 2010). In image segmentation problems from computer vision, they have been utilized to encourage smoothness over large blocks of pixels (Kohli et al., 2009), and Vicente et al. (2009) show that optimizing out a histogram-based appearance model leads to an energy function that contains cardinality terms.

2.2 Maximization Algorithms

As noted previously, there is substantial work on performing MAP inference in models containing one or more cardinality potentials. In these works, there is a division between methods for restricted classes of cardinality-based potential, and those that work for arbitrary cardinality potentials. When the form of the cardinality potential is restricted, tractable exact maximization can sometimes be performed in models that contain many such potentials, e.g., Kohli et al. (2009); Ramalingham et al. (2008); Stobbe and Krause (2010); Gould (2011). A related case, where maximization can only be done approximately is the "pattern potentials" of Rother et al. (2009). For arbitrary functions of counts, the main approaches are that of Gupta et al. (2007) and Tarlow et al. (2010). The former gives

a simple $\mathcal{O}(D \log D)$ algorithm for performing MAP inference, and the latter gives an algorithm with the same complexity for computing messages necessary for max-product belief propagation.

2.3 Summation Algorithms

Relatively less work in the machine learning community has examined efficient inference of marginal probabilities in models containing cardinality potentials. The best-known approach is by Potetz and Lee (2008) (here PL). Also related is the line of work including de Salvo Braz et al. (2005) and Milch et al. (2008), but these works assume restrictions on unary potentials, and it is not clear that they are efficient in the case where there are many distinct unary potentials.

PL works with potentials $\theta(\boldsymbol{y}; \boldsymbol{w}) = f(\boldsymbol{y} \cdot \boldsymbol{w})$, where $\boldsymbol{y}$ and $\boldsymbol{w}$ are real-valued vectors. This is a general case that is more involved than cardinality potentials, requiring a clever strategy for representing messages, e.g., with adaptive histograms. However, if $\boldsymbol{y}$ is binary and $\boldsymbol{w}$ is the all-ones vector, then $f(\cdot)$ is a standard cardinality potential.

The starting point for PL is to to write down the expression for a sum-product message from f to, say, the last variable y_D:

$$m_{fD}(y_D) = \sum_{\boldsymbol{y} \setminus \{y_D\}} \left[f(\sum_d y_d) \prod_{d' \neq D} m_{d'f}(y_{d'}) \right]. \quad (3)$$

Next, PL defines a change of variables into a new set of integer-valued variables, $\boldsymbol{z}$, as follows:

$$z_1 = y_1 \qquad z_2 = z_1 + y_2 \qquad \ldots \qquad z_{D-1} = z_{D-2} + y_{D-1}.$$

Eq. (3) can then be expressed in terms of $\boldsymbol{z}$ as $\sum_{\boldsymbol{z} \setminus \{z_d\}} \Big[f(y_D + z_{D-1}) \prod_{d' \neq d} m_{d'f}(z_{d'} - z_{d'-1}) \Big]$.[1] Finally, the sums can be pushed inwards as in variable elimination, and the internal sums can be computed from inside outwards naively in time $\mathcal{O}(D^2)$. There are D summations to perform, so computing one message takes $\mathcal{O}(D^3)$ time. As observed by Felzenszwalb and Huttenlocher (2004) and noted by PL, the internal sums can be performed via FFTs in $\mathcal{O}(D \log D)$ time. Computing all D messages or marginals, then, requires $\mathcal{O}(D^3 \log D)$ time.

3 Other Summation Algorithms

Here, we review lesser-known work from the statistics and reliability engineering literature, where efficient algorithms for very similar tasks have been developed.

The idea of a recursive procedure that sums configurations in a chain-structure i.e. by using a definition of z variables similar to that of PL, dates back at least to Gail et al. (1981). In this work, the algorithmic challenge is to compute the probability that exactly k of D elements are chosen to be on, given that elements turn on independently and with non-uniform probabilities. Naively, this would require summing over $\binom{D}{k}$ configurations, but Gail et al. shows that it can be done in $\mathcal{O}(Dk)$ time using dynamic programming.

A similar task is considered by Barlow and Heidtmann (1984) and Belfore (1995) in the context of reliability engineering. The task considered computing the probability that exactly k elements are chosen to be on, or the probability that between k and l elements are chosen to be on. Belfore gives a divide-and-conquer algorithm that recursively calls an FFT routine, leading to an $O(D \log^2 D)$ algorithm. This algorithm is very similar to the approach we take in this work, and in the case of ordinary cardinality potentials (i.e. not RC potentials), it is equivalent to the upward pass of message passing that we will present in Section 5.

Finally, there is work in statistics on Poisson-Binomial (PB) distributions, which are the marginal distributions over cardinalities that arise if we have a model that contains only unary potentials. These distributions have been used in several applications in the statistics literature. We refer the reader to Chen and Liu (1997) and references therein for more details on applications.

One algorithm for computing the cumulative distribution function (CDF) of the PB distribution that uses an FFT was proposed in Fernandez and Williams (2010) and analyzed by Hong (2011). The idea is to first compute the characteristic function of the distribution, and then directly apply the inverse FFT in order to recover the CDF. The benefit of this approach is that the FFT only needs to be applied once, however computing the characteristic function still takes $\mathcal{O}(D^2)$ time.

For further discussion of other algorithms similar to the ones discussed above, we recommend Hong (2011) and references therein.

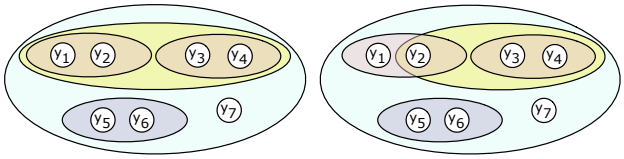
4 Recursive Cardinality Potentials

4.1 Model Structure

The first contribution in this paper is to generalize the structure of the cardinality potential to the Recursive Cardinality potential. Recursive Cardinality potentials are defined in terms of a set of subsets $\mathcal{S}$ of a set of D binary variables. The joint probability over vector $\boldsymbol{y}$ is defined as

$$p(\boldsymbol{y}) \propto \prod_{s_k \in \mathcal{S}} f_k(\sum_{y_d \in s_k} y_d), \quad (4)$$

[1] For notational convenience, assume we have $z_0 = 0$.



(a) Nested (b) Not nested

Figure 1: Examples of nested and non-nested subsets.

where the only constraint is that $\mathcal{S}$ is *nested*, as illustrated in Fig. 1. We call a set of subsets $\mathcal{S}$ nested if for every pair of subsets in $\mathcal{S}$, either they are disjoint or one is a subset of the other. Each f_k can be arbitrary, and different per k. By defining subsets over single variables, we can represent unary potentials, so we do not explicitly separate them out here.

This new construction extends the standard cardinality potential to handle multiple scales, ranging from purely local (e.g., for a pair of variables) to global, and potentially including all scales in between.

4.2 Example Cardinality Potentials

Cardinality potentials can be applied in diverse ways in order to capture a variety of interesting properties. Here we give some examples, and note that this list is far from exhaustive.

4.2.1 Ordinary Cardinality Potentials

Noisy-OR: Consider a set of D binary variables $\boldsymbol{y}$ along with a single binary variable t that depends on $\boldsymbol{y}$: $P(t=1|\boldsymbol{y}) = 1-(1-\epsilon)\prod_{d=1}^{D}(1-\lambda_d)^{y_d}$. For the special case where each λ_d is equal, we can represent this as a conditional model with a cardinality potential:

$$P(t=1|\boldsymbol{y}) = 1-(1-\epsilon)(1-\lambda)^{\sum_{d=1}^{D} y_d} \qquad (5)$$

This is simply a function of $\sum_d y_d$, and can therefore be viewed as a cardinality potential.

Smoothness and Competition: Note that even unimodal cardinality potentials have interesting properties. A convex cardinality potential is related to smoothness: it will tend to favor configurations where all of the variables are either on together or off together. In a similar manner, a concave function will cause competition amongst the binary variables.

4.2.2 Recursive Cardinality Potentials

Group and structured sparsity: By placing a cardinality potential over subsets of variables consisting of a uniform distribution over counts (or any general distribution) along with a spike at 0, one can represent the preference that variables should tend to turn off together in groups. Indeed, one can represent hierarchical sparsity using a recursive model. This gives an interesting alternative to the traditional approaches of ℓ_0 and ℓ_1 priors, as well as their group counterparts that are commonly used in structured sparsity (Zhao et al., 2006).

Hierarchical CRFs: A common approach to image segmentation in the computer vision literature is to construct a hierarchy of increasingly coarse segmentations, then to perform the segmentation jointly at the different levels of coarseness. To enforce consistency across levels of coarseness, a widely-used form of potential is the P^n (Kohli et al., 2009) potential, which encourages sets of variables to all take on the same label. If the segmentations at different levels of granularity have a nested structure, then this model can be represented using an RC potential, and thus exact marginal inference (and therefore learning) can be done efficiently.

5 Fast Sum-Product Formulation

Overview. Here, we present the fast FFT algorithm as an auxiliary variable method, where auxiliary variables are invented in such a way that the distribution over $\boldsymbol{y}$ remains unchanged, but inference in the expanded model can be done very efficiently. In other words, we are defining an augmented model $q(\boldsymbol{y}, \boldsymbol{z})$ that has the property that $\sum_z q(\boldsymbol{y}, \boldsymbol{z}) = p(\boldsymbol{y})$, but where computing all marginals in q (for both $\boldsymbol{y}$ and $\boldsymbol{z}$ variables) can be done more efficiently than directly computing marginals for each y in the original $p(\boldsymbol{y})$ (at least by using any existing method).

More specifically, the algorithm can be described as follows: auxiliary variables $\boldsymbol{z}$ will be integer-valued variables that represent the count over subsets of original variables $\boldsymbol{y}$. The auxiliary variables are structured into a binary tree, as illustrated in Fig. 2, with original $\boldsymbol{y}$ variables at leaves of the tree, so z variables at higher levels of the tree represent sums of increasingly large subsets of $\boldsymbol{y}$. There is one auxiliary variable at every internal binary tree node, so with a balanced tree structure, the joint model over $\boldsymbol{y}$ and $\boldsymbol{z}$ is a tree of depth $\log D$. The utility of this formulation is that we can now represent cardinality potentials over subsets of $\boldsymbol{y}$ variables as unary potentials over $\boldsymbol{z}$ variables.

Having constructed the auxiliary variable model, the algorithm will be simply to run an inwards and outwards pass of sum-product belief propagation. The key computational point is that due to the structure of potentials over auxiliary variables, sum-product messages can be computed efficiently even when $\boldsymbol{z}$ variables have large cardinality, by using FFTs.

5.1 Detailed Description

The algorithm takes as input a binary tree $\mathcal{T}$ with D leaf nodes, where each leaf corresponds to one y_d

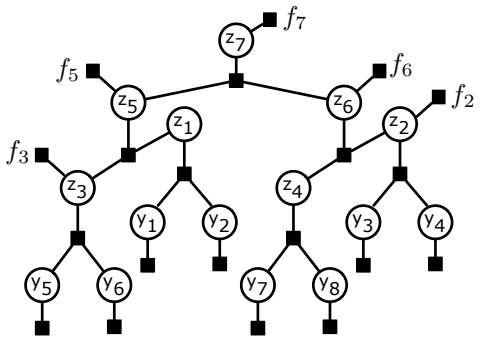


Figure 2: Each internal node z represents the count over the subset of original y variables that are descendants of the internal node. Cardinality potentials on the subset then can trivially be added as unary potentials on internal nodes. Here, in addition to a standard cardinality potential f_7, we add subset cardinality potentials f_2, f_3, f_5, and f_6.

variable. To instantiate latent variables $\boldsymbol{z}$, traverse up the tree from leaves to root, associating a z variable with each internal node. When instantiating a new variable z_p, set a deterministic relationship between it and its two children, z_l and z_r, as $z_p = z_l + z_r$. In graphical model terms, for each parent in the tree, add a deterministic potential $g_p(z_p, z_l, z_r) = \mathbf{1}_{\{z_p = z_l + z_r\}}$ to the model. With these definitions, we can define the distribution q as,

$$q(\boldsymbol{y}, \boldsymbol{z}) \propto p(\boldsymbol{y}) \prod_{p \in \mathcal{P}} \mathbf{1}_{\{z_p = z_{l(p)} + z_{r(p)}\}}, \tag{6}$$

where $\mathcal{P}$ is the set of parent nodes in $\mathcal{T}$, and $l(p)$ and $r(p)$ are indices of the left and right children of z_p.

Define the set of leaf node descendants of z_p as $s_p = \{y_d \mid z_p \text{ is an ancestor of } y_d\}$. For any setting of $\boldsymbol{z}$ to have nonzero probability, it clearly must be the case that $z_p = \sum_{y_d \in s_p} y_d$. Thus, a high order potential over subset s_p can equivalently be represented as a unary potential on z_p. Expanding the definition of p from within Eq. (6), the computational benefit becomes clear, as we can rewrite all high order potentials as unary potentials:

$$\begin{aligned} q(\boldsymbol{y}, \boldsymbol{z}) &\propto \prod_{k | s_k \in \mathcal{S}} f_k\Big(\sum_{y_d \in s_k} y_d\Big) \prod_d \theta_d(y_d) \prod_{p \in \mathcal{P}} \mathbf{1}_{\{z_p = z_{l(p)} + z_{r(p)}\}} \\ &= \prod_{k | s_k \in \mathcal{S}} f_k(z_k) \prod_d \theta_d(y_d) \prod_{p \in \mathcal{P}} \mathbf{1}_{\{z_p = z_{l(p)} + z_{r(p)}\}} \end{aligned} \tag{7}$$

The following proposition justifies correctness and makes the relationship between p and q precise:

Proposition 1. *For all $\boldsymbol{y}$, $p(\boldsymbol{y}) = \sum_{\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z})$.*

Proof. There is exactly one joint setting of $\boldsymbol{z}$ with nonzero probability for each joint setting of $\boldsymbol{y}$. To see this, observe that given a setting of $\boldsymbol{y}$, the one and only setting of $\boldsymbol{z}$ that satisfies all the deterministic relationships is for each z_p to set $z_p = \sum_{y_d \in s_p} y_d$. The proposition then follows directly. □

5.2 Aligning Nested Subsets with $\mathcal{T}$

We have shown how adding auxiliary variables $\boldsymbol{z}$ enables us to convert high order cardinality potentials $f_k(\sum_{y_d \in s_k} y_d)$ into a unary potential on an individual z_k variable. However, this transformation only works if there is an internal z variable for each subset s_k that we wish to put a cardinality potential over. This restriction is what leads to the nested property that we require of sets of subsets $\mathcal{S}$. For any nested set of subsets $\mathcal{S}$, however, it is possible to construct a binary tree $\mathcal{T}$ such that an internal node in the tree is created for every subset s_k. A question for future work is whether a weaker condition than nestedness can be enforced while still guaranteeing efficient exact inference.

Finally, all that remains is to show how sum-product messages can be computed efficiently.

5.2.1 Upward Messages

Let $g(z_p, z_l, z_r)$ be a factor that enforces the deterministic relationship $z_p = z_l + z_r$ between parent z_p and children z_l and z_r. The upward message vectors that we need to compute take the following form:

$$\begin{aligned} m_{g,z_p}(z_p) &= \sum_{z_l=0}^{c_l} \sum_{z_r=0}^{c_r} g(z_p, z_l, z_r) m_{z_l,g}(z_l) m_{z_r,g}(z_r) \\ &= \sum_{z_l=z_p-z_r}^{c_l} m_{z_l,g}(z_l) m_{z_r,g}(z_p - z_l). \end{aligned}$$

Expressed in this way, it becomes clear that the entire message vector (the above quantity, for all values of $z_p \in \{0, \ldots, c_p\}$) can be computed as a 1D discrete convolution. Since 1D discrete convolutions of vectors of length N can be computed in $\mathcal{O}(N \log N)$ time using FFTs, these message vectors can be computed in $\mathcal{O}(c_p \log c_p)$ time.

5.2.2 Downward Messages

Let $g(z_p, z_l, z_r)$ be a factor that enforces the deterministic relationship $z_p = z_l + z_r$ between parent z_p and children z_l and z_r. The downward message vectors that we need to compute take the following form (assume w.l.o.g. that the message is to z_l):

$$m_{g,z_l}(z_l) = \sum_{z_r=0}^{c_r} m_{z_p,g}(z_l + z_r) m_{z_r,g}(z_r).$$

This also can be computed as a 1D discrete convolution, after reversing the message vector $m_{z_r,g}$.

5.2.3 Asymptotics

Assuming balanced binary trees, the algorithm runs in $\mathcal{O}(D \log^2 D)$ time. This can be seen by using the Master theorem to solve the recurrence $T(n) = 2T(n/2) + n \log n$. If binary trees are not balanced, the worst case runtime can be $O(D^2)$. The algorithm uses $\mathcal{O}(D \log D)$ space.

5.3 Minor Extensions

We argue that a main benefit of the auxiliary variable formulation is that it allows for several variants and elaborations. We discuss some of them in this section, to illustrate the range of other similar models models where learning and inference can be done tractably.

Drawing a Joint Sample. Given the auxiliary variable formulation, drawing a joint sample from a RC model is straightforward: pass messages inward to the root as before; compute the belief at the root, which is a distribution over global counts, and draw the value for the root variable from that distribution; now proceed outwards from the root towards the leaves. The one non-triviality is that values for the two children given a parent must be drawn simultaneously. To do this, first construct the belief at the trinary factor $f(z_p, z_l, z_r)$ conditioned on the value of z_p, which has been sampled already. Given z_p, there is a diagonal along the belief matrix corresponding to the values of z_l and z_r such that $z_l + z_r = z_p$. To draw the joint sample for z_l and z_r, normalize this diagonal to sum to 1, then draw a value from that distribution. This gives the values for z_l and z_r. Recurse downwards.

Other minor extensions appear in the Appendix.

5.4 Major Extension

Up until now, we have presented RC models as if the modeler who desires efficient exact inference must choose between standard pairwise trees or RC models. In fact, this is not necessary. It is possible to do exact inference in the following model in $\mathcal{O}(D \log^2 D)$ time:

$$p(\boldsymbol{y}) \propto \prod_{(d,d') \in \mathcal{E}} \theta_{dd'}(y_d, y_{d'}) \prod_{s_k \in \mathcal{S}(\mathcal{E})} f_k(\sum_{y_d \in s_k} y_d), \quad (8)$$

where $\mathcal{E}$ is an acyclic set of edges over variables $\boldsymbol{y}$, and $\mathcal{S}(\mathcal{E})$ is a set of nested subsets with subset structure that is "compatible" with $\mathcal{E}$. In other words, the modeler can choose the structure of either $\mathcal{E}$ or $\mathcal{S}(\mathcal{E})$ arbitrarily, and there is some non-degenerate choice of the other that allows for efficient inference, but not all combinations of trees and subset structures are compatible. Note that this structure cannot be represented by a standard Recursive Cardinality potential, because having e.g., edges (d, d') and (d', d'') would violate the nested subset structure requirement. The approach is similar to the base algorithm, but it involves constructing a junction tree that has separator sets involving one y variable and one z variable. We give details in the Appendix.

6 Experiments

In this section, we empirically explore the properties of the RC model, and demonstrate its usage in several interesting scenarios. Code will be made available implementing the convolution tree algorithm for computing marginals over $\boldsymbol{y}$ and $\boldsymbol{z}$, and for joint sampling.

6.1 Chain vs Tree as D grows

The version of the RC algorithm that we presented in Section 5 is the most efficient that we have discovered. There are, however, other approaches that are more efficient than $\mathcal{O}(D^3 \log D)$, but which are less efficient than the algorithm with the best asymptotic runtime. In this section, we compare the runtime of our algorithm (the "FFT Tree") against two baselines, both of which are improvements over the PL algorithm reviewed in Section 2.3.

The first baseline introduces auxiliary variables in a chain rather than tree structure. If we then follow the approach as in Section 5, this would lead to a $\mathcal{O}(D^2 \log D)$ algorithm. It turns out that in this case, messages can be computed via a summation of two arrays, so using FFTs is unnecessary. This yields a $\mathcal{O}(D^2)$ algorithm equivalent to that of Barlow and Heidtmann (1984), which we term the "Chain" algorithm. A drawback of this algorithm is that it also requires $\mathcal{O}(D^2)$ space. However, we note that if cardinalities greater than k are disallowed by the cardinality potential, then this algorithm can be made to run in $\mathcal{O}(Dk)$ time, and it is perhaps the best choice.

The second baseline is the fast algorithm where FFTs are not used to compute messages, and instead we use an efficient but brute-force computation of the 1D convolutions required inside the message computations. We refer to this as the "Tree" algorithm. Solving the recurrence $T(n) = 2T(n/2) + n^2$ using the Master theorem, we see that the runtime is again $\mathcal{O}(D^2)$. The space usage is $\mathcal{O}(D \log D)$.

We run these algorithms on problems of size up to 2^{19} variables with a single random cardinality potential. The runtimes are reported in Fig. 3. The Chain algorithm fails after $D = 16000$ due to memory limits. The Tree algorithm is faster than the chain algorithm for larger D, but its quadratic time usage causes it to become quite slow once D nears 100k. The FFT Tree algorithm behaves nearly linearly in practice, running on problems with half a million variables in less than 100 seconds. We note that in practice, for large values

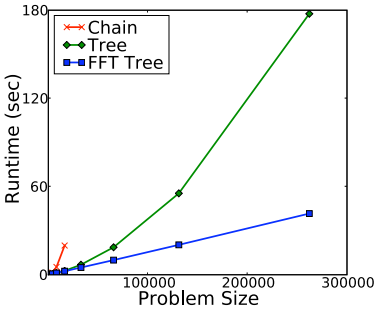

Figure 3: Runtimes of the different algorithms versus problem size. For very small D, the Chain algorithm is slightly faster, but it runs out of memory after around $D = 15000$, due to its quadratic memory usage. The FFT Tree algorithm runtime grows near linearly up through all experiments.

of D, care must be taken to avoid numerical issues for certain settings of model parameters.

6.2 Generalized Bipartite Matching

We have variables $\boldsymbol{y} = \{y_{ij}\}_{(i,j)\in D_I \times D_J}$, where D_I is the number of rows, and D_J is the number of columns. Here, we consider the Gibbs distribution defined by the following energy function:

$$E(\boldsymbol{y}) = \sum_{ij} \theta_{ij} y_{ij} + \sum_i f_c(\sum_j y_{ij}) + \sum_j f_r(\sum_i y_{ij}),$$

where f_r and f_c are functions of row and column counts. Note that if a constraint is placed on each row, saying that exactly one binary variable in each column can be on, then this formulation can also be used to represent cardinality potentials for multilabel problems. One motivation for this model comes from the problem of paper-to-reviewer matching, where y_{ij} represents the event that paper i is matched to reviewer j. The row and column functions can then be used to enforce the constraints that each paper should be given to e.g., 3 to 4 reviewers, and each reviewer should be assigned e.g., 6 to 8 papers. Note that the energy function can clearly represent the bipartite matching problem (by constraining row and column counts to be exactly 1), so computing marginals is #P-complete. Our approach will be to perform approximate inference using loopy belief propagation (LBP), where messages are computed using the FFT tree algorithm.

We compare against several baselines on small and medium-sized problems where we constrain columns to have 1 or 2 variables labeled 1, and rows are constrained to have 2 or 3 variables labeled 1. The first, "Node Marginals" is a naive approximation that simply ignores the constraints and computes marginals under the factorized distribution consisting of just the node potentials. The second is to find the exact MAP solution to the problem using a linear program (LP) and assume that the marginals are 0 or 1. The final baseline, which we take as the ground truth for the intractable medium-sized problem, is to use a block Gibbs sampler where blocks are chosen as the four variables $y_{i_1,j_1}, y_{i_1,j_2}, y_{i_2,j_1}, y_{i_2,j_2}$ for some choice of rows i_1 and i_2 and columns j_1 and j_2. To find a valid initial configuration, we initialize the sampler with the LP solution. We attempted multiple runs using random parameter settings. The results in Fig. 4 show that LBP achieves a low bias in a relatively short amount of time. For small problems, the constraints do not always greatly influence the marginals, as exhibited by the low bias of the naive approach in some runs; however, they clearly influence the larger problems. Finally, the LP method tends to be slower than LBP, becomes relatively slower on larger problems, and exhibits significant bias. We have run our algorithm on larger problems, and it converges quickly even on e.g., 100x100 problems, but we are unable to measure accuracy, because accurate baselines are prohibitively slow.

It is worth mentioning that this is a hard problem, and designing sampling schemes for many cases is nontrivial. Indeed, the Gibbs sampler we used will not be ergodic for disjoint cardinality constraints (e.g. only 3 or 10). By contrast, our method is relatively fast, accurate, and applies to a wide variety of constraints.

6.3 Multiple Instance Learning

In multiple instance learning (MIL), we are given "bags" of instances, which are labeled as either "positive" (at least one instance in the bag is positive) or "negative" (all instances in the bag are negative). This can be framed as a problem of learning with weak labels, where the weak labels take the form of a cardinality potential over individual instance labels. Indeed, MIL models where bag labels are modeled as noisy-OR can be seen as exactly this formulation, using the

form of noisy-OR from Eq. (5). However, given the fast algorithms for Recursive Cardinality potentials developed in this work, it becomes tractable to assert other forms of the distribution over within-bag counts. In this section, we experiment with this alternative.

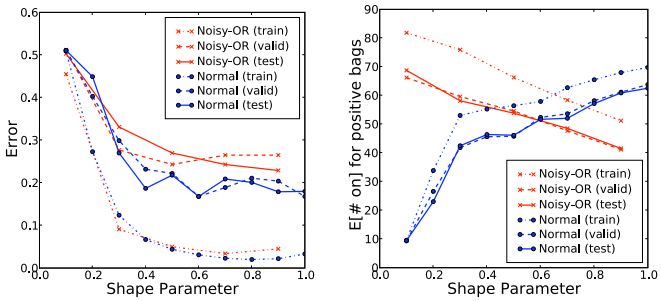
More formally, for variables $\boldsymbol{y}$ appearing in a bag labeled as $t = 0$ (negative) or $t = 1$ (positive), we can rewrite the likelihood of a label as $\sum_{\boldsymbol{y}} p(t, \boldsymbol{y})$, where

$$p(t, \boldsymbol{y}) \propto f^{(t)}(\sum_d y_d) \prod_d \exp\{\theta_d \cdot y_d\}, \qquad (9)$$

where $f^{(t)}$ is some cardinality function that imposes a preference on the number of binary variables turned on for bags labeled as t, and θ_d is a unary potential. All of the required quantities for learning can be computed in two calls to our algorithm (corresponding to $t = 0$ and $t = 1$).

The standard data set for evaluating MIL learners is the Musk dataset from Dietterich et al. (1997). In the data, bags molecules are labeled as to whether they are "musks." A molecule is considered to be a musk if any low energy conformations of the molecule is a musk. The bags in this data set correspond to molecules, and the instances are features of many different low energy conformations. We compared two methods on the musk1 version of the dataset: a standard Noisy-OR model, and a "Normal" model, where $f^{(0)}(c) = \exp\{-(\frac{c}{D})/2\sigma^2\}$ and $f^{(1)}(c) = \exp\{-(\mu - \frac{c}{D})/2\sigma^2\}$.

As is common in the MIL literature, we divide the data into 10 evenly-sized folds and run 10-fold cross-validation. We use 20% of bags for validation, and 10% for testing in each split. To set an $L1$ regularization parameter, and to choose the σ and ϵ parameters in the Normal and Noisy-OR models, respectively, we do a grid search and choose the setting that produced the best average validation error across folds. Fig. 5 (a) reports results showing how error varies as a function of the μ and λ parameters for Normal and Noisy-OR, respectively. We note that the musk1 dataset has only 92 instances, and the standard deviation of errors across validation folds was high, so these results are not statistically significant. However, we do see a trend where varying the f functions can affect performance, and that a Normal cardinality potential out-performs the standard Noisy-OR. For this problem, it appears that setting the μ parameter to be large is beneficial for learning, but in general this should be a parameter that is set via prior knowledge or cross validation. Also note that Gehler and Chapelle (2007) enforced a similar bias on bag counts within an SVM formulation, and their results also suggested that encouraging the model to turn on more binary variables within positive bags improved performance on the musk1 data. In Fig. 5 (b), we show how parameter values in the



(a) Error (b) # on in Positive Bags

Figure 5: Multiple instance learning results.

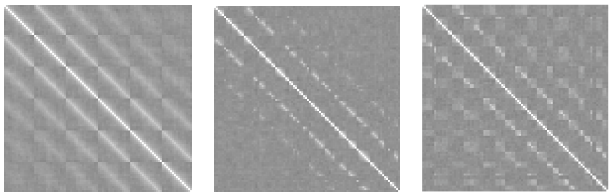
cardinality potential affects the expected number of instances labeled as "on" within positive bags. The trend in this plot shows that varying f does indeed affect how many instances within a positive bag that the model chooses to label as positive examples.

6.4 Generative Image Models

In this set of experiments, we attempt to distinguish between the representational abilities of pairwise tree-structured graphical models, and the RC model. We consider a synthetic dataset that has been sampled from an Ising model near the critical temperature resulting in images with highly correlated regions. The pairwise edges form a grid structure, and the resulting data consists of 1000 16×16 images. In order to compare the pairwise tree and the RC models we first learn their parameters on each dataset using nonlinear conjugate gradients to minimize the negative log-likelihood. After learning each model, we generate the same number of samples as the original dataset and use these to compare statistics. After learning, the log-likelihoods for the pairwise tree model was 145.22, while the log-likelihoods for the RC model was 146.78. We hypothesize that this difference is because the pairwise tree model is able to do a better job at directly capturing pairwise statistics, however the RC model is better at capturing long-range, higher-order statistics. We demonstrate this in our experiments below.

Heuristic choice of transformation structure. For each dataset, in order to determine the structure of the nested cardinality potential, we run hierarchical agglomerative clustering on images, where the similarity between pixels is determined by how often they take the same label. This gives us a full tree structure over the pixels, which we then directly use to give the nested subset structure. We leave a study of other ways for choosing trees to future work.

Pairwise statistics. We analyze the pairwise statistics of the learned distributions in comparison to the original datasets. Fig. 6 shows the pairwise correla-



(a) Actual data (b) Pairwise tree (c) RC

(a) Adaptive clustering (b) Anti-clustering

Figure 7: Error in higher-order count statistics between the empirical and model distributions as a function of the number of variables in a subset.

tions between each pixel, with lighter shading corresponding to stronger correlation. The Ising model enforces strong correlation between neighbouring pixels, and this is reflected in the banded nature of the correlation matrix. Visually, we can see that the RC model does a better job of capturing long range correlations corresponding to the more faded bands away from the main diagonal.

Higher-order statistics. As a final comparison, we analyze the ability of both models to capture higher-order statistics in the data. Specifically, we test the ability of the RC model to capture higher-order count statistics over subsets that it does not directly encode. To do this, we first build a nested tree over the variables using hierarchical clustering. Using this tree, we look at the count distributions of subsets and compare the empirical and model distributions. In Fig. 7, we show the root mean squared error between the empirical and model distributions as a function of the number of variables in a subset for the Ising dataset. We compare both models on nested trees constructed from two heuristics: the first is the same scheme we use to parameterize the RC model, which we call adaptive clustering. For the second, we attempt to create a "worst case" clustering by taking the distance values used for the adaptive method and negating them before clustering; we call this scheme anti-clustering. We also tried random clusterings, however the results were not qualitatively different from the anti-clustering scheme. Our results show that the RC model does a better job than the pairwise tree model at capturing higher-order count statistics, even if it does not encode them directly. Particularly interesting is that for the adaptive tree, the pairwise model does significantly worse than the RC model. This is due to the confluence of two effects: first, the hierarchical clustering that determines the RC structure seeks to choose subsets of variables that are highly correlated to merge into a subset; second, the spanning tree is unable to model this "all-or-none" effect, and instead tends towards a binomial-like distribution with mode near the 50% full point. This leads to large errors.

7 Discussion

We have presented a new class of high order model where exact inference can be done very efficiently. This model can be used on its own, and it is already able to capture a mix of high and low order statistics that would be difficult for other tractable models. The model can also be used as a subcomponent within outer approximate inference procedures, allowing efficient approximate marginal inference for hard problems that few other approaches are able to tackle.

The general approach—of adding a set of auxiliary variables with highly structured interactions so as to guarantee efficient message passing inference—leads to efficient exact inference in other extended models such as tree structured models augmented with a cardinality potential, and we believe the approach to extend even beyond that.

Finally, we have presented a diverse set of applications and shown how many problems that are not naturally thought of in terms of cardinality potentials can be cast as such. We believe that the highly efficient algorithms discussed here will only increase the number of applications where cardinality potentials are useful.

Abstract

Recently, Petrik et al. demonstrated that L_1-Regularized Approximate Linear Programming (RALP) could produce value functions and policies which compared favorably to established linear value function approximation techniques like LSPI. RALP's success primarily stems from the ability to solve the feature selection and value function approximation steps simultaneously. RALP's performance guarantees become looser if sampled next states are used. For very noisy domains, RALP requires an accurate model rather than samples, which can be unrealistic in some practical scenarios. In this paper, we demonstrate this weakness, and then introduce Locally Smoothed L_1-Regularized Approximate Linear Programming (LS-RALP). We demonstrate that LS-RALP mitigates inaccuracies stemming from noise even without an accurate model. We show that, given some smoothness assumptions, as the number of samples increases, error from noise approaches zero, and provide experimental examples of LS-RALP's success on common reinforcement learning benchmark problems.

1 Introduction

Markov Decision Processes (MDPs) are applicable to a large number of real-world Artificial Intelligence problems. Unfortunately, solving large MDPs is computationally challenging, and it is generally accepted that such MDPs can only be solved approximately. This approximation is often done by relying on linear value function approximation, in which the value function is chosen from a low-dimensional vector space of features. Generally speaking, agent interactions with the environment are sampled, the vector space is defined through feature selection, a value function is selected from this space by weighting features, and finally a policy is extracted from the value function. Each of these steps contains difficult problems and is an area of active research. The long-term hope for the community is to handle each of these topics on increasingly difficult domains with decreasing requirements for expert guidance (providing a model, features, etc.) in application. This will open the door to wider application of reinforcement learning techniques.

Previously, Petrik et al. [12] introduced L_1-Regularized Approximate Linear Programming (RALP) to combine and automate the feature selection and feature weighting steps of this process. Because RALP addresses these steps in tandem, it is able to take advantage of extremely rich feature spaces without overfitting. However, RALP's hard constraints leave it especially vulnerable to errors when noisy, sampled next states are used. This is because each sampled next state generates a lower bound on the value of the originating state. Without a model, the LP will not use the expectation of these next state values but will instead use the max of the union of the discounted values of sampled next states. Thus, a single low probability transition can determine the value assigned to a state when samples are used in lieu of a model. This inability to handle noisy samples is a key limitation of LP based approaches.

In this paper, we present Locally Smoothed L_1-Regularized Approximate Linear Programming (LS-RALP), in which a smoothing function is applied to the constraints of RALP. We show this smoothing function reduces the effects of noise, without the requirement of a model. The result is a technique which accepts samples and a large candidate feature set, and then automatically chooses features and approximates the value function, requiring neither a model, nor human-guided feature engineering.

Standard ALP approaches produce value functions and require a model at policy execution time to determine the optimal action with respect the value function returned by the LP. We extend LS-RALP to produce Q-functions, rather than value functions, thereby removing the dependence on a model from both value function learning and policy execution.

After introducing notation, this paper first examines RALP in Section 3 to demonstrate the effect of noise on solution quality. Section 4 then introduces LS-RALP, and explains the approach. In Section 5, we prove that as samples are added, the error from noise in LS-RALP's value function approximation approaches zero. Finally, in Section 6, we empirically demonstrate LS-RALP's success in high-noise environments, even with a small number of samples. Finally, in Section 7, we make our concluding remarks.

2 Framework and Notation

In this section, we formally define Markov decision processes and linear value function approximation. A *Markov decision process* (MDP) is a tuple $(\mathcal{S}, \mathcal{A}, p, R, \gamma)$, where $\mathcal{S}$ is a measurable subset of Euclidean space, and $\mathcal{A}$ is a finite set of actions. p is a transition kernel, where $p(s'|s,a)$ represents the conditional density for next states. The function $R : \mathcal{S} \mapsto \Re$ is a measurable reward function, and γ is a discount factor.

We are concerned with finding a value function V that maps each state $s \in \mathcal{S}$ to the expected total γ-discounted reward for the process. Value functions can be useful in creating or analyzing a measurable policy function $\pi : \mathcal{S} \times \mathcal{A} \to [0,1]$ such that for all $s \in \mathcal{S}$, $\sum_{a \in \mathcal{A}} \pi(s,a) = 1$. The transition and reward functions for a given policy are denoted by P_π and R_π. We denote the Bellman operator for a given policy as $\bar{T}_\pi$, and the max Bellman operator simply as $\bar{T}$. That is, for some state $s \in \mathcal{S}$:

$$\bar{T}_\pi V(s) = R(s) + \gamma \int_{\mathcal{S}} P(s'|s,\pi(s)) V(s') ds'$$

$$\bar{T} V(s) = \max_{\pi \in \Pi} \bar{T}_\pi V(s).$$

We additionally denote the Bellman operator for a policy which always selects action a as

$$\bar{T}_a V(s) = R(s) + \int_{\mathcal{S}} P(s'|s,a) V(s') ds'.$$

If $\mathcal{S}$ is finite, the above Bellman operators can be expressed for all states using matrix notation, in which V and R are vectors of values and rewards for each state, respectively, and P is a matrix containing probabilities of transitioning between each pair of states:

$$\bar{T}_\pi V = R_\pi + \gamma P_\pi V$$

$$\bar{T} V = \max_{\pi \in \Pi} \bar{T}_\pi V$$

$$\bar{T}_a V = R + \gamma P_a V$$

The optimal value function V^* satisfies $\bar{T} V^* = V^*$.

Because $\bar{T}$ computes an exact expectation over next states, we refer to $\bar{T}$ as the Bellman operator *with expectation*. This requires *sampling with expectation*, defined as $\bar{\Sigma} \subseteq \{(s, a, \mathbb{E}[R(s)]), p(\cdot|s,a) | s \in \mathcal{S}, a \in \mathcal{A}\}$. This kind of sampling assumes that the complete density over next states is provided with every sample, a rather unrealistic assumption. It is therefore usually convenient to use *one-step simple samples* $\Sigma \subseteq \{(s,a,r,s') | s, s' \in \mathcal{S}, a \in \mathcal{A}\}$, where s' is a single draw from $p(s'|s,a)$. An individual (s,a,r,s') sample from sets $\bar{\Sigma}$ and Σ will be denoted $\bar{\sigma}$ and σ, respectively. An individual element of a sample σ will be denoted with superscripts; that is, the s component of a $\sigma = (s,a,r,s')$ sample will be denoted σ^s. Simple samples have an associated *sampled* Bellman operator T_σ, where $T_\sigma V(\sigma^s) = \sigma^r + \gamma V(\sigma^{s'})$.

We will also define the optimal Q-function $Q^*(s,a)$ as the value of taking action a at state s, and following the optimal policy thereafter. More precisely, $Q^*(s,a) = R(s,a) + \gamma \int_{\mathcal{S}} P(s'|s,a) V^*(s') ds'$.

We focus on *linear value function approximation* for discounted infinite-horizon problems, in which the value function is represented as a linear combination of *nonlinear basis functions (vectors)* which are assumed to be measurable on S. For each state s, we define a vector $\Phi(s)$ of features. The rows of the basis matrix Φ correspond to $\Phi(s)$, and the approximation space is generated by the columns of the matrix. That is, the basis matrix Φ, and the value function V are represented as:

$$\Phi = \begin{pmatrix} - & \Phi(s_1) & - \\ & \vdots & \end{pmatrix} \qquad V = \Phi w.$$

This form of linear representation allows for the calculation of an approximate value function in a lower-dimensional space, which provides significant computational benefits over using a larger or complete basis; if the number of features is small, this framework can also guard against overfitting any noise in the samples though small features sets alone cannot protect ALP methods from making errors due to noise.

3 L_1-Regularized Approximate Linear Programming

This section includes our discussion of L_1-Regularized Approximate Linear Programming. Subsection 3.1 will review the salient points of the method, while Subsection 3.2 will discuss the weaknesses of the method and our motivation for improvement.

3.1 RALP Background

RALP was introduced by Petrik et al. [12] to improve the robustness and approximation quality of Approximate Linear Programming (ALP) [13, 1]. For a given set of samples with expectation $\bar{\Sigma}$, feature set Φ, and regularization pa-

rameter ψ, RALP calculates a weighting vector w by solving the following linear program:

$$\begin{aligned} \min_{w} \quad & \rho^T \Phi w \\ \text{s.t.} \quad & \bar{T}_{\sigma^a} \Phi(\sigma^s) w \leq \Phi(\sigma^s) w \ \ \forall \sigma \in \Sigma \\ & \|w\|_{1,e} \leq \psi, \end{aligned} \tag{1}$$

where ρ is a distribution over initial states, and $\|w\|_{1,e} = \sum_i |e(i)w(i)|$. It is generally assumed that ρ is a constant vector and $e = \mathbf{1}_{-1}$, which is a vector of all ones but for the position corresponding to the constant feature, where $e(i) = 0$.

Adding L_1 regularization to the constraints of the ALP achieved several desirable effects. Regularization ensured bounded weights in general and smoothed the value function. This prevented missing constraints due to unsampled states from leading to unbounded or unreasonably low value functions. By using L_1 regularization in particular, the well-known sparsity effect could be used to achieve automated feature selection from an extremely rich Φ. Finally, the sparsity in the solution could lead to fast solution times for the LP even when the number of features is large because the number of active constraints in the LP would still be small.

As a demonstration of the sparsity effect, RALP was run on the upright pendulum domain (explained in detail in Section 6) using a set of features for each action consisting of three Gaussian kernels centered around each sampled state, one polynomial kernel based around each sampled state, and a series of monomials calculated on the sampled states. On one randomly-selected run of 50 sample trajectories (a trajectory consists of states reached as a result of randomly selected actions until the pendulum falls over), to represent the Q-values of the first action RALP selected zero of the narrowest Gaussian kernels, nine of the intermediate-width Gaussian kernels, five of the widest Gaussian kernels, five of the polynomial kernels, and zero of the monomials. For the second action, the Q value was represented with zero narrow, seven intermediate, and four wide Gaussian kernels, six polynomial kernels, and one monomial. For the final action, these numbers were one, four, four, seven, and zero. Selecting this same mixture of features by hand would be extremely unlikely.

Petrik et al. [12] demonstrated a guarantee that the error on the RALP approximation will be small, as will be further discussed in the next subsection. Additionally, in experiments, policies based on RALP approximations outperformed policies generated by Least-Squares Policy Iteration [9], even with very small amounts of data.

RALP is not the only approach to leverage L_1 regularization in value function approximation; others include LARS-TD [7], and LC-MPI [6], which both attempt to calculate the fixed point of the L_1-penalized LSTD problem. Unlike RALP, this solution is not guaranteed to exist when samples are drawn off-policy. These methods have the advantage of handling noise more gracefully than LP based approaches, but require on-policy sampling for reliable performance. On-policy sampling is often a challenging requirement for real-life applications.

3.2 RALP Weaknesses

The RALP constraints in LP 1 are clearly difficult to acquire – samples with expectation require a model that provides a distribution over next states, or access to a simulator that can be easily reset to the same states many times to compute an empirical next state distribution for each constraint.

Petrik et al. [12] previously presented approximation bounds for three constructions of RALP, depending upon the sampling regime. In the *Full ALP*, it is assumed every possible state-action pair is sampled with expectation. The *Sampled ALP* contains constraints for only a subset of state-action pairs sampled with expectation. The third form, the *Estimated ALP*, also has constraints defined on sampled state-action pairs, but of the form

$$\Phi(\sigma^s) w \geq T_\sigma \Phi(\sigma^s) w \ \ \forall \sigma \in \Sigma.$$

Note that the Estimated ALP uses one-step simple samples and the sampled Bellman operator.

These three forms are presented in order of decreasing accuracy, but increasing applicability. The Full ALP requires a manageably small and discrete state space, as well as a completely accurate model of the reward and transition dynamics of the system. The Sampled ALP still requires the model, but allows for constraint sampling; this introduces constraint violation error (denoted ϵ_p), as the approximation may violate unsampled constraints. Finally, the Estimated ALP requires neither the model nor experience at every state; because replacing an accurate model with a sample is likely to be imprecise in a noisy domain, this introduces model error (denoted ϵ_s). However, this is the most realistic sampling scenario for learning problems that involve physical systems.

For reference, and to understand the effect of model error, we reproduce the RALP error bounds for the Sampled and Estimated ALP here. We denote the solution of the Sampled ALP $\bar{V}$, and the solution of the Estimated ALP V. ϵ_c is error from states that do not appear in the objective function because they were not samples. Since ρ is often chosen fairly arbitrarily, we can assume the unsampled states have 0 weight and that $\epsilon_c = 0$.

$$\|\bar{V} - V^*\|_{1,\rho} \leq \epsilon + 2\epsilon_c(\psi) + 2\frac{\epsilon_p(\psi)}{1-\gamma} \tag{2}$$

$$\|V - V^*\|_{1,\rho} \leq \epsilon + 2\epsilon_c(\psi) + \frac{3\epsilon_s(\psi) + 2\epsilon_p(\psi)}{1-\gamma} \tag{3}$$

To understand the source of model error ϵ_s, consider a case where a state-action pair is sampled twice. Further suppose that in one of these samples, the agent transitions to a high-value state; in the other, it transitions to a lower-valued state. The resulting value function is constrained by the high-valued sample, while the constraint related to the low-valued experience remains loose; that sample might as well have not occurred. The approximate value at that state will be inaccurately high. This scenario is depicted in Figure 1.

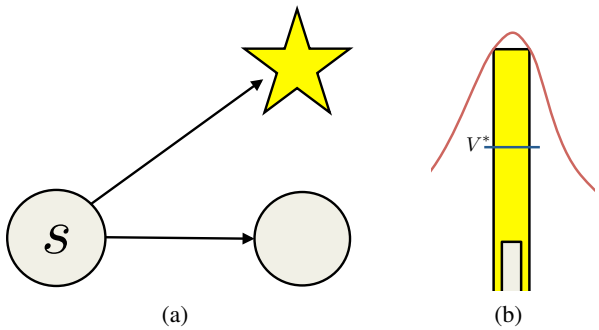

Figure 1: Subfigure 1(a) illustrates two samples beginning at state s; one transitions to the low-valued circle state, while the other transitions to the high-valued star state. Subfigure 1(b) illustrates the resulting constraints and value function approximation. V^* is the actual value of this state, but the red line representing the approximate function is constrained by the max of the two constraints. Under realistic sampling constraints, it is more likely this scenario would occur with two samples drawn from very nearly the same state, rather than both originating from the same sample s.

The inability of LP approaches to value function approximation to handle noisy samples is well known. One proposed solution is Smoothed Approximate Linear Programming (SALP), in which the LP is given a budget with which to violate constraints [2]. Note, however, that there is nothing connecting the constraint violation budget to the problem dynamics unless additional information is provided. In Figure 1, for example, SALP could fortuitously choose the right amount of constraint violation to mix between the next state values for state s in the proportions dictated by the model. However it is also possible for SALP to yield exactly the same value for this state as ordinary ALP, having spent its constraint violation budget on some other state which might not even be noisy.

4 Locally Smoothed L_1-Regularized Approximate Linear Programming

To address the weaknesses introduced in Subsection 3.2, we introduce Locally Smoothed L_1-Regularized Approximate Linear Programming (LS-RALP). The concept behind LS-RALP is simple; by averaging between nearby, similar samples, we can smooth out the effects of noise and produce a more accurate approximation. We define "nearby" to mean two things: one, the states should be close to each other in the state space, and two, the actions taken should be identical. The goal is to achieve the performance of the Sampled ALP with the more realistic sampling assumptions of the Estimated ALP.

We now introduce the smoothing function $k_b(\sigma, \sigma_i)$. A smoothing function spreads the contribution of each sampled data point σ_i over the local neighborhood of data point σ; the size of the neighborhood is defined by the bandwidth parameter b. If $\sigma_i^a \neq \sigma^a$, the function returns zero. We also stipulate that $\sum_{\sigma_i \in \Sigma} k_b(\sigma, \sigma_i) = 1$ for all σ, and that $k_b(\sigma, \sigma_i) \geq 0$ for all σ, σ_i. Smoothing functions of this sort are commonly used to perform nonparametric regression; as sampled data are added, the bandwidth parameter is tuned to shrink the neighborhood, to allow for a balance between the variance from having too few samples in the neighborhood and the bias from including increasingly irrelevant samples which are farther away.

Observation 4.1 *Consider the regression problem of estimating the function f of the response variable $y = f(x) + N(x)$, given n observations $(x_i, y_i)(i = 1, \cdots, n)$, where $N(x)$ is a noise function. Assume the samples x_i are drawn from a uniform distribution over a compact set G, that $f(x)$ is continuously differentiable, and that $N(x)$ satisfies certain regularity conditions. There exists a smoothing function $k_b(x, x_i)$ and associated bandwidth function $b(n)$ such that $\forall x \in G$, as $n \to \infty, \sum_i k_{b(n)}(x, x_i) y_i \to f(x)$, almost surely.*

Smoothing functions that suffice to provide the consistency guarantees in the above observation include kernel estimators [3] and k-nearest-neighbor averagers [4]. Similar results exist for cases without uniform sampling [5, 3].

The regularity conditions on the noise function depend upon the type of estimator and allow for a variety of noise models [3, 4]. In some of these cases, other assumptions in Observation 4.1 can be weakened or discounted altogether.

Literature on nonparametric regression also contains extensive theory on optimal shrinkage rates for the bandwidth parameter; in practice, however, for a given number of samples, this is commonly done by cross-validation.

We now modify our LP to include our smoothing function:

$$\begin{aligned} \min_{w} \quad & \rho^T \Phi w \\ \text{s.t.} \quad & \textstyle\sum_{\sigma_i \in \Sigma} k_b(\sigma, \sigma_i) T_{\sigma^a} \Phi(\sigma_i^s) w \leq \Phi(\sigma_i^s) w \;\; \forall \sigma \in \Sigma \\ & \|w\|_{1,e} \leq \psi. \end{aligned} \tag{4}$$

In this formulation, we are using our smoothing function to estimate the constraint with expectation $\bar{T}\Phi(\sigma^s)w$ by

smoothing across our easily obtained $T_\sigma\Phi(\sigma^s)w$.

Note that unsmoothed RALP is a special case of LS-RALP, where the bandwidth of the smoothing function is shrunk until the function is a delta function. Therefore, LS-RALP, with correct bandwidth choice, can always do at least as well as RALP.

We note that smoothing functions have been applied to reinforcement learning before, in particular by Ormoneit and Sen [11], whose work was later extended to policy iteration by Ma and Powell [10]. In this formulation, a kernel estimator was used to approximate the value function; this differs significantly from our approach of using a smoother to calculate weights more accurately for a parametric approximation. Additionally, because their approximation simply averages across states and does not use features, it will tend to have a poor approximation for novel states unless the space is very densely sampled. More recently, and independently from our work, Kroemer and Peters [8] proposed an approach to policy evaluation that first used kernel density estimation to approximate the dynamics and then solved for the value function of resulting approximate system using dynamic programming.

5 Convergence Proof

The goal of this section is to demonstrate that the application of a smoothing function to the constraints of the Estimated ALP will mitigate the effects of noise. In particular, we show that as the number of samples approaches infinity, the LS-RALP solution using one-step samples approaches the RALP solution using samples with expectation.

We begin by providing an explicit definition of ϵ_s that is consistent with the usage in Petrik et al. [12]. For a set of samples Σ,

$$\epsilon_s = \max_{\sigma\in\Sigma} \left|\bar{T}\Phi(\sigma^s)w - T_\sigma\Phi(\sigma^s)w\right|. \tag{5}$$

We now introduce and prove our theorem. We denote the number of samples $|\Sigma|$ as n.

Theorem 5.1 *If the reward function, transition function, and features are continuously differentiable, samples are drawn uniformly from a compact state space, and the noise models of the reward and transition functions satisfy the conditions of Observation 4.1 that would make kernel regression converge, then there exists a bandwidth function $b(n)$ such that as $n \to \infty$, the LS-RALP solution using one-step samples approaches the Sampled RALP solution for all states in the state space.*

We begin by restating the definition of ϵ_s:

$$\epsilon_s = \max_{\sigma\in\Sigma} \left|\bar{T}\Phi(\sigma^s)w - T_\sigma\Phi(\sigma^s)w\right|.$$

We then expand upon the portion within the max operator for some arbitrary σ:

$$\begin{aligned}&\bar{T}\Phi(\sigma^s)w - T_\sigma\Phi(\sigma^s)w\\ &= \left[R(\sigma^s) + \gamma\int_{\mathcal{S}} P(ds'|\sigma^s,\sigma^a)\Phi(s')w\right] - \left[\sigma^r + \gamma\Phi(\sigma^{s'})w\right]\end{aligned}$$

We now introduce the smoothing function so as to match the constraints of LS-RALP; that is, we replace $T_\sigma\Phi(\sigma^s)w$ with $\sum_{\sigma_i\in\Sigma} k_b(\sigma,\sigma_i)T_\sigma\Phi(\sigma_i^s)w$.

ϵ_s remains the maximum difference between the ideal constraint $\bar{T}\Phi(\sigma^s)w$ and our existing constraints, which are now $\sum_{\sigma_i\in\Sigma} k_b(\sigma,\sigma_i)T_\sigma\Phi(\sigma_i^s)w$.

$$\begin{aligned}&\bar{T}\Phi(\sigma^s)w - \sum_{\sigma_i\in\Sigma} k_b(\sigma,\sigma_i)T_\sigma\Phi(\sigma_i^s)w\\ &= \left[R(\sigma^s) + \gamma\int_{\mathcal{S}} P(ds'|\sigma^s,\sigma^a)\Phi(s')w\right]\\ &\quad - \sum_{\sigma_i\in\Sigma} k_b(\sigma,\sigma_i)\left[\sigma_i^r + \gamma\Phi(\sigma_i^{s'})w\right]\\ &= R(\sigma^s) - \sum_{\sigma_i\in\Sigma} k_b(\sigma,\sigma_i)\sigma_i^r\\ &\quad + \gamma\int_{\mathcal{S}} P(ds'|\sigma^s,\sigma^a)\Phi(s')w - \gamma\sum_{\sigma_i\in\Sigma} k_b(\sigma,\sigma_i)\Phi(\sigma_i^{s'})w\end{aligned}$$

The smoothing function is performing regression on all observed data, rather than just the single, possibly-noisy sample. The first two terms of the above equation are the difference between the expected reward and the predicted reward, while the second two are the difference between the expected next value and the predicted next value. The more accurate our regression on these two terms, the smaller ϵ_s will be.

It follows from Observation 4.1 that as n increases, if $R(s), P(s'|s,a)$, and $\Phi(s)$ are all continuously differentiable with respect to the state space, and if samples are drawn uniformly from a compact set, and the noise model of the reward and transition functions is one of several allowed noise models, there exists a bandwidth shrinkage function $b(n)$ such that $\sum_{\sigma_i\in\Sigma} k_b(\sigma,\sigma_i)T_\sigma\Phi(\sigma_i^s)w$ will approach $\bar{T}\Phi(\sigma^s)w$ almost surely, and ϵ_s will approach 0 almost surely.

When $\epsilon_s = 0$, the smoothed constraints from one-step samples of LS-RALP are equivalent to the constraints with expectation of the Sampled RALP. ∎

The assumptions on $R(s), P(s'|s,a)$, and $\Phi(s)$ required for our proof may not always be realistic, and are stronger than the bounded change assumptions made by RALP. However, we will demonstrate in the next section that meeting these assumptions is not necessary for the method to be effective.

This theorem shows that sample noise, the weak point of all ALP algorithms, can be addressed by smoothing in a principled manner. Even though these results address primarily

the limiting case of $n \to \infty$, our experiments demonstrate that in practice we can obtain vastly improved value functions even with very few samples.

6 Experiments

In this section, we apply LS-RALP to noisy versions of common reinforcement learning benchmark problems to demonstrate the advantage of smoothing. We will use two domains, the inverted pendulum [15] and the mountain-car [14]. While we have proved that LS-RALP will improve upon the value function approximation of RALP as the number of samples grows large, our experiments demonstrate that there is significant improvement even with a relatively small number of samples.

In the mountain-car domain, we approximate the value function, and then apply the resulting greedy policy. We generate the policy via the use of a model; at each state, we evaluate each candidate action, and calculate the approximate value at the resulting state. The action which resulted in the highest value is then chosen in the trajectory.

In the pendulum problem, we extend the method to the approximation of Q-functions, and again apply the resulting greedy policy. When using Q-functions, the model is unnecessary; the action with the highest Q-value is chosen.

6.1 Mountain Car

In the mountain car problem, an underpowered car must climb a hill by gaining momentum. The state space is two-dimensional (position and velocity), the action space is three-dimensional (push, pull, or coast), and the discount factor is 0.99. Traditionally, a reward of -1 is given for any state that is not in the goal region, and a reward of 0 is given for any state that is. For this problem we applied Gaussian noise with standard deviation .5 to the reward to demonstrate the ability of LS-RALP to handle noisy rewards. This is a very large amount of noise that greatly increases the difficulty of the problem.

Features are the distributed radial basis functions suggested by Kolter and Ng [7]; however, because LSPI with LARS-TD requires a distinct set of basis functions for each action, while RALP methods do not, our dictionary is one-third of the size. For sake of a baseline comparison, we note that in the deterministic version of this problem, we repeated experiments by Kolter and Ng [7] and Johns et al. [6] on LARS-TD and LC-MPI, respectively and RALP outperformed both.

Sample trajectories started at a random state, and were allowed to run with a random policy for 20 steps, or until the goal state was reached. After the value function was calculated, it was tested by placing the car in a random state; the policy then had 500 steps for the car to reach the goal state. Unlike the paper which introduced RALP [12], only one action at each state was sampled.

Figure 2 shows the success rate over 50 trials for both RALP and LS-RALP. The regularization parameter for the RALP methods was 1.4, and the smoothing function for LS-RALP was a multivariate Gaussian kernel with a standard deviation spanning roughly 1/85 of the state space in both dimensions. These parameters were chosen using cross validation.

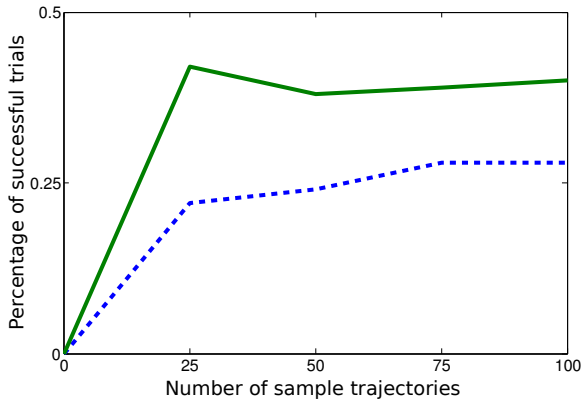

Figure 2: Percentage of successful trials vs. number of sample trajectories for the mountain-car domain with value functions approximated by RALP (blue, dotted) and LS-RALP (green, solid).

6.2 Inverted Pendulum

The focus of this paper is value function approximation, but our theory extends trivially to Q-function approximation. We demonstrate this by using RALP and LS-RALP to approximate Q-functions; this completely removes the need for a model in policy generation.

In the inverted pendulum problem the agent tries to balance a stick vertically on a platform by applying force to the platform. The state space is the angle and angular velocity of the stick, and the action space contains three actions: a push on the table of 50N, a pull on the table of 50N, and no action. The discount factor is 0.9. The goal is to keep the pendulum upright for 3000 steps. The noise in the pendulum problem is applied as Gaussian noise of standard deviation 10 on the force applied to the table. This is significantly greater than the noise traditionally applied in this problem, resulting in much worse performance even by the best controller we could produce.

We compare RALP and LS-RALP, using the same set of features; Gaussian kernels of three different widths, a polynomial kernel of degree 3, $s[1], s[2], s[1] * s[2], s[1]^2, s[2]^2$, and a constant feature, where $s[1]$ is the angle, and $s[2]$ is the angular velocity. For a number of samples n, this was therefore a total of $4n + 6$ features for each action. We also

compare against LSPI, using the radial basis functions used by Lagoudakis and Parr [9], and LARS-TD wrapped with policy iteration, using the same features used by RALP and LS-RALP.

Sampling was done by running 50 trajectories under a random policy, until the pendulum fell over (around six steps). For the LP methods, the regularization parameter was set to 4000, and for LS-RALP, the smoothing function was a multivariate Gaussian kernel. These parameters were chosen by cross validation. 50 trials were run for each method, and the number of steps until failure averaged; if a trial reached 3000 steps, it was terminated at that point. As with the mountain car experiments, only one action for each sampled state was included. Results are presented in Figure 3.

Notice that while LSPI was competitive with the Q-functions approximated with RALP, the addition of the smoother resulted in superior performance even with very little data.

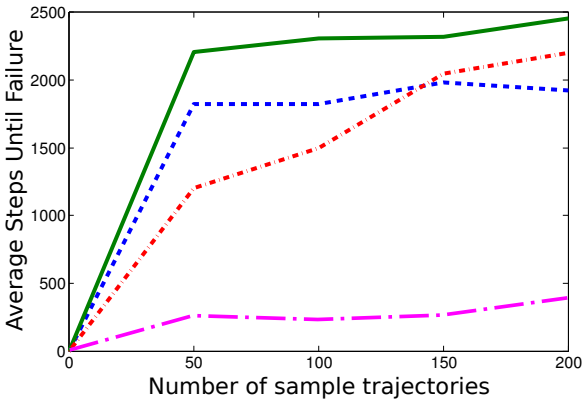

Figure 3: Average number of steps until failure vs. number of sample trajectories for the pendulum domain with Q-functions approximated with LARS-TD with policy iteration (violet, hashed), LSPI (red, hashed), RALP (blue [dark gray], dotted), and LS-RALP (green, solid).

7 Conclusion

In this paper, we have demonstrated the difficulties RALP can have in using noisy, sampled next states, and we have shown that the introduction of a smoothing function can mitigate these effects. Furthermore, we proved that as the amount of data is increased, error from inaccurate samples approaches zero. However, our experiments show drastic improvement with only a small number of samples.

In fairness, we also point out some limitations of our approach: LS-RALP makes stronger smoothness assumptions about the model and features than does RALP (continuous differentiability vs. the Lipschitz continuity necessary for the RALP bounds). LS-RALP also requires an additional parameter that must be tuned - the kernel bandwidth. We note, however, that the RALP work provides some guidance on choosing the regularization parameter and that there is a rich body of work in non-parametric regression that may give practical guidance on the selection of the bandwidth parameter.

The nonparametric regression literature notes that the bandwidth of a smoother can be adjusted not just for the total number of data points, but also for the density of data available in the particular neighborhood of interest [5]. The addition of this type of adaptiveness would greatly increase accuracy in areas of unusual density.

There are further opportunities to make better use of smoothing. First, we note that while smoothing the entire constraint has proven to be extremely useful, it is inevitable that applying two separate smoothing parameters to the reward and transition components would be even more helpful. For example, in the mountain-car experiments of Subsection 6.1, only the reward was noisy; applying smoothing to the reward, and not to the transition dynamics, would improve the approximation. The introduction of an automated technique of setting bandwidth parameters on two separate smoothing functions would likely result in more accurate approximations with less data.

Additionally, while the experiments done for this paper were extremely quick, this was due to the small number of samples needed. For larger, more complex domains, the LP can get large and may take a long time to solve; while LP solvers are generally thought of as efficient, identification of constraints doomed to be loose or features which will not be selected could cause a drastic improvement in the speed of this method.

Abstract

Multi-modal data collections, such as corpora of paired images and text snippets, require analysis methods beyond single-view component and topic models. For continuous observations the current dominant approach is based on extensions of canonical correlation analysis, factorizing the variation into components shared by the different modalities and those private to each of them. For count data, multiple variants of topic models attempting to tie the modalities together have been presented. All of these, however, lack the ability to learn components private to one modality, and consequently will try to force dependencies even between minimally correlating modalities. In this work we combine the two approaches by presenting a novel HDP-based topic model that automatically learns both shared and private topics. The model is shown to be especially useful for querying the contents of one domain given samples of the other.

1 INTRODUCTION

Analysis of objects represented by multiple modalities has been an active research direction over the past few years. If the analysis of a single modality is characterized as learning some sort of components that describe the data, the task in analysis of multiple modalities can be summarized as learning components that describe both the variation within each modality but also the variation shared between them (Klami and Kaski, 2008; Jia et al., 2010). The fundamental problem is in learning how to correctly factorize the variation into the shared and private components, so that the components can be intuitively interpreted. For continuous vector-valued samples the problem can be solved efficiently by a structural sparsity assumption (Jia et al., 2010; Virtanen et al., 2011), resulting in an extension of canonical correlation analysis (CCA) that models not only the correlations but also components private to each modality.

One prototypical example of multi-modal analysis is that of modeling collections of images and associated text snippets, such as captions or contents of a web page. When both text and image content can naturally be represented with bag of words -type vectors, the assumptions made by the above methods fail. Instead, such count data calls for topic models such as latent Dirichlet allocation (LDA): several extensions of LDA have been presented for multi-modal setups, including Blei and Jordan (2003); Mimno and McCallum (2008); Salomatin et al. (2009); Yakhnenko and Hovavar (2009); Rasiwasia et al. (2010) and Puttividhya et al. (2011). However, none of these extensions are able to find shared and private topics in the same sense as the CCA-based models do for continuous data. Instead, the models attempt to enforce strong correlation between the modalities, which is a reasonable assumption when analyzing e.g. multi-lingual textual corpora with similar languages but that does not hold for analysis of images associated with free-flowing text. In most cases, the images will contain a considerable amount of information not related to the text snippet, and it is not even guaranteed that the text is related at all to the visual content of the image.

In this work, we introduce a novel topic model that combines the two above lines of work. It builds on the correlated topic models (CTM) by Blei and Lafferty (2007) and Paisley et al. (2011), by modeling correlations between topic allocations and by using a hierarchical Dirichlet process (HDP) formulation for automatically learning the number of the topics. The proposed factorized multi-modal topic model integrates the technical improvements of these single-modality topic models to the multi-modal application, and in particular automatically learns to make some topics

specific to each of the modalities, implementing the factorization idea of Klami and Kaski (2008) and Jia et al. (2010) used for continuous data. The component selection plays a crucial role in implementing this property, implying that the HDP-based technique for automatically selecting the complexity is even more important for factorized multi-modal models than it would be a for a regular topic model.

The primary advantage of the new model is that is does not enforce correlations between the modalities, like the earlier multi-modal topic models do, but instead factorizes the variation into interpretable topics describing shared and private structure. The model is very flexible and does not enforce any particular factorization structure, but instead learns it from the data. For example, the model can completely ignore the shared topics in case the modalities are independent or find almost solely shared topics when they are strongly correlated. In this work we demonstrate the model in analyzing modalities that have only weak relationships, a scenario for which the previous models would not work. In particular, we analyze a collection of Wikipedia pages that consist of images and the whole text on the page. Such a collection has relatively low between-modality correlation and in particular includes considerable amount of text that is not related to the image at all, necessitating topics private to the text modality. The proposed model is shown to clearly outperform alternative HDP-based topic models as well as correspondence LDA (Blei and Jordan, 2003) in the task of inferring the contents of a missing modality.

2 BACKGROUND: TOPIC MODELS

To briefly summarize the topic models and to introduce the notation used in the paper, we describe the standard topic model of Latent Dirichlet Allocation (LDA) (Blei et al., 2003) through its generative process. We assume that words occurring in a document are drawn from K topics. Each topic specifies a multinomial probability distribution over the vocabulary, parameterized through $\boldsymbol{\eta}_k$ drawn from the Dirichlet distribution $\mathrm{Dir}(\gamma\mathbf{1})$, and the topic proportions are multinomial with parameters $\boldsymbol{\theta} \sim \mathrm{Dir}(\nu\mathbf{1})$. The documents are generated by repeatedly sampling a topic indicator $z \sim \mathrm{Multi}(\boldsymbol{\theta})$ and then drawing a word from the corresponding topic as $x \sim \mathrm{Multi}(\boldsymbol{\eta}_z)$.

We will also heavily depend on the concept of correlated topic models (CTM) (Blei and Lafferty, 2007). In the standard LDA the topic proportions $\boldsymbol{\theta}$ drawn from the Dirichlet distribution become independent except for weak negative correlation stemming from the normalization constraint. CTM replaces this choice by logistic normal distribution, first drawing an auxiliary variable from a Gaussian distribution $\boldsymbol{\xi} \sim \mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ and specifying the topic distribution as $\boldsymbol{\theta} \propto \exp(\boldsymbol{\xi})$. The topics become correlated when $\boldsymbol{\Sigma}$ is not diagonal, and empirical experiments show increased predictive accuracy.

Finally, our model will be formulated through a hierarchical Dirichlet process (HDP) formulation (Teh et al., 2006), to enable automatic choice of the number of topics. As mentioned in the introduction, the choice is even more critical for multi-modal models, since we will have several sets of topics instead of just a single one; specifying the complexity for all of those in advance would not be feasible. Our model will use elements from the recently introduced Discrete Infinite Logistic Normal (DILN) model by Paisley et al. (2011), which incorporates HDP into CTM. The key idea of DILN is that the topic distributions $\boldsymbol{\theta}$ are made sparse by multiplying the $\exp(\boldsymbol{\xi})$ by sparse topic-selection terms. The topic distribution is given by $\boldsymbol{\theta}_k \propto \mathrm{Gamma}(\beta\mathbf{p}_k, \exp(-\boldsymbol{\xi}_k))$, where both β and $\mathbf{p}_k$ come from a stick-breaking process: β is the second level consentration parameter, and $\mathbf{p}_k = V_k \prod_{i=1}^{k-1}(1 - V_i)$, where $V_k \sim \mathrm{Beta}(1, \alpha)$ with α as the first level concentration parameter. The expected value of $\boldsymbol{\theta}_k$ is proportional to $\beta\mathbf{p}_k \exp(\boldsymbol{\xi}_k)$, illustrating the way the different parameters influence the topic weights. For any finite data collection, $\mathbf{p}_k > 0$ only for a finite subset of topics and hence the model automatically selects the number of topics.

3 FACTORIZED MULTI-MODAL TOPIC MODEL

Consider a collection of documents each containing M weakly correlated modalities, where each modality has its own vocabulary. In the application of this paper the two vocabularies are textual and visual words collected from Wikipedia pages with text and a single image (though the model would directly generalize to multiple images). We introduce a novel multi-modal topic model that can be used to learn dependencies between these modalities, enabling e.g. predicting the textual content associated with a novel image. The problem is made particularly challenging by the weak relationship between the modalities; several of the documents will contain large amounts of text not related to the image content.

For modeling the data, we will use M separate vocabularies, so that words (or visual words) for each modality are drawn from separate dictionaries $\boldsymbol{\eta}^{(m)}$ specific to each view m. The topic proportions $\boldsymbol{\theta}^{(m)}$ will also be specific to each modality, whereas the actual words are sampled independently for each modal-

ity given the topic proportions. The essential modeling question is then how the topic proportions are tied with each other, in order to achieve the factorization into shared and private topics. In brief, we will do this by (i) modeling dependencies between topics both within and across modalities and (ii) automatically selecting the number of topics for each type (shared or private to any of the modalities).

The topic proportions $\boldsymbol{\theta}^{(m)}$ are made dependent by introducing auxiliary variables $\boldsymbol{\xi}^{(m)}$, denoting by $\boldsymbol{\xi} = (\boldsymbol{\xi}^{(1)}, ..., \boldsymbol{\xi}^{(M)})$ the concatenation of them, and using the CTM prior $\boldsymbol{\xi} \sim \mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. This part of the model corresponds to the 'multi-field CTM with different topic sets' by Salomatin et al. (2009), and the different blocks in $\boldsymbol{\Sigma}$ describe different types of dependencies between the topic proportions. In particular, the blocks around the diagonal describe dependencies between the topic proportions of each modality, whereas the off-diagonal blocks describe dependencies in topic proportions between the modalities.

Having a CTM for the joint topic distribution is not yet sufficient for separating the shared topics from private ones, since we can only control the correlation between the topic proportions. A large correlation between two topics for different modalities would imply that it is shared, but lack of correlation (that is, $\boldsymbol{\Sigma}_{kl} = 0$) would not make either component private. Instead, the weights would simply be determined independently. To create separate sets of shared and private topics we need to be able to switch some of the topics off in one or more of the modalities, similarly to how Jia et al. (2010) and Virtanen et al. (2011) switch off components to make the same distinction in continuous data models. In the case of multi-field CTM this could only be done by driving $\boldsymbol{\mu}_k$ (the mean of the Gaussian prior for $\boldsymbol{\xi}_k$) towards minus infinity, which is not encouraged by the model and is difficult to achieve with mean-field updates.

We implement the shared/private choice by separate HDPs, one for each modality, switching a subset of topics off for each modality separately by a mechanism similar to how the single-view DILN model (Paisley et al., 2011) selects the topics. We introduce $\beta^{(m)}$ and $\mathbf{p}^{(m)}$ for each modality $m = 1, ..., M$, and draw them from separate HDPs, resulting in $\boldsymbol{\theta}^{(m)} \propto \mathrm{Gamma}(\beta^{(m)}\mathbf{p}^{(m)}, \exp(-\boldsymbol{\xi}^{(m)}))$ as the final topic proportions. The topic distributions are still shared through $\boldsymbol{\xi}^{(m)}$ that were drawn from a single high-dimensional Gaussian, but for each modality the stick weights $\mathbf{p}^{(m)}$ select different subsets of topics to be switched off. In the end, a finite number of topics remain for each modality, and the private topics can be identified as ones that have non-zero weight for one modality and are not correlated with topics active in other modalities.

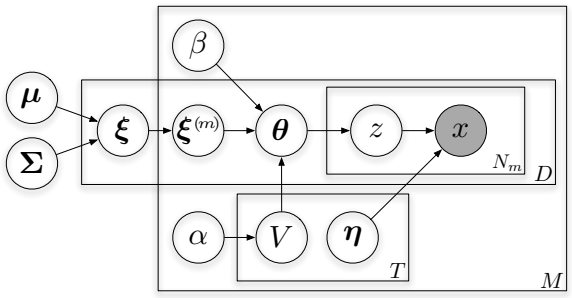

Figure 1: A graphical representation of the factorized multi-modal topic model. The data has D documents described by M modalities. For each modality, the words $\mathbf{x}^{(m)}$ are drawn from dictionary specific to that modality, according to topic proportions $\boldsymbol{\theta}^{(m)}$ also specific to the modality. The topic proportions are generated by logistic transformation of latent variables $\boldsymbol{\xi}^{(m)}$ that model the correlations between the topics both within and across modalities, followed by topic selection with a HDP (denoted by V and β in the plate; see text for details) for each modality. As a result, the model learns both topics modeling correlations between the modalities as well as topics private to each modality.

The final generative model motivated by the above discussion results in a collection of M correlated BOW data sets $\mathbf{X}^{(m)}$, generated as follows (see Figure 1 for graphical representation). For the whole collection we:

- create a dictionary of $T^{(m)}$ topics for each modality by drawing $\boldsymbol{\eta}_k^{(m)} \sim Dir(\gamma^{(m)}\mathbf{1})$ for $k = 1, .., T^{(m)}$
- draw the parameters $\alpha^{(m)}, \beta^{(m)}, V^{(m)}$ of the DILN distribution for each modality from the stick-breaking formulation and construct $\mathbf{p}^{(m)}$.

For each document d we then draw $\boldsymbol{\xi} \sim \mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ and partition it into the different modalities as $\boldsymbol{\xi} = (\boldsymbol{\xi}^{(1)}, ..., \boldsymbol{\xi}^{(M)})$. For each modality, we then generate the words independently as follows:

- form the topic proportion by drawing $Y_k^{(m)} \sim \mathrm{Gamma}(\beta^{(m)}\mathbf{p}_k^{(m)}, \exp(-\boldsymbol{\xi}_k^{(m)}))$ and set $\boldsymbol{\theta}_k^{(m)} = \frac{Y_k^{(m)}}{\sum_{i=1}^{T^{(m)}} Y_i^{(m)}}$
- draw $N^{(m)}$ words by choosing a topic $z \sim \mathrm{Multi}(\boldsymbol{\theta}^{(m)})$ and drawing a word $x \sim \mathrm{Multi}(\boldsymbol{\eta}_z^{(m)})$

3.1 INFERENCE

For learning the model parameters we use a truncated variational approximation following closely the algorithm given by Paisley et al. (2011), the main difference being that we have M separate sets of $\boldsymbol{\eta}$, β and $\mathbf{p}$, one for each modality. The above generative process is truncated by setting $V^{(m)}_{T^{(m)}} = 1$, forcing the stick lengths beyond the truncation level $T^{(m)}$ to be zero, and the resulting factorized approximation is given by

$$Q = \prod_{m=1}^{M}\prod_{d=1}^{D}\prod_{n_m=1}^{N_m}\prod_{k=1}^{T} q(z^{(m)}_{dn_mk})q(Y^{(m)}_{dn_mk})q(\xi^{(m)}_{dk})q(\boldsymbol{\eta}^{(m)}_{k})$$
$$q(V^{(m)}_{k})q(\alpha_m)q(\beta_m)q(\boldsymbol{\mu})q(\boldsymbol{\Sigma}),$$

where to simplify notation we assume $T_m = T \;\forall\; m$. The algorithm proceeds by updating each factor in turn while keeping the others fixed, using either gradient ascent or analytic solution for maximizing the lower bound of the approximation for each of the terms (see Paisley et al. (2011) for details).

The main difference in the algorithms comes from updating $\boldsymbol{\xi}$, since in our case it goes over M sets of topics instead of just one, yet the activities within each set are governed by separate HDPs. We use a diagonal Gaussian factor $q(\boldsymbol{\xi}) = \mathrm{N}(\tilde{\boldsymbol{\xi}}, \mathrm{diag}(\tilde{\mathbf{v}}))$, where $\tilde{\mathbf{v}}$ denotes the variances of the dimensions, and use gradient ascent for jointly updating the parameters. To simplify notation we use $\boldsymbol{\xi}$ and $\mathbf{v}$ to denote the expectation and variance of the factorial distribution. The relevant part of the lower bound is

$$\begin{aligned}\mathcal{L}_{\boldsymbol{\xi},\mathbf{v}} = &-\sum_{m=1}^{M}\beta^{(m)}{\mathbf{p}^{(m)}}^T\boldsymbol{\xi}^{(m)} \\ &-\sum_{m=1}^{M}\mathbb{E}[\boldsymbol{\theta}^{(m)}]^T\mathbb{E}[\exp(-\boldsymbol{\xi}^{(m)})] \\ &-(\boldsymbol{\xi}-\boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\boldsymbol{\xi}-\boldsymbol{\mu})/2 \\ &-\mathrm{diag}(\boldsymbol{\Sigma}^{-1})^T\mathbf{v}/2 + \log(\mathbf{v})^T\mathbf{1}/2.\end{aligned} \tag{1}$$

Here $\boldsymbol{\Sigma}^{-1}$ couples the separate $\boldsymbol{\xi}^{(m)}$ terms in the partial derivatives as

$$\begin{aligned}\frac{\partial\mathcal{L}_{\boldsymbol{\xi},\mathbf{v}}}{\partial\boldsymbol{\xi}^{(m)}} = &-\beta^{(m)}\mathbf{p}^{(m)} + \mathbb{E}[\boldsymbol{\theta}^{(m)}]\mathbb{E}[\exp(-\boldsymbol{\xi}^{(m)})] \\ &-(\boldsymbol{\Sigma}^{-1})_{m,m}(\boldsymbol{\xi}^{(m)}-\boldsymbol{\mu}^{(m)}) \\ &-\sum_{j\neq m}(\boldsymbol{\Sigma}^{-1})_{m,j}(\boldsymbol{\xi}^{(j)}-\boldsymbol{\mu}^{(j)}),\end{aligned}$$

with $(\boldsymbol{\Sigma}^{-1})_{i,j}$ denoting a block of $\boldsymbol{\Sigma}^{-1}$ corresponding to modalities i and j. The inverse of $\boldsymbol{\Sigma}$ remains constant during the gradient descent, and hence only needs to be evaluated once for every time the factor $q(\boldsymbol{\xi})$ is updated.

We use maximum marginal likelihood to update $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ resulting in closed form updates

$$\boldsymbol{\mu} = \frac{1}{D}\sum_{d=1}^{D}\boldsymbol{\xi}_d$$
$$\boldsymbol{\Sigma} = \sum_{d=1}^{D}\big((\boldsymbol{\xi}_d-\boldsymbol{\mu})(\boldsymbol{\xi}_d-\boldsymbol{\mu})^T + \mathrm{diag}(\mathbf{v}_d)\big)/D.$$

3.2 PREDICTION

The model structure is well suited for prediction tasks, where the task is to infer missing modalities for a new document given that one of them is observed (e.g. infer the caption given the image content). This is because the correlations between the topic proportions provide a direct link between the modalities, and the private topics explain away all the variation that is not useful for predictions.

Here we present the details of the prediction for the special case with just one observed modality (j) and one missing modality (i). Given the observed data we first infer the topic proportions $\hat{\boldsymbol{\theta}}^{(j)}$ and then auxiliary variable $\hat{\boldsymbol{\xi}}^{(j)}$ by maximizing a cost similar to (1), but only using the newly inferred topic proportions of the observed modality and the corresponding part of $\boldsymbol{\Sigma}$. As $\hat{\boldsymbol{\xi}}$ comes from a Gaussian distribution we can infer $\hat{\boldsymbol{\xi}}^{(i)}$ given $\hat{\boldsymbol{\xi}}^{(j)}$ with the standard conditional expectation as

$$\begin{aligned}\hat{\boldsymbol{\xi}}^{(i)} &= \boldsymbol{\mu}^{(i)} + \boldsymbol{\Sigma}_{i,j}\boldsymbol{\Sigma}^{-1}_{j,j}(\hat{\boldsymbol{\xi}}^{(j)} - \boldsymbol{\mu}^{(j)}) \\ &= \boldsymbol{\mu}^{(i)} + \mathbf{W}(\hat{\boldsymbol{\xi}}^{(j)} - \boldsymbol{\mu}^{(j)}).\end{aligned} \tag{2}$$

Here $\mathbf{W}$ involves the corresponding part of the between-topic covariance matrix $\boldsymbol{\Sigma}$ as indicated above, and can be seen as a projection matrix transforming the components of one modality to another. Finally, the newly estimated $\hat{\boldsymbol{\xi}}^{(i)}$ for the missing views is converted back to the expecteed topic proportion $\hat{\boldsymbol{\theta}}$ by exponentiation and multiplying with the corresponding stick lengths $\mathbf{p}^{(i)}$.

3.3 SHARED AND PRIVATE TOPICS

The key novelty of the model is its capability to learn both topics that are shared and that are private to each modality, without needing to specify them in advance. Since the way these topics appear is by no means transparent in the above formulation, we will here discuss the property in more detail. In brief, the distinct nature for the topics comes from an interplay of the correlations between the topics of different modalities and the HDP procedure that turns some of the topics off

for each modality. In particular, neither of these properties alone would be sufficient.

As mentioned already in Section 3, merely having separate $\boldsymbol{\xi}^{(m)}$ drawn from a single Gaussian is not sufficient for finding private topics. At best, the correlation structure can specify that the weights will be independent for the modalities. Next we explain how the other key element of the model, separate selection of active topics for each modality, is not sufficient alone either. We do that by considering a special case of the model that assumes equal $\boldsymbol{\xi} = \boldsymbol{\xi}^{(m)}$ for all views but has separate stick-breaking processes switching some of the topics off for each of the views. We call this alternative model mmDILN, due to the fact how it implementes multi-modal LDA of Blei and Jordan (2003) with DILN-style component selection.

Intuitively, mmDILN model could find private topics simply by setting $\mathbf{p}_k^{(m)}$ to small value for topics that are not needed in that modality. However, it cannot make correct predictions from one modality to another, and hence fails in achieving one of the primary goals for shared-private factorizations. If $\mathbf{p}_k^{(m)}$ is small then the model has no information for inferring $\boldsymbol{\xi}_k$ from that view, and hence also all other elements $\boldsymbol{\xi}_l$ that correlate with $\boldsymbol{\xi}_k$ will be incorrect. If $\boldsymbol{\xi}_k$ was an important topic for the other view, the predictions will be severely biased. Our model avoids this issue by having the separate $\boldsymbol{\xi}^{(m)}$ parameters, leading to correct across-modality predictions as described in the previous section. In the experimental section we will empirically compare the proposed model with mmDILN, demonstrating how mmDILN indeed has very poor predictive accuracy despite modeling the training data almost as well. Hence, even though the structure is in principle sufficient for learning private topics, the model has no practical value as a shared-private factorization.

In order to recognize the nature of each of the topics, we need to look at both the covariance $\boldsymbol{\Sigma}$ between the topic weights and the modality-specific stick weights $\mathbf{p}_k^{(m)}$. Since the topics can be (potentially strongly) correlated both within and across modalities, we can identify private topics only by searching for topics that do not correlate with any topic that would be active in any other modality. In the experiments we demonstrate how the topics can be ranked according to how strongly they are shared with another modality, by inspecting the elements of $\boldsymbol{\Sigma}$.

4 RELATED WORK

In this section we relate the model to other approaches for modeling multi-modal count data.

4.1 MULTI-MODAL TOPIC MODELS

The multi-modal extension of LDA (mmLDA) by Blei and Jordan (2003) and its non-parametric version mmHDP by (Yakhnenko and Hovavar, 2009) assume all modalities to share the same topic proportions, and essentially extend LDA only by having separate dictionaries for each modality and generating the words for the domains independently. For many real world data sets the assumption of identical topic proportions is too strong, and the model tries to enforce correlations even when they do not exist. While the assumption may help in picking up topics that would be weak in either modality alone, it makes identifying the true correlations almost impossible.

Such models fail especially when modeling data having strong private topics in one modality. Since the topic proportions are shared, the topic must be present in other modalities as well and becomes associated with a dictionary that merely replicates the overall distribution of the words. Such topics are particularly harmful for prediction tasks. When the dictionary of a topic matches that of the background word distribution, it will be present in every document in that modality. For example, when predicting text from images we could learn to associate politics (a strong topic private to the text modality) with the overall visual word distribution, resulting in all of the predictions including terms from the politics topic.

Salomatin et al. (2009) took a step towards our model with their multi-field CTM. It extends CTM by introducing separate $\boldsymbol{\xi}^{(m)}$ for each modality, similarly to our model. However, as described in the previous section the separate topic proportions are not yet sufficient for separating the shared topics from private ones.

4.2 CONDITIONAL TOPIC MODELS

Lots of recent work on multi-modal topic modeling framework has focused on building conditional models, largely for image annotation task. Correspondence LDA (corrLDA) proposed simultaneously to mmLDA in (Blei and Jordan, 2003) is a prominent example, assuming that the image is generated first and the text depends on the image content. Both modalities are assumed to share the same topic weights. While such models are very useful for modeling the conditional relationship, they do not treat the modalities symmetrically as in our model. Recently Puttividhya et al. (2011) proposed an extension of corrLDA, replacing the identical topic distributions with a regression module from image topics to the textual annotation topics. The added flexibility results in better predictive performance, but the model remains a directional one,

in contrast to our model that generates all modalities with equal importance. For applications treating only two modalities and having a specific task that makes one of them more important (say, image annotation) the conditional models often work well. However, they do not easily generalize to multiple modalities and are not flexible in terms of the eventual application.

Other conditional models focus on conditioning on meta-data, such as author or link structure (Mimno and McCallum, 2008; Hennig et al., 2012). Such models allow integrating data that are not necessarily in count format, but the same distinction of directional versus generative applies. However, this family of models could be integrated with our solution, incorporating a meta-data link into our multi-modal model. In essence, the choice of whether meta-data is modeled or not is independent of the choice of how many count data modalities the data has.

4.3 CANONICAL CORRELATIONS

As described earlier, the model bears close resemblance to how CCA models correlations between continuous data, the similarities being most apparent with the recent re-interpretations of CCA as shared-private factorization (Klami and Kaski, 2008; Jia et al., 2010). The technical details of the solutions are, however, very different as the normalization of topic proportions makes the techniques used for continuous data not feasible for topic models.

Despite the mismatch of data types, CCA can be used for modeling count data as well. The most promising direction would be to apply kernel-CCA, but there are no obvious choices for the kernel function that would directly match the analysis of image-text pairs. As one practical remedy, (Rasiwasia et al., 2010) combined CCA and LDA directly by first estimating a separate LDA model for each modality and then combining the resulting topic proportions with CCA. Our approach does not rely on two separate analysis steps that do not result in directly interpretable private topics.

5 EXPERIMENTS AND RESULTS

5.1 DATA AND MEASURES

We validate the model on real data collected from Wikipedia[1]. We constructed a data collection with $D = 20,000$ documents, each consisting of a single image represented with 5000 SIFT patches and text (the contents of the whole Wikipedia page) represented with a vocabulary of 7500 most frequent terms, after stopword removal. We make a random 50/50-split into test and train data. To demonstrate the ability of the proposed model to correctly model the relationships between the two modalities, we evaluate the model with conditional perplexity of a missing modality for a new sample:

$$\mathcal{P}^{(m)}_{\text{train}} = \exp\left(- \frac{\sum_{d \in D_{train}} \log p(\mathbf{x}^{(m)}_d)}{\sum_{d \in D_{train}} \mathbf{x}^{(m)}_d} \right)$$

$$\mathcal{P}^{(i)|(j)}_{\text{test}} = \exp\left(- \frac{\sum_{d \in D_{test}} \log p(\mathbf{x}^{(i)}_d | \mathbf{x}^{(j)}_d)}{\sum_{d \in D_{test}} \mathbf{x}^{(i)}_d} \right),$$

where $\mathbf{x}^{(m)}_d$ denotes concatenation of $N^{(m)}_d$ words. These quantities measure how well the model can relate the visual content to the textual content, corresponding to the document completion task of Wallach et al. (2009) but computed across modalities.

We compare our model to three alternatives representing various kinds of multi-modal topic models: mmDILN (Section 3.3), mmHDP (Section 4.1) and corrLDA (Section 4.2). Both mmDILN and mmHDP are comparable to our model in making automatic topic number selection and modeling both modalities symmetrically. Consequently, the experiments will focus on demonstrating the importance of finding the correct factorization into shared and private topics. The corrLDA is included as an example of a conditional model that gives an alternative approach to solving a similar prediction task. Note that we need to learn two separate corrLDA models, one for predicting text from images and one for the other direction, whereas the other models can do both types of predictions. For corrLDA we use 100 topics (the threshold we used for nonparametric models).

5.2 INFERENCE SPEED

First we show that the variational approximation used for inference is efficient. Figure 2 shows how the algorithm converges for both $N = 400$ and $N = 10000$ documents already after some tens of iterations. For both experiments we used a maximum of $T = 100$ topics. The convergence of mmHDP and mmDILN is similar (not shown).

5.3 PREDICTING TEXT FROM IMAGES AND VISE VERSA

Figure 3 shows the evaluation for training and test sets for the proposed model and the comparison methods, measured as the perplexity on training data and the conditional perplexity of images given the text and text given the images. The proposed method, which is more flexible than the alternatives, reaches better

[1] Available from `http://www.eecs.berkeley.edu/~jiayq/`

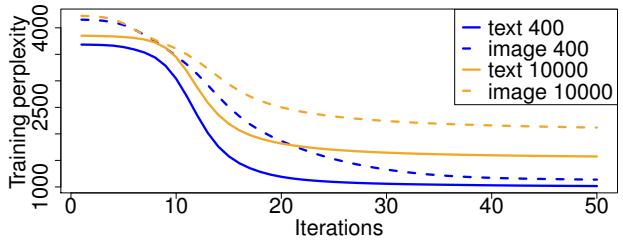

Figure 2: Training perplexity as function of algorithm iterations.

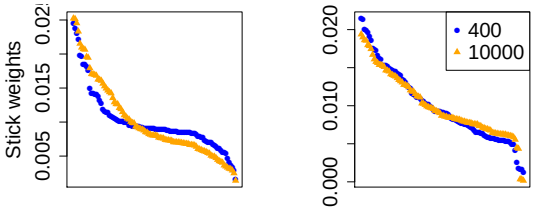
(lower) perplexity on the training and testing data due to being able to describe both variation not shared by the other modality without needing to introduce noise topics.

A notable observation is that the baseline methods perform worse at predicting text from images as the amount of training data increases. This illustrates clearly the fundamental problem in modeling multi-modal collections without separate private topics. Since the text documents are easier to model than the images, the alternative models start to focus more and more on modeling the text when there is large amount of data. The dominant topics start describing the text alone, yet they are also active in the image modality but with a topic that does not contain any information. Given a new image sample, the estimated topic proportions will be arbitrary and hence do not enable meaningful prediction. The proposed model, however, learns to make those textual topics private to the text modality, while capturing weaker correlations between the two modalities with shared topics. The model still cannot predict textual information not correlated with the image content, but it learns correctly not to even attempt that and manages to make accurate predictions for the aspects that are correlated.

5.4 SHARED AND PRIVATE TOPICS

To illustrate how the HDP-formulation chooses the topics, we visualize the stick parameters $\mathbf{p}$ in Figure 4. First, we notice that the last sticks have close to zero weight, indicating that the chosen truncation level $T = 100$ is sufficient. More importantly, we see that the weights for the text and image topics are different (the image topics are more spread out), motivating the choice of separate weights for the modalities.

To further understand how the proposed model is able to find both shared and private topics, we explore the nature of the individual topics. Since the SIFT vocabulary is not easily interpretable by visual inspection, we illustrate the property for the textual topics. For each textual topic we measure the amount of correlation between the other modality by inspecting the correlation structure in $\mathbf{\Sigma}$, and then rank the topics according to this measure. This results in a ranked list of the text topics, the first ones being strongly shared by the two modalities while the last ones are private to the text modality.



(a) Our model: text (b) Our model: image

Figure 4: Visualization of stick parameter $\mathbf{p}$ of the proposed model for the text modality (a) and the image modality (b) reveals how they are not identical for the two modalities. Both figures show the weights for two models learned with 400 and 10,000 documents, revealing how the distribution is learned fairly accurately already from a small collection.

More specifically, denoting the separate blocks in the covariance matrix as

$$\mathbf{\Sigma} = \begin{pmatrix} \mathbf{\Sigma}_{t,t} & \mathbf{\Sigma}_{t,i} \\ \mathbf{\Sigma}_{i,t} & \mathbf{\Sigma}_{i,i} \end{pmatrix}, \quad (3)$$

we convert it to a correlation matrix, $\mathbf{\Omega}$, threshold small values out (we used a threshold of 0.2) and extract the cross-correlation between textual (rows) and visual topics (columns), to get $\mathbf{\Omega}_{t,i}$. Then for each textual topic we define visual relevance, $\boldsymbol{\rho}_k$, as row mean of absolute values of $\mathbf{\Omega}_{t,i}$, written as $\boldsymbol{\rho} = \frac{1}{T}|(\mathbf{\Omega}_{t,i})|\mathbf{1}$ [2]. This quantity captures general and rich visual combinations that co-occur with the textual topics, and it is worth noticing how the measure is very general: It allows multiple visual topics to correlate with one textual topic (and vise versa), and includes both positive and negative correlations that are typically equally relevant (negative correlation can be seen as absence of a visual component) (See Figure 5 for demonstration).

The textual topics are ranked according to $\boldsymbol{\rho}$ in Figure 6 . There are a few very strong shared topics between text and image modalities, and at the end of the list we have several topics private to the text modality, indicated by zero correlation with the image modality. This matches with the intuition that the full text of a Wikipedia page cannot be mapped to the image content in all cases. Table 1 summarizes the six text topics most strongly correlating with the image modality, as well as six topics that are private

[2]We also tried using the maximum element instead of the mean; it results in fairly similar ranking.

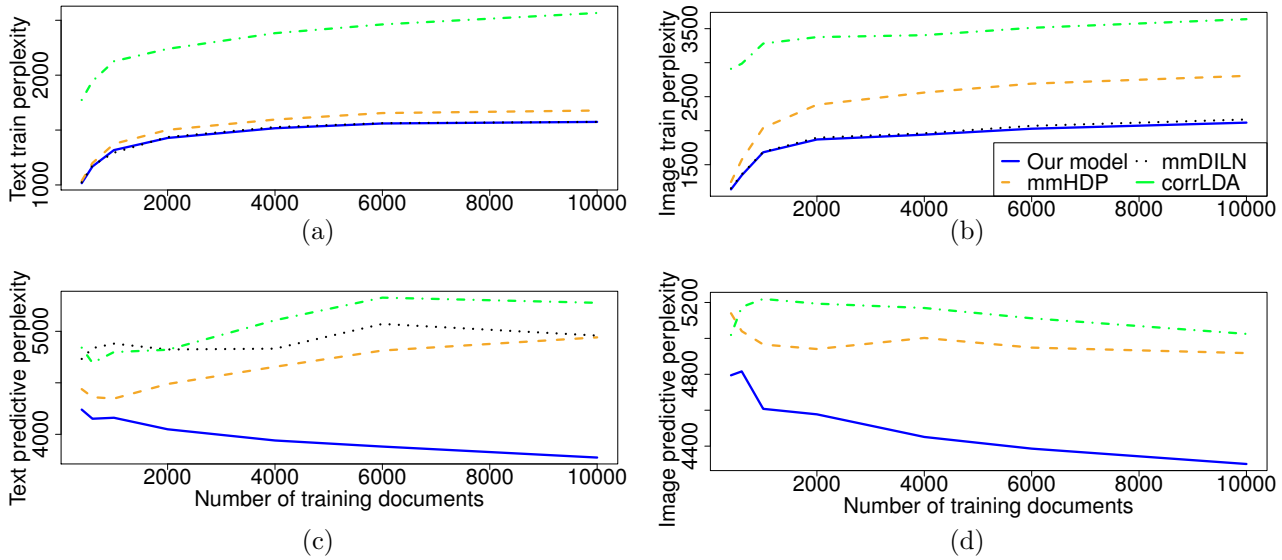


Figure 3: Training and test perplexities (lower is better) for the two modalities. For training data we show the perplexity of modeling the text (a) and images (b) separately. For test data, we show the conditional perplexity of predicting text from images (c) and predicting images from text (d), corresponding to the document completion task used for evaluating topic models. The proposed method outperforms the comparison ones in all respects. The comparison methods mmHDP, mmDILN and corrLDA that are not able to extract topics private to either modality are not able to learn good predictive models, demonstrated especially by the error increasing as a function of training samples in (c). The image prediction perplexity for mmDILN is outside the range depicted in (d), above 5400 for all training set sizes.

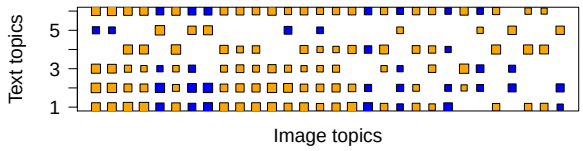

Figure 5: Illustration of part of cross-correlation between text topics and image topics corresponding to subset of $\mathbf{\Omega}_{(t,i)}$, where yellow represents positive correlations, and blue represents negative ones. The size of the boxes corresponds to the absolute value.

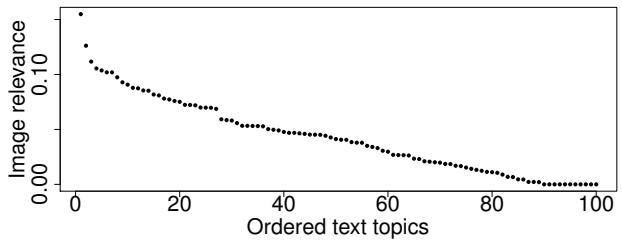

Figure 6: Text topics ordered according to visual relevance $\boldsymbol{\rho}$. We see that there are a few strongly correlating topics, and that the model has found roughly 10 topics that are private to the text domain. Note that such topics may still be important for modeling the whole multi-modal corpus, whereas they do not contribute to the cross-modal information transfer.

to the text modality, revealing very clear interpretations. The most strongly correlating topic covers airplanes, which are known to be easy to recognize from the images due to the distinct shapes and background. The second topic is about maps that also have clear visual correspondence, and the other strongly correlated topics also cover clearly visual concepts like buildings, cars and railroads. The topics private to the text domain, in turn, are about concepts with no clear visual counterpart: economy, politics, history and research. In summary, the model has separated the components nicely into shared and private ones, and provides additional interpretability beyond regular multi-modal topic models.

6 DISCUSSION

Our paper ties together two separate lines of work for analysis of multi-modal data. In particular, we created a novel multi-modal topic model which extends earlier tools for analysis of multi-modal count data by incorporating elements found useful in the continuous-valued case. We explained how learning topics private to each modality is of crucial importance while modeling modalities with potentially weak correlations, and

Table 1: Text topics ranked according to visual relevance, summarized by the words with highest probability. The topic indices match the ranking in Figure 6. The shared topics have clear visual counterparts, whereas the private ones do not relate with any kind of visual content.

demonstrated empirically how such a property can only be obtained by combining two separate elements: modeling correlations between separate topic weights for each modality, and learning modality-specific indicators switching unnecessary topics off. For implementing these elements we combined state-of-art techniques in topic models, integrating the DILN distribution (Paisley et al., 2011) into a model similar to the multi-field correlated topic model of Salomatin et al. (2009), to create an efficient learning algorithm readily applicable for relatively large document collections.

Abstract

Understanding the adaptation process of plants to drought stress is essential in improving management practices, breeding strategies as well as engineering viable crops for a sustainable agriculture in the coming decades. Hyper-spectral imaging provides a particularly promising approach to gain such understanding since it allows to discover non-destructively spectral characteristics of plants governed primarily by scattering and absorption characteristics of the leaf internal structure and biochemical constituents. Several drought stress indices have been derived using hyper-spectral imaging. However, they are typically based on few hyper-spectral images only, rely on interpretations of experts, and consider few wavelengths only. In this study, we present the first data-driven approach to discovering spectral drought stress indices, treating it as an unsupervised labeling problem at massive scale. To make use of short range dependencies of spectral wavelengths, we develop an online variational Bayes algorithm for latent Dirichlet allocation with convolved Dirichlet regularizer. This approach scales to massive datasets and, hence, provides a more objective complement to plant physiological practices. The spectral topics found conform to plant physiological knowledge and can be computed in a fraction of the time compared to existing LDA approaches.

1 Introduction

Water scarcity is a principal global problem that causes aridity and serious crop losses in agriculture. It has been estimated that drought can cause a depreciation of crop yield up to 70% in conjunction with other abiotic stresses (Boyer, 1982; Pinnisi, 2008). Climate changes and a growing human population in parallel thus call for a sincere attention to advance research on understanding of plant adaptation under drought. A deep knowledge of the adaptation process is essential in improving management practices, breeding strategies as well as engineering viable crops for a sustainable agriculture in the coming decades. Accordingly, there is a dire need for crop cultivars with high yield and strong resistance against biotic and abiotic stresses.

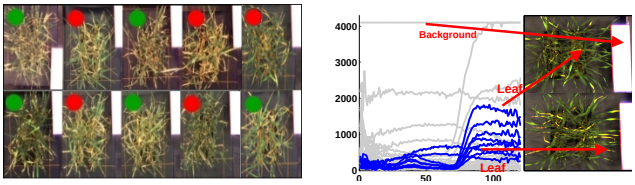

Figure 1: What are the specific spectral characteristics of plants suffering from drought stress? (Left) A collection of hyper-spectral images (projected to RGB space) within the flowering period. Stressed plants are indicated by red dots, control plants by green dots. Visually it is difficult to distinguish between control and stressed plant; compare e.g. the 2nd and 3rd image in the bottom row. (Right) Example spectral signatures taken from a hyper-spectral image for leaf and background pixels. (Best viewed in color)

Unfortunately, understanding stress is not an easy task. Stress resistance is the result of a complex web of interactions between the genotype and the environment leading to phenotypic expressions. It is contributed by a number of related traits that are controlled mostly by polygenic inheritance. In the past, a slow progress in the development of improving cultivars was mainly due to poor understanding of genetic factors that impact tolerance to drought (Passioura, 2002). Recently, progress has been made in under-

*Both authors contributed equally. °Contact author: mirwaes.wahabzada@iais.fraunhofer.de

standing the genetic basis of drought related quantitative trait loci (QTL), see e.g. (Lebreton et al., 1995; McKay et al., 2008). More recently, OMICS approaches have offered a direct molecular insight into drought tolerance mechanism, see e.g. (Rabbani et al., 2010; Guo et al., 2010; Abdeen et al., 2010). However, genetic and biochemical approaches are time consuming and still fail to fully predict the performance of new lines in the field. In recent years it is discussed that phenomic approaches, that measure the structural and functional status of plants may overcome the limited predictability and some authors have attributed this lack of high throughput phenomic data as the "phenomic bottleneck" (Richards et al., 2010).

Hyper-spectral imaging provides a particularly promising approach to sensor-based phenotyping. Its measurements were observed to contain early indicators of plant stress, see e.g. (Rascher et al., 2007; Rascher and Pieruschka, 2008). In contrast to conventional cameras, which record only 3 wavelengths per pixel, hyper-spectral cameras record a spectrum of several hundred wavelengths ranging from approximately 300nm to 2500nm resulting in big data cubes. These spectra contain information as to changes of the pigment composition of leaves which are the result of metabolic processes involved in plant responses to biotic or abiotic stresses. This information can be used e.g. using SVMs for classification of hyper-spectral signatures and in turn for prediction of biotic stress before symptoms become visible to the human eye, see e.g. (Rumpf et al., 2010; Römer et al., 2010), or for finding archetypical signatures (Kersting et al., 2012).

More important for the present study, hyper-spectral imaging was proven to be successful in discovering relationship between the spectral reflectance properties of vegetation and the structural characteristics of vegetation and pigment concentration in leaves (Govender et al., 2009); the spectral characteristics of vegetation are governed primarily by scattering and absorption characteristics of the leaf internal structure and biochemical constituents, such as pigments (e.g. chlorophyll a and b), water, nitrogen, cellulose and lignin, see (Curran et al., 1990; Gitelson and Merzlyak, 1996; Blackburn, 2007; Govender et al., 2009) and references in there). For instance, Gitelson and Merzlyak (1996) observed a increase of reflectance for the band 670nm if the amount of chlorophyll in the leaf was dropped as it is case in the presence of drought stress.

However, since stress reactions are the result of a complex web of interactions between the genotype and the environment, indices involving very few distinct wavelengths only run the risk of providing a oversimplified and actually wrong spectral characterization of drought reactions. In this study, we present a data-driven approach to discovering spectral drought stress indices, treating it as an unsupervised labeling problem at massive scale and solving it using an online variational Bayes approach (Hoffman et al., 2010; Wahabzada and Kersting, 2011) to latent Dirichlet allocation (Blei et al., 2003). Although, there are other data-driven approaches, such as low-rank matrix factorization based on sub-sampling (Mahoney and Drineas, 2009; Sun et al., 2008) or computing extreme data points (Thurau et al., 2012), these methods have a major limitation: they are not part-based. Part-based methods such as NMF, however, do not easily deal with additional information, e.g. relational information and short range dependencies.

Using a topic model is a sensible idea since it is common practice in plant physiology to talk about integral wavelength-reflectance pairs only (the words) within signatures (the documents). However, we have to be a little bit more careful. Signatures are still "curves" showing important short range dependencies among spectral wavelengths. In order to preserve the dependencies, we develop an online variational Bayes approach with convolved Dirichlet regularizer (Newman et al., 2011). Indeed, one may argue that subsampling is a valid alternative to deal with the massive amount of data at hand. However, plant physiologists often do not get used to the idea of throwing away information and actually do not trust the results of sample-based methods. In contrast, our regularized online VB scales well to massive datasets and does not throw away information, hence, provides a more objective complement to plant physiological practices. Moreover, the spectral topics found by LDA conform to plant physiological knowledge and can be computed in a fraction of the time compared to existing LDA approaches.

We proceed as follows. We start off by reviewing online variational Bayes for LDA. Afterwards, we develop the regularized variant. Before concluding we will present our main experimental evaluation on hyper-spectral images of plants with two treatments (control and stressed) as well as supplemental evaluations on two additional real world datasets, the network of human diseases and Wikipedia articles.

2 Online Variational Bayes for LDA

LDA is a Bayesian probabilistic model of collections of text documents (Blei et al., 2003). It assumes a fixed number of K underlying topics in a document collection. Topics are assumed to be drawn from a Dirichlet distribution, $\beta_k \sim Dir(\eta)$, which is a convenient conjugate to the multinomial distribution of words appearing in documents. According to LDA, documents

are generated by first drawing topic proportions according to $\theta_d \sim Dir(\alpha)$, where α is the parameter of the Dirichlet prior on the per-document topic distributions. Then for each word i a topic is chosen according to $z_{di} \sim Mult(\theta_d)$ and the observed word w_{di} is drawn from the selected topic, $w_{di} \sim Mult(\beta_{z_{di}})$.

In this paper, we focus on variational Bayesian (VB) inference. Here, the true posterior is approximated using a simpler, fully factorized distribution q. Following Blei et al. (2003); Hoffman et al. (2010), we choose $q(z, \theta, \beta)$ of the form $q(z_{di} = k) = \phi_{dw_{di}k}$, $q(\theta_d) = Dir(\theta_d, \gamma_d)$, and $q(\beta_k) = Dir(\beta_k, \lambda_k)$. The variational parameters ϕ, γ, and λ are optimized to maximize the Evidence Lower BOund (ELBO)

$$\log p(w \mid \alpha, \eta) \geq \mathcal{L}(w, \phi, \gamma, \lambda)$$

$$\triangleq \mathbb{E}_q[\log p(w, z, \theta, \beta \mid \alpha, \eta)] - \mathbb{E}_q[\log q(z, \theta, \beta)],$$

which is equivalent to minimizing the Kullback - Leibler divergence between $q(z, \theta, \beta)$ and the true posterior $p(z, \theta, \beta \mid w, \alpha, \eta)$.

Based on VB, Hoffman et al. (2010) have introduced an online variant that we here present for the batch case running over mini-batches (chunks of multiple observations). That is, we assume that the corpus of documents has been sorted uniformly at random and chunked into l mini-batches $B_1, B_2, \ldots, B_l$ of size S. That is, the ELBO $\mathcal{L}$ is set to maximize $\mathcal{L}(w, \phi, \gamma, \lambda) \triangleq \sum_{B_i} \sum_{d \in B_i} \ell(n_d, \phi_d(n_d, \lambda), \gamma_d(n_d, \lambda), \lambda)$, where n_d is the word count vector and $\ell(n_d, \phi_d(n_d, \lambda), \gamma_d(n_d, \lambda), \lambda)$ denotes the contribution of document d to the ELBO. As Hoffman et al. (2010) have shown this mini-batch VB-LDA corresponds to a stochastic natural gradient algorithm on the variational objective $\mathcal{L}$. Using mini-batches reduces the noise in the stochastic gradient estimation as we consider multiple observations per update: $\tilde{\lambda}_{kw} = \eta + D/S \sum_{s \in B_i} n_{sw} \phi_{skw}$ where n_{sw} is the s-th document in the i-th mini-batch and D denote the number of documents. The rate of change ρ_t is set to $\rho_t \triangleq (\tau_0 + t)^{-\kappa}$ where $\tau_0 \geq 0$ and $\kappa \in (0.5, 1]$.

3 Regularized Variational Bayes

For introducing a structured prior to regularize the word-topic probabilities, we are inspired by the recent regularized Gibbs (regGS) approach due to Newman et al. (2011), who have demonstrated that regularization improves the topic coherence. Specifically, we view each topic as a mixture of word probabilities given by the word-pair dependency matrix C (a $W \times W$ matrix, where W denotes the size of vocabulary and $C_{ij} \geq 0$), that is

$$\beta_k \propto C b_k \text{ where } b_k \sim Dir(\eta), \tag{1}$$

In VB the true posterior is approximated using fully factorized distributions q. Consequently, we parametrize the word probabilities b by introducing a new variational parameter ν, i.e. $q(b_k) = Dir(b_k, \nu_k)$. The per-word topic assignments z are parametrized by ϕ, and the posterior over the per-document topic weights θ are parametrized by γ, as for the standard LDA (Blei et al., 2003). With this, the part of the likelihood including the specific parameter ν can be written as

$$\begin{aligned}\mathcal{L}_{[\nu]} =& \mathbb{E}_q[\log p(w \mid z, C, b)] \\ &+ \mathbb{E}_q[\log p(b \mid \eta)] - \mathbb{E}_q[\log q(b)] \,. \end{aligned} \tag{2}$$

The remaining part of the ELBO does not change. To approximate the first term of Eq. (2) we adapt the lower bound on the log-sum-exp function (Boyd and Vandenberghe, 2004, page 72), $\mathbb{E}_q[\log \sum_i X_i] \geq \log \sum_i \exp(\mathbb{E}_q[\log X_i])$ (for a detailed proof see e.g. (Paisley, 2010)) to our case, which follows by applying Jensen's inequality: $\mathbb{E}_q[\log p(w \mid z = k, C, b)]$

$$\begin{aligned} &= \sum_i^W \Phi_{ik} \mathbb{E}_q[\log \sum_j^W C_{ij} b_{jk}] \\ &\geq \sum_i^W \Phi_{ik} \log \sum_j \exp(\mathbb{E}_q[\log C_{ij} b_{jk}]) \\ &= \sum_i^W \Phi_{ik} \log \sum_j C_{ij} \exp(\mathbb{E}_q[\log b_{jk}]) \end{aligned} \tag{3}$$

where $\sum_w^W \Phi_{wk} = \sum_d^D \sum_w^W \phi_{dwk}$. This is still a lower bound, so maximizing it will improve the ELBO. The expectation of $\log b$ under the distribution q is: $\mathbb{E}_q[\log b_{wk}] = \Psi(\nu_{wk}) - \Psi(\sum_s \nu_{sk})$. The remaining terms of the Eq. (2) (for a topic k) are

$$\begin{aligned} \mathbb{E}_q[\log p(b \mid \eta)]_{[k]} &= \log \Gamma(W\eta) - W \log \Gamma(\eta) \\ &\quad + \sum_w^W (\eta - 1)(\Psi(\nu_{wk}) - \Psi(\sum_s^W \nu_{sk})) \,, \\ \mathbb{E}_q[\log q(b)]_{[k]} &= \log \Gamma(\sum_s^W \nu_{wk}) - \sum_w^W \log \Gamma(\nu_{wk}) \\ &\quad + \sum_w^W (\nu_{wk} - 1)(\Psi(\nu_{wk}) - \Psi(\sum_s^W \nu_{sk})) \,. \end{aligned}$$

To derive a VB approach, we compute the derivative of Eq. (2) with respect to the variational parameter ν_{wk}. After applying the chain rule and rearranging terms, this gives e.g. $\partial \mathbb{E}_q[\log p(w \mid z, C, b)] / \partial \nu_{wk} =$

$$\begin{aligned} &= \Psi_1(\nu_{wk}) \sum_i \Phi_{ik} \frac{C_{iw} \exp(\mathbb{E}_q[\log b_{ik}])}{\sum_j C_{ij} \exp(\mathbb{E}_q[\log b_{jk}])} \\ &\quad - \Psi_1(\sum_s v_{sk}) \sum_i \Phi_{ik} \,. \end{aligned}$$

Taking the derivatives for all terms together we arrive at: $\partial \mathcal{L} / \partial \nu_{wk} =$

$$\begin{aligned} &\Psi_1(\nu_{wk})(\sum_i^W \Phi_{ik} \frac{C_{iw} \exp(\mathbb{E}_q[\log b_{ik}])}{\sum_j^W C_{ij} \exp(\mathbb{E}_q[\log b_{jk}])} + \eta - \nu_{wk}) \\ &- \Psi_1(\sum_s^W \nu_{sk}) \sum_i^W (\Phi_{ik} + \eta - \nu_{ik}) \,. \end{aligned} \tag{4}$$

Setting the above derivative to zero, we get the following fixed point update:

$$\nu_{wk} = \eta + \sum_i^W \Phi_{ik} \frac{C_{iw} \exp(\mathbb{E}_q[\log b_{ik}])}{\sum_j^W C_{ij} \exp(\mathbb{E}_q[\log b_{jk}]))} \ . \quad (5)$$

This is a proper generalization of the standard VB approach. To see this simply set the word-pair dependency matrix C to the identity matrix. Then, it follows that $\nu_{kw} = \eta + \sum_d n_{dw}\phi_{dwk}$; see also (Blei et al., 2003) for more details.

To derive a learning algorithm, i.e., to actually optimize $\mathcal{L}$, we follow a coordinate ascent on the variational parameters ϕ, γ and ν. Given the word topic probabilities β from Eq. (1), this yields the following per-document updates for ϕ and γ in the E-step:

$$\phi_{dwk} \propto \beta_{wk} * \exp(\mathbb{E}_q[\log \theta_{dk}]) \ , \quad (6)$$

$$\gamma_{dk} = \alpha + \sum_w^W n_{dw}\phi_{dwk} \ . \quad (7)$$

In the M step, we perform fixed point updates, as given in Eq. (5), and compute the values β_{wk} using Eq. (1) as follows:

$$\beta_{wk} \propto \sum_i^W C_{iw} \exp(\Psi(\nu_{ik}) - \Psi(\sum_s^W \nu_{sk})) \ . \quad (8)$$

However, recall that one of our main goals is the application of regularised VB to hyper-spectral images of plants. Since a single image can already consists of hundreds of thousands of signatures (documents) so that several images (as in our experiments) easily scale to several million documents, batch VB is likely to be overtaxed in terms of running time. Consequently, we will develop an online variant of regularized VB (regVB) that scales well to massive datasets.

4 Online Regularized VB

Since setting the word-dependency matrix C to identity matrix results in standard VB, it is intuitively clear that we can extend the regularized VB to the online case (regOVB) by adapting (Hoffman et al., 2010). Specifically, the variational lower bound for the regVB can be written as $\mathcal{L} =$

$$\sum_d^D \Big\{ \mathbb{E}_q[\log p(w_d \mid \theta_d, z_d, C, b)] + \mathbb{E}_q[\log p(z_d \mid \theta_d)] - \mathbb{E}_q[\log q(z_d)] + \mathbb{E}_q[\log p(\theta_d \mid \alpha)] - \mathbb{E}_q[\log q(\theta_d)] + (\mathbb{E}_q[\log p(b \mid \eta)] - \mathbb{E}_q[\log q(b)])/\mathbf{D} \Big\}$$

$$\triangleq \sum_d^D \ell(n_d, \phi_d, \gamma_d, \boldsymbol{C}, \boldsymbol{\nu}) \ , \quad (9)$$

where $\ell(n_d, \phi_d, \gamma_d, \boldsymbol{C}, \boldsymbol{\nu})$ is the dth document's contribution to the variational bound. The per-corpus terms

Algorithm 1: Online regularized LDA. The changes to online LDA are highlighted using blue fonts.

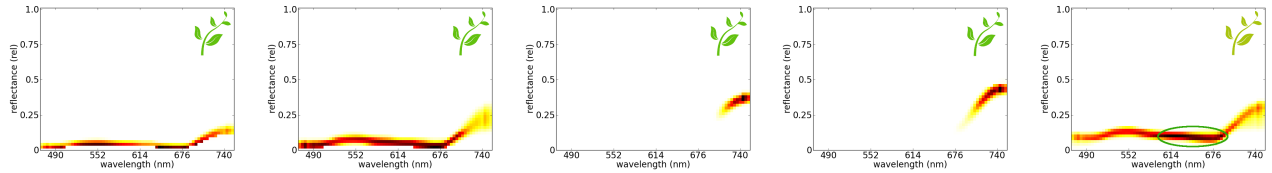
  Initialize $\tilde{\nu}$ randomly;
  for $i = 1 : RegIter$ **do**
    $\tilde{\nu}_{wk} = \frac{D}{S} \sum_{d \in \tilde{D}} \sum_i^W \phi_{dik} \frac{C_{iw} \exp(\mathbb{E}_q[\log b_{wk}])}{\sum_j C_{ij} \exp(\mathbb{E}_q[\log b_{jk}]))} + \eta$;
  Set $\boldsymbol{\nu} = (1 - \rho_t)\boldsymbol{\nu} + \rho_t \tilde{\boldsymbol{\nu}}$;
  $\beta_{wk} \propto \sum_i^W C_{iw} \exp(\Psi(\nu_{ik}) - \Psi(\sum_s \nu_{sk}))$;
  Increment $t := t + 1$;
until *converged* ;

are summed together and divided by the number of documents D. Doing so allows one to derive the online approach since the optimal ν is the one for which $\mathcal{L}$ maximized after fitting the per-document parameter. In other words, we can use the regularized updates in a per-document manner. This is summarized in Alg. 1. That is, we start off by randomly selecting documents form entire dataset by forming a mini-batch $\tilde{D}$. Then an *E step* is performed to find locally optimal values of γ and ϕ holding β fix. In the *M step* several fixed point updates for $\tilde{\nu}$ are computed using $\tilde{\nu}_{wk} =$

$$\frac{D}{S} \sum_{d \in \tilde{D}} \sum_i \phi_{dik} \frac{C_{iw} \exp(\mathbb{E}_q[\log b_{ik}])}{\sum_j C_{ij} \exp(\mathbb{E}_q[\log b_{jk}]))} + \eta \quad (10)$$

given the document-specific parameter ϕ_d with $d \in \tilde{D}$ (currently observed mini-batch), where we rescale by $\frac{D}{S}$ to update as though we would have seen all documents. Multiple documents are used per update to reduce variance. The parameter $\boldsymbol{\nu}$ is updated through a weighted average of its previous value, and $\tilde{\nu}$ (computed for the current mini-batch using fixed point updates as in Eq. (10)). Furthermore, the new values of β are computed given $\boldsymbol{\nu}$ and word-dependency matrix C. Following Hoffman et al. (2010), the rate of change ρ_t is set to $\rho_t \triangleq (\tau_0 + t)^{-\kappa}$ with $\kappa \in (0.5, 1]$ in order to guarantee convergence. Note, as in the non-regularized case, we recover regularized batch VB when setting the batch size to $S = D$ and $\kappa = 0$.



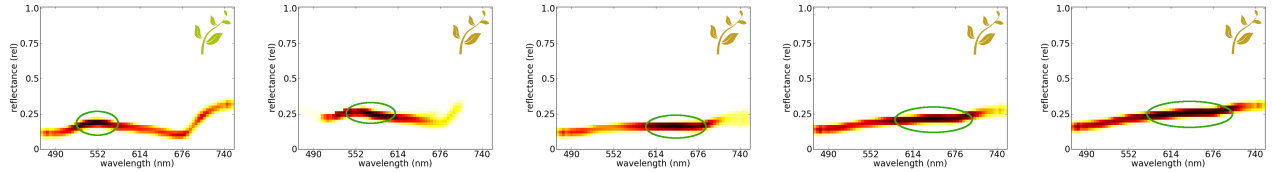
(a) Low reflectance for wavelengths <680nm with a small peak at 550nm, which indicate high chlorophyll content (Gitelson and Merzlyak, 1996)

(b) Low reflectance for wavelengths <680nm with a small peak at 550nm, which indicate high chlorophyll content (Gitelson and Merzlyak, 1996)

(c) "Red-Edge": High reflectance for near-infrared spectral bands >700. Sensitive to chlorophyll content (Curran et al., 1990; Seager et al., 2005)

(d) "Red-Edge": High reflectance for near-infrared spectral bands >700. Sensitiv to chlorophyll content (Curran et al., 1990; Seager et al., 2005)

(e) Top words for chlorophyll specific wavebands between 600nm-680nm (Blackburn, 1998).



(f) High sensitivity to chlorophyll concentration near wavelength 550nm (Blackburn, 2007; Gitelson and Merzlyak, 1996).

(g) High sensitivity to chlorophyll concentration near wavelength 550nm (Blackburn, 2007; Gitelson and Merzlyak, 1996).

(h) High reflectance for spectral bands between 600nm-680nm indicate low chlorophyll content (Gitelson and Merzlyak, 1996).

(i) High reflectance for spectral bands between 580nm-680nm indicate low chlorophyll content (Gitelson and Merzlyak, 1996).

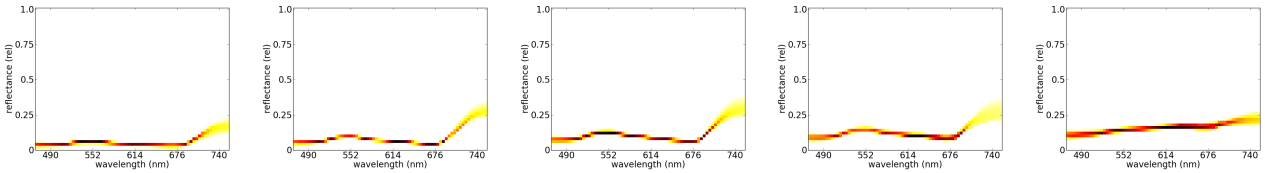
(j) High reflectance for spectral bands between 580nm-680nm indicate low chlorophyll content (Gitelson and Merzlyak, 1996).

Figure 2: Example topics learned by regularized online VB (K = 15). Most of the topics can be found to reflect results received by experts (see Table 1 in (Govender et al., 2009) and references in there). Top words (here in dark red) consists mostly of highly correlated spectral bands. Furthermore, given the reflectances one can identify whether a topic represent a healthy (e.g. low reflectance in chlorophyll specific bands, large reflectance in near infrared wavebands (Blackburn, 2007)) or non-healthy signature. (Best viewed in color)

5 Uncovering Spectral Drought Stress Characteristics

In our main experiment, drought stress was applied to barley cultivar Scarlett. Hyper-spectral images of the 5 stressed and 5 control Barleys were taken with a resolution of 640x640 pixels, where each pixel is a vector with 120 recorded wavelengths from the range of 394-891nm with approximately 4nm spectral resolution, using the SOC-700 hyper-spectral imaging system (Rascher et al., 2007), manufactured by Surface Optics. A normalization of the images was done by calculating the spectral reflectance for each pixel. For that, the spectrum of a pixel was divided by the spectrum of the incoming radiation estimated from a white reference panel that exhibits Lambertian reflectance located in each scene. Because the monitoring started with the flowering time of Barley, both the control and stressed Barleys developed senescent leaves. In our experiments we used 7 measurements for 10 plants, which were done every 3-4 day. Five control plants grew in a fully water capacity of the substrate conditions while the 5 stressed plants were exposed to 50% water supply reduction (at BBCH 30; BBCH is a scale used to identify the phenological development stages of a plant). This yielded 70 data cubes of resolution 640x640x120. Although the SOC-700 measured from 394nm to 890nm, the wavelengths below 470nm and above 750nm were discarded because they appeared to be very noisy. The reason for this is most likely an unstable source of illumination for these frequencies. Therefore, only the bandwidths from 470nm to 750nm were used. We transform each cube into a dense 'pixel x spectra' matrix. This resulted in 70 data matrices of soze 69x409,600; overall a dataset with about 30 Million signatures.

Furthermore, for our analysis we are interested in finding not just specific wavelength patterns but also reflectance values. For that reason, and to get the data sparse, we discretize the corresponding signatures in the following way: we decompose the space covering the full signatures (with $Wl = 69$ spectral bands) additionally into $R = 50$ possible reflectance words. Thus, in a signature each wavelength can consist of one of the R distinct reflectance words, which results in a total number of $Wl \times R$ different possible *spectral words*. The use of discretised values instead of continuous is also motivated by the fact that according to plant physiologist small difference in reflectance values are not of great importance. They instead study the spectral characteristics of plants in order to get spectral



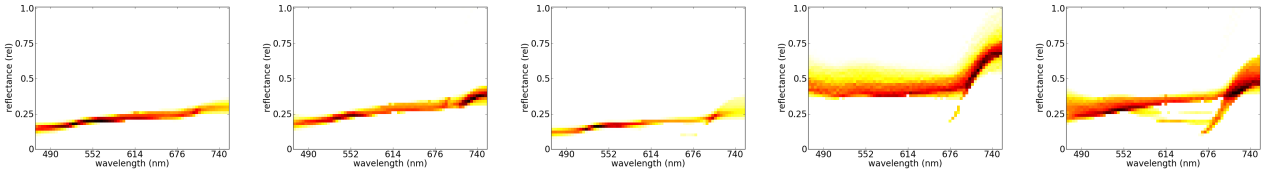
(a) Low reflectance for wavelengths <680nm with a small peak at 550nm, which indicate high chlorophyll content (Gitelson and Merzlyak, 1996)

(b) Low reflectance for wavelengths <680nm but **no** small peak at 550nm

(c) Peak at 550nm but **no** low reflectance for for wavelengths <680nm

(d) Top words for chlorophyll specific wavebands between 600nm-680nm **but** also for lower waveband

(e) High reflectance for spectral bands between 600nm-680nm indicating low chlorophyll content **but** also for other spectral bands



(f) Increasing slope but high reflectance for spectral bands **below** 600nm-680nm.

(g) **Mixture** of "red edge", peak at 550nm and increasing slope.

(h) **Mixture** of top words for chlorophyll specific wavebands between 600nm-680nm and peak at 550nm.

(i) Junc topic with elements of "red edge"

(j) Junc topic with elements of "red edge" and peak at 550nm

Figure 3: Topics learned by standard online VB (K = 15). As one can see the topics are less distinct compared to the regularized ones and actually mix known indices in particular for stressed and controlled plants.

indices more sensitive to pigment content. Furthermore, we excluded all biologically implausible signatures (*"background"* signatures) using Simplex Volume Maximization (SiVM) (Thurau et al., 2012) algorithm, by taken out all signatures with a high coefficient to an extreme spectra which was identified as *"background"* (non-leaf). This resulted in a dataset with about $9,2$ Million signatures (documents).

The word-dependency matrix C was created using pointwise mutual information (PMI) (Newman et al., 2011). For plants, in order to also get the cooccurrences between different reflectance's within a wavelength, we proceeded as follows: we first aggregated the signatures in the images within each non-overlapping squares of 5x5 pixel. *Spectral word* cooccurrences were computed using a sliding window of length 1 in each direction (wavelength and reflectances) in the aggregated signatures. We compute the PMI only for the 1000 words with the highest frequency. The matrix C was computed from 8 plants (56 images, with approx. $7,3$ Million signatures), for the remaining two plants (one control and one stressed, with approx. $1,9$ Million signatures) an regularized/non-regularized online LDA was learned on non aggregated signatures. For both methods we set the batchsize $S = 1024$, κ close to 0.5, $\alpha = 0.01$, $\eta = 0.01$ and (for the regularized online VB) 10 fixed point iterations in the M step. For both methods we stopped when each signature (document) was seen once. The computation took for both methods less than one hour (for $K = 15$) on a standard Intel-Quadcore 3.4 GHz computer, but only using a single core. In contrast, running batch LDA on two plants took more than 15 hours.

5.1 Uncovered Characteristics

Fig. 2 shows examples of topics discovered by regularized online VB (K = 15). The topics conform to common plant physiological knowledge (see also Table 1 in (Govender et al., 2009) and references in there). For example topics (a), (b), (f) and (g) clearly show that high probable words appear for the spectral band 550nm. This wavelength was found to have a maximum sensitivity to a wide range of chlorophyll contents (Blackburn, 2007; Gitelson and Merzlyak, 1996), which are the most important pigments as they are necessary for photosynthesis. Furthermore, topics (a) and (b) show a high probability wavelengths close to 500nm and 670nm. As mentioned by Gitelson and Merzlyak (1996), these bands/wavelength have high correlation for yellow-green to dark-green leaves. Additionally Gitelson and Merzlyak report that the reflectance in 550nm does not exceed 0.1 in green leaves (for Maple and Chestnut). This is also supported by topics (a) and (b) but now for Barley. An up-rising slope between bands 690nm and 750nm is known as the "red edge" and is due to the contrast between the

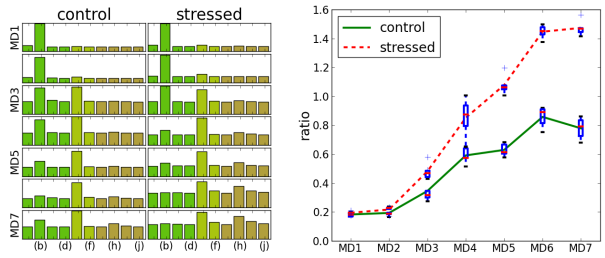


Figure 4: (**Left**) Evolution of "non-healthy" and "healthy" topics shown in Fig.2 over time. Each row stands for different measurement days 1-7. The larger the bar the more prominent a topic is. As one can see, the most prominent topics for control plants consists of "healthy" yellow-green topics, whereas for the stressed plants the probabilities of "healthy" topics drop rapidly and "stress" topics (brown) become more likely in latter days. (**Right**) The ratio of relative importance of a "non-healthy" and "healthy" topic. Beginning by measurement day 3 we have a significant difference (paired t-test, p = 0.05) between stressed and control plants. (Best viewed in color)

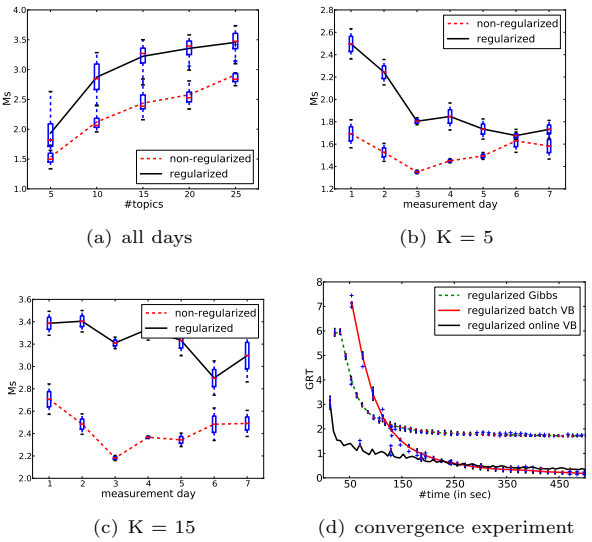


(a) all days (b) K = 5

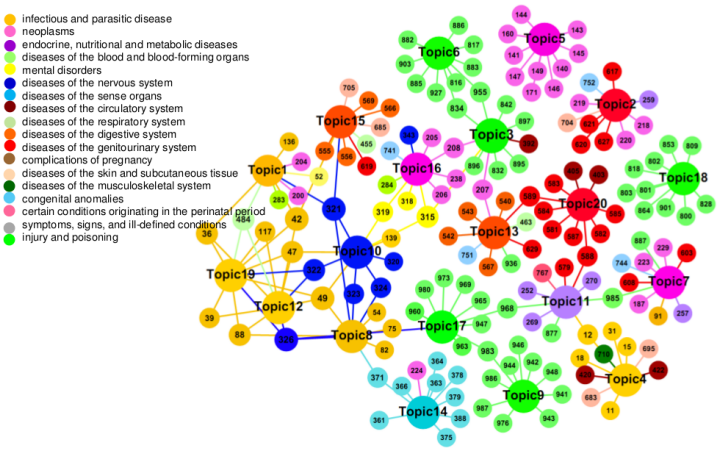
(c) K = 15 (d) convergence experiment

Figure 5: Regularization produces more specific topics. Shown are the averages per topic KL-distance to a "background topic" when taking (a) all days as a function of the number of topics, (b) for 5 topics and (c) 15 topics as a function of measurement days. The topic proportions of the signatures from each images were taken separately in order to compute the distance to "background topic". As one can see the regularized topics are more specific than non-regularized ones; they have significantly larger KL-distance. Interestingly, for the last three measurement days the picture gets more diverse. Actually, regularized topics capture the spectral characteristics less well for smaller (b) than for large number of topics (c). This indicates that their is a diverse set of spectral characteristics required to capture drought stress. Furthermore, (d) regularized VB converges significantly faster than regularized semi-collapsed Gibbs-Sampling (Wikipedia, K = 20). Shown are the expected change of word probabilities in topics over time. This speed-up puts high throughput hyper-spectral topic models of several plants per day for several weeks in reach. (Best viewed in color)

strong absorption of chlorophyll and the otherwise reflective leaf (Seager et al., 2005). The "red edge" is detected by topics (c) and (d). The discovered important wavelengths in the topics (h)-(j) (between 580nm-680nm) also closely mirror known indices. Blackburn (1998) define the "optimal" individual bands for pigment estimation as 680 nm for chlorophyll a and 635 nm for chlorophyll b. Gitelson and Merzlyak (1996) observed a increase of reflectance for the band 670nm if the amount of chlorophyll in the leaf drops, as it is the case for stressed plants. Taking both results together, topics (h)-(j) clearly describe "non-healthy" resp. "drought-stressed" topics and also conform to plant physiological knowledge.

The discovered topics/indices can be used in various ways to investigate drought stress reactions. For instance, we can computed the distributions of topics for plants over time. Fig. 4 (**left**) shows this topic distribution over all the measurement days 1-7 (recall that images were taken every 2-3 days so we cover several weeks). Since, LDA is giving us a topic distribution per signature only, we actually estimated the concentration parameters of the Dirichlet distribution over the topics induced by all signatures of single images (Minka, 2000). Then, we used the expected probability of each topic for visualization.

As one can see, the probability of "non-healthy" topics increases for the stressed plant over time, whereas for the control plant "healthy" yellow-green to green topics have higher weights. Furthermore, Fig. 4 (**right**) show the ratio between the expected probability of a "non-healthy" and "healthy" topic (ratio = h/b, for topics (b) and (h) in Fig. 4 (**left**)). For this experiment we also computed the distribution of topics for all plants and measurement days using the model shown in Fig. 2. Beginning by measurement day 3 this ratio shows a significant difference (paired t-test, p = 0.05) between stressed and control plants. This are yet another validations that the discovered topics capture drought stress relevant characteristics.



Topic 20: **kidney disease**	
581	Nephrotic syndrome
583	Nephritis and nephropathy
588	Disorders resulting from impaired renal function
403	Hypertensive kidney disease
585	Chronic kidney disease (ckd)
405	Secondary hypertension
589	Small kidney of unknown cause
582	Chronic glomerulonephritis
587	Renal sclerosis unspecified
584	Acute kidney failure
Topic 8: **viral infections**	
326	Late effects of intracranial abscess or pyogenic infection
49	Other non-arthropod-borne viral diseases
75	Infectious mononucleosis
323	Encephalitis myelitis and encephalomyelitis
321	Meningitis due to other organisms
88	Other arthropod-borne diseases
54	Herpes simplex
82	Tick-borne rickettsioses
371	Corneal opacity and other disorders of cornea
324	Intracranial and intraspinal abscess

Figure 6: Regularized VB LDA can discover composite topics in Human Disease Network: (Left) A graph representing topics learned by regularized VB (K = 20). Topics (big circles) are connected with top 10 diseases (small circles). The different colors indicate different categories of ICD9 codes. As one can see, most of the topics are dominated by one of the categories. But there are also mixed topics of common diagnosed diseases across several categories. (Right) Two example topics learned with regularized VB LDA about "kidney diseases" and "viral infections". (Best viewed in color)

5.2 Regularization improves the topic coherence

To accommodate the qualitative results so far with quantitative ones, we compared the results produced by regularized and non-regularized oLDA in terms of their topic coherence. A topic is specific or has authentic identity if it is far from generating words in wide range of documents. To measure this, Alsumait et al. (2009) define a "background topic" to be a topic that is equally probable in all the documents, i.e., $P(d_m \mid \xi) = 1/D$ for $m \in (1, 2, ..., D)$. In turn, the distance between a topic and the "background topic" can be viewed as measure for how much background or common the information is provided by the topic. Since we are interested in overall performance of a model, we measured the average per topic distance to the "background topic" using KL-Divergence:

$$Ms = \frac{1}{K} \sum_k D_{kl}(\boldsymbol{\theta}_k, \xi) \text{ where } \boldsymbol{\theta}_k = (\theta_{1k}, \theta_{2k}, ..., \theta_{Dk}) \ .$$

The results are summarized in Fig.5 (a)-(c). As one can see, the regularized topics are more specific than non-regularized ones (a), i.e. they have larger KL-distance . More interestingly, for the last three measurement days regularized online LDA does worst for lower number of topics (b) than for large number of topics (c). This can be due to wide range of different signatures in the images (in terms of "non-healthy" signatures). This can be also seen in Fig.4 where for the first days there just a few topics with high probability, whereas for the latter days more topics are needed to represent the data.

6 Supplementary Evaluation

To further investigate the performance of regularized VB works even if LDA fails to learn anything meaningful, and that it is comparable with semi-collapsed Gibbs Sampling inference by Newman et al. (2011) we provide experiments with two additional datasets.

Human Disease Network: Here we investigate the question: can regularized VB learn meaningful and interpretable topics models even if "no information" in documents are available? To answer this we make use of human disease network dataset (Hidalgo et al., 2009), which consist originally of approximately 32 Million inpatient claims, pertaining 13039018 individuals of 65 years and older patients. The corresponding human disease network includes cooccurrences of diagnosis (specified by ICD9 codes) and up to 9 secondary diagnosis.

Here we applied regularized VB by using disease dependency matrix which was computed using PMI. We used only diseases with more than 500 occurrences, resulted in a total of 742 diseases. In order to learn a regularized topic model, we created a synthetic datasets of D = W documents each consisting of one word (actually an identity matrix with $W \times W$ dimensionality). We used the following settings: $\alpha = 0.01$, $\eta = 0.01$ and 10 fixed point iterations in the M step. The results of the regularized VB (for K = 20) are shown in Fig.6. As one can see, regularized VB LDA can discover coherent topics in human disease network, even if LDA would fail. Topics (big circles) are connected with top 10 diseases (small circles). The different colors indi-

cate different categories of ICD9 codes. As one can see, most of the topics are dominated by one of the categories. But there are also mixed topics of common diagnosed diseases across several ICD9 categories, as shown in the table on Fig.6, with topic about "kidney diseases" and "viral infections".

Wikipedia Dataset: Further, to compare regularized VB with regularized Gibbs Sampling we used a small set of D = 5000 Wikipedia articles, with W = 7312 words in the vocabulary and N ≈ 750000 total number of terms. The word cooccurrences were computed using an extern data of 3441010 titles of Wikipedia articles. The titles include naturally the short range word dependencies of words. Here we used the normalized cooccurrences (matrix C) for all regularized methods. We set $\alpha = 0.05\frac{N}{DK}$ (as suggested by Newman et al. (2011)), $\eta = 0.01$ and the number of topics was set to K = 20, and in each M step 10 fixed point iterations were applied. For the online case the batchsize was set to S = 500, κ close to 0.5 and $\tau_0 = 1024$. The regularized Gibbs LDA was run for 1250 iterations where we applied regularization (10 fixed point updates) every 50 iterations. The VB methods were run until each document was seen 50 times. The results are shown in Table 1. As one can see, all methods produce topic models of similar quality in terms of the interpretability. Additionally, to show convergence of the different methods, we computed the change of the probabilities of words $\boldsymbol{\beta}$ between two iterations when $\boldsymbol{\beta}$ was computed. To measure this, we use: $GRT = \sum_w \sum_k \mid \beta_{kw}^t - \beta_{kw}^{t-1} \mid$, where t indicate the current iteration. The results are represented in Fig.5 (d). As one can see, the regularized batch VB converges faster than semi-collapsed Gibbs-Sampling. Moreover, regularized online VB outperforms regularized batch VB and is comparable in terms of the interpretability of the topics.

7 Conclusion

Understanding drought stress in plants is not an easy task. In this context, hyper-spectral image sensors are an established, sophisticated method for discovering spectral stress indices. However, they gather massive, high dimensional data clouds over time, which together with the demand of physical meaning of the prediction model present unique computational problems in scale and interpretability. Motivated by this, we developed a regularized variational Bayes approach to latent Dirichlet allocation and presented the — to the best of our knowledge — the first application of probabilistic topic models to discovering drought stress characteristics from hyper-spectral image sequences. Our experimental results on a large-scale plant phenotyping dataset demonstrate that the estimated spectral characteristics are meaningful, conform to existing plant physiological knowledge, and are fast to compute. In contrast to indices established in plant physiology, topics are not based on single or few wavelengths but provide a distributional view on the characteristics of complete signatures. Overall, our results are an encouraging sign that the vision of high throughput precision phenotyping is not insurmountable. Detailed measurements of plant characteristics can be analysed at massive scale to collectively provide estimates of trait phenotypes for many of the underlying genotypes that comprise a typical plant breeding population.

Our work provides several interesting avenues for future work. Next to experiments under field conditions e.g. in an experimental agricultural site, one should aim at improving the topics quality even further by applying hierarchical, (semi-)supervised and relational versions of topic models. Active LDA approaches could speed up computations even further. Ultimately, the models should be used to identify the most relevant moment when biologists have to gather samples for invasive, molecular examinations.

Acknowledgements: The authors thank the anonymous reviewers for their valuable comments, Edwin Bonilla, Wray Buntine, and Zhao Xu for helful discussions on regluarized LDA, and Anja Pilz and Hannah Lanzrath for helping with the data for the supplementary evaluation. Abstract

We describe theoretical bounds and a practical algorithm for teaching a model by demonstration in a sequential decision making environment. Unlike previous efforts that have optimized learners that watch a teacher demonstrate a static policy, we focus on the teacher as a decision maker who can dynamically choose different policies to teach different parts of the environment. We develop several teaching frameworks based on previously defined supervised protocols, such as Teaching Dimension, extending them to handle noise and sequences of inputs encountered in an MDP. We provide theoretical bounds on the learnability of several important model classes in this setting and suggest a practical algorithm for dynamic teaching.

1 Introduction

In situations where one agent teaches another, the AI community has largely focused on teachers that demonstrate a static policy to the learning agent [Abbeel and Ng, 2005; Walsh et al., 2010]. However, demonstration of even an optimal policy is often not the best way to teach. For instance, consider a learner being trained to play billiards by observing a near-optimal player. Since a hallmark of good play is simplifying the next shot, an optimal player will likely only demonstrate easy shots. But if we really want to teach the learner to shoot pool, we need to show it difficult shots and novel situations that the optimal policy will rarely encounter. More generally, teachers can improve learning efficiency by showing highly informative examples that a static policy might not often encounter. In this paper, we show how to cast the problem of optimal teaching as a decision problem in its own right, and provide bounds on the teachability of several important model classes in Reinforcement Learning (RL) [Sutton and Barto, 1998].

Our approach uses lessons from the supervised-learning community, which has established a number of frameworks for quantifying the teachability of a domain class. Specifically, we extend the classical *Teaching Dimension* framework (TD) [Goldman and Kearns, 1992] and the recently described *Subset Teaching Dimension* (STD) [Zilles et al., 2011], which quantify the teachability of deterministic hypothesis classes. We adapt these frameworks for the type of data encountered in RL, particularly handling noise and sequential inputs. This allows us to characterize the teachability of several RL concept classes such as Bernoulli distributions, k-armed bandits and DBNs in a supervised setting.

These supervised algorithms and analyses form the foundation for our teaching algorithms in the sequential decision making setting, where teachers are constrained in the examples they can select by the dynamics of their environment and their current state. We show how to cast the problem of optimal teaching as a decision problem in its own right and that exact optimization is often intractable. We then use our results from the supervised setting to construct approximations to the optimal teaching strategy that are successful in practice. The end result is a general algorithm for a teacher in a Markov Decision Process (MDP) [Puterman, 1994] that, in contrast to work on demonstrating static policies, dynamically chooses highly informative examples to teach the model.

2 Alternate Approaches

We now describe competing protocols for teaching in the RL setting. We will cover previous work on teaching in the supervised setting in later sections.

Static policies for teaching RL agents have been studied in Inverse Reinforcement Learning (IRL) [Abbeel

and Ng, 2004, 2005] and Apprenticeship Learning [Walsh et al., 2010]. However, in both of these settings, the emphasis is on better learning algorithms to interpret a static teaching policy repeated over many episodes. By contrast, we are providing algorithms for the teaching side so that the teacher can show trajectories built to teach, not just to demonstrate. Also, learning efficiency with static demonstrators is measured by either the time needed to achieve the same policy as the teacher (IRL) or perform as well or better than the teacher (Apprenticeship). In our current work we will focus on algorithms to teach the *entire model* of a given environment rather than a specific policy. We note this is a different problem because the learner cannot rely on a policy bias towards the teacher demonstrations.

There has been significant work on human teachers guiding RL agents, including by direct demonstration [Argall et al., 2009] and providing shaping rewards [Knox and Stone, 2010]. Most of these works focus on either optimizing the learner for human inputs or studying how different human interfaces or reward signals impact the learner. An area of future work is studying how similar our optimal teaching policies are to human teachers, as results indicate these behaviors may be very different [Khan et al., 2011].

In some domains, teaching a model may be less efficient than directly teaching the optimal policy or value function. For instance, in the bandit setting, teaching the model (the payout of all arms) requires pulling each arm a number of times, but teaching the optimal policy directly might require (if the learner knows only one arm is optimal) only pulling the optimal arm once. This situation is similar to behavioral cloning [Bain and Sammut, 1995; Khardon, 1999], where supervised learning techniques are employed in the policy space, though the focus of that field is on learning algorithms, not teaching. We focus on teaching a model because in large structured domains, the number of parameters in the model is usually much smaller than the number of parameters needed to encode the value function or policy, though our techniques could be extended to teach in the policy space.

3 Teachers and Learners

In this section, we begin by describing several teaching frameworks from the supervised-learning literature. We then describe modifications to these protocols to accommodate teaching in an RL setting. Specifically, we need to account for (1) noise in the labels and (2) sequences of instances rather than sets. We deal with the first problem in this section and then describe several domain classes that can be taught in this noisy supervised model.

3.1 Supervised Teaching Frameworks

We now describe two frameworks that can be used to measure the sample complexity of teaching in a supervised setting where a teacher is picking the examples. These frameworks differ considerably in how much the teacher and learner can infer about one another. First, we consider the classical *Teaching Dimension* model [Goldman and Kearns, 1992] where the teacher is providing helpful examples to the learner, but the learner is unaware that it actually has a teacher.

Definition 1. *The* Teaching Dimension *of a concept class* $\{c \in C\} : X \mapsto Y$ *over instance space* X *and labels* Y *is* $TD(C) = \max_{c \in C} \min_{|S|}(Cons(S, C) = \{c\})$, *with* $Cons$ *being the concepts in* C *consistent with* S. *This makes* S *a* teaching set *TS(c,C) for c.*

Intuitively, TD represents the minimum number of examples needed to uniquely identify any $c \in C$. Because the learner may not know it is being taught and the teacher does not know what learner it is providing samples to, TD teachers may not act optimally for a specific learner. However, a natural extension is a protocol where the learner and teacher both understand they are interacting with a shared goal (for the learner to realize a concept). Such notions were formalised first by Balbach and Zeugmann [2009] who devised a protocol where the learner would make inferences about hypotheses that the teacher was clearly not trying to teach based on the size of the teaching set. This reasoning between the teacher and learner was further formalised in the *Subset Teaching Dimension* (STD) [Zilles et al., 2011] where the learner and teacher both assume the other is optimal.

Definition 2. *The* Subset Teaching Dimension *(STD) of a hypothesis class* $\{c \in C\} : X \mapsto Y$ *(*$STD(C)$*) is equal to the worst case number of samples needed to teach a learner when both the teacher and the learner know that the other is performing their task optimally. This is done by iteratively constructing Subset Teaching Sets* $STS^i(c, C)$ *starting from* $STS^0(c, C) = TS(c, C)$, *such that* $STS^i \subseteq STS^{i-1}$ *and* $STS^i(c, C)$ *is not a subset of* $STS^{i-1}(c', C)$ *for* $c' \neq c$ *(a "consistent subset").*

Intuitively, STD captures the fixed point behavior of a learner and teacher that recursively assume the other is doing their job optimally. One can think through the process of reaching this fixed point iteratively starting with the teaching sets for all concepts in the original TD framework, denoted $\text{STS}^0 = TS$. In the first step of reasoning, the learner assumes it is being taught using STS^0, and therefore it can assume the instances it will see will come from an optimal teaching set. This

in turn allows it to notice when it has seen subsets of instances that must be leading to one (and only one) set from STS^0. The next step of reasoning goes back to the teacher, who infers it can teach using one of these subsets from STS^1. The process repeats until there are no more changes to STS. The uniqueness and reachability of this fixed point is detailed by Zilles et al. While the reasoning process may be complicated, the resulting behavior can be quite intuitive. For instance, in the original TD setting, when teaching any singleton concept over n variables with the empty set also a possibility, n negative instances are needed to show the empty hypothesis is correct. However in STD, all hypotheses can be taught using just one example (positive for the singleton, negative for empty).

3.2 Teaching Frameworks for Noisy Concepts

In this section, we extend the protocols above to the setting where the concept being learned is noisy. We begin by defining a stochastic concept and unordered collection (a "set" that may contain duplicates):

Definition 3. *A* stochastic concept $c : X \mapsto D(Y)$ *maps each possible instance $x \in X$ to a distribution over the label space ($D(Y)$). An* unordered example collection *U of a concept c consists of (potentially overlapping) pairs of inputs and labels $\{x_0, y_0 ... x_n, y_n\}$ with each y_i drawn from $c(x_i)$.*

Next, we need to address the consistency of the learner, which can no longer be expected to predict the exact label of every instance. Instead, we consider learners that predict a distribution of labels for a given input.

Definition 4. *A* distribution consistent learner *with parameters ϵ and δ makes predictions for input x based on the current unordered collection U in the form of a predicted distribution $D'(x)$ over the label space Y. Consistency means $||\hat{D}(x) - D'(x)||_{TV} \leq \epsilon$ with probability $1 - \delta$, where $|| \cdot ||_{TV}$ is the total variation (half the L1-norm) over the labels and $\hat{D}$ is the distribution observed in U (in most cases $\hat{D}$ is the distribution determined by the maximum-likelihood estimate).*

Now we can extend the notion of a teaching set from Definition 1 in three ways. First, instead of sets, we consider collections with duplicates. Second, we assume the teacher does not control the label associated with a given input, but can see the label (produced by the true concept) once an instance is added to the teaching collection. Therefore, the teacher can choose instances one at a time to add to the collection and always knows how all the current examples have been labeled. In practical terms, the teacher will then be able to choose when to execute a *stop* action to declare the collection finished *but* notice that the learner will not be aware of the order in which examples were added. Finally, we say such a collection is a teaching collection (denoted TS in an abuse of notation) if any distribution consistent learner must have $||D(x) - \hat{D}(x)|| \leq \epsilon$, with probability $1 - \delta$ after seeing that sequence.

We now have all of the components to define the noisy teaching dimension (NTD):

Definition 5. *The* noisy teaching dimension (NTD) *with parameters ϵ and δ of a stochastic concept class C (*NTD*(C)) is the maximum size minimum teaching collection $\tau \in TS(c)$ over all concepts $c \in C$. That is,* $\max_c min_{\tau \in TS(c)} |\tau|$

Next, we consider the case of a Noisy Subset Teaching Dimension (NSTD), which will extend STD. Here, we need to redefine the notion of subset used in the original STD to account for duplicates and the incremental construction of the teaching collection. To do so we introduce the *consistent subcollection* relation:

Definition 6. *A collection U' is a* consistent subcollection *of another collection U ($U' \subseteq U$) if (1) every element of U' is mapped by a function to an element of U and (2) the range and probability of distributions represented by U and U' are the same.*

Replacing the original "consistent subset" requirement from Definition 2 with a requirement that each iteration of reasoning must produce a consistent subcollection and assuming the learner is distribution consistent gives us a full definition of NSTD. In most cases the original NTD collection (NSTD^0) will not be improved upon in the worst case, but in many cases the teachers ability to *stop* constructing the collection will cause a significant decrease in the *expected* teaching time for NSTD over NTD (see Theorems 2 and 3). While the definitions above assumes the teacher's construction ordering is hidden from the learner, we will later see the sequential setting reveals this order and allows stronger inference.

4 Concept Classes

We now describe several concept classes that are relevant for RL agents. Our analysis in this section is carried out in the supervised setting.

4.1 Monotone Conjunctions

Conjunctions of terms are a simple but important model for pre-conditions of actions and simple conditional outcomes. A monotone conjunction over an input space of n boolean terms is labeled 1 if all of the relevant variables are 1, and 0 otherwise. In the TD setting, the complexity of learning a monotone conjunction is $O(n)$ [Goldman and Kearns, 1992], but the types of examples are slightly different than in the

classical mistake-bound [Littlestone, 1988] case, which only requires positive examples. This is because in TD we cannot assume anything about how the learner defaults in its predictions. Instead, the TD teacher should present the most specific positive example (only relevant variables set to 1), and then negative examples with each *relevant* variable alone set to 0.

In the STD protocol, the bound actually becomes 1 [Zilles et al., 2011]. The optimal STD strategy is to show the positive example from the TD case because the learner can infer all of the other negative examples. These results provide intuition about how preconditions or conditional effects can be taught in the sequential setting, a topic we return to in Section 5.3.

4.2 Coin Learning

One of the fundamental noisy hypothesis classes in model-based RL is the Bernoulli distribution learned through observation outcomes, (i.e. determining the bias (p^*) of a coin by observing flips). In the NTD case, because the teacher has to provide samples that may be interpreted by any type of consistent learner, the following strategy produces the optimal teaching set with high probability.

Theorem 1. *In the NTD setting, the proper teaching strategy is to collect* $m = H(\epsilon, \delta) = \frac{1}{2\epsilon^2} ln(\frac{2}{\delta})$ *samples of the Bernoulli distribution and then say* stop.

Proof. This strategy produces enough samples for learners that requires m samples before they make any predictions (e.g. KWIK learners [Li et al., 2011]). Suppose a learner existed that made inaccurate ($> \epsilon$ error) predictions with probability $> \delta$ after seeing these samples with empirical mean $\hat{p}$. Then by Definition 4 this learner would be inconsistent because Hoeffding's inequality states $Pr[|\hat{p} - p^*| > \epsilon] < \delta$. □

This is not surprising since this is also the sample complexity as an autonomous coin learner [Li et al., 2011]. However, in NSTD, the teacher has a significant impact. The following two theorems lay out (1) the reasoning that leads to the different behavior and (2) the sample complexity of coin learning in this protocol.

Theorem 2. *The general NSTD teaching policy for teaching the probability of a weighted coin is to flip the coin at most* $H(\epsilon, \delta)$ *times, but the teacher can* stop *building the collection whenever the empirical mean* $\hat{p}$ *of the coin's bias is within* $\epsilon/2$ *of the true probability.*

Proof. After processing a teaching collection of some size m, a learner can construct a confidence interval (using Hoeffding's inequality), denoting the upper and lower limits of p^* (the true probability of heads) with probability $1 - \delta$. We call this region the *consistent* region and the hypotheses outside of this region are deemed *inconsistent*. In addition, we can define the empirical mean $\hat{p} = \sum_{i=1}^{m} y_i/m$ and a region $[\hat{p} - \frac{\epsilon}{2}, \hat{p} + \frac{\epsilon}{2}]$ that we call the *instantaneous* region.

In NTD (NSTD^0) we just saw the teacher's only recourse is to provide $m = H(\epsilon, \delta)$ samples. For NSTD^1, where the learner is aware it is being taught, suppose the teacher presents a collection of size $m' < m$ to the learner. If p^* is in the inconsistent region, then the label set has probability $< \delta$, so the teacher was correct in stopping early. If p^* was in the consistent region but *not* in the instantaneous region, then the teacher would not have stopped construction, because treating this as a consistent subcollection will not guarantee the learner picks a distribution within ϵ of p^*. Therefore, in the case where the teacher stops the construction while the consistent region is still larger than the instantaneous region, the teacher's current collection is a consistent subcollection of a possible NTD collection and the learner can pick any hypothesis from the instantaneous region and be correct. □

We will now prove that the expected time for teaching a distribution in the NSTD framework is significantly smaller than the standard Hoeffding bound ($H(\epsilon, \delta)$) that determines the number of samples needed to learn in the NTD protocol. We believe the result is interesting in its own right as it describes a useful fact about the expected time the empirical average needs to first hit an interval of interest centered at the true expected value of a random variable.

The key technique we will use is formulating the evolution of the empirical average as a random walk and reducing the problem of hitting the desired interval to the problem of computing the mean first passage time through a fixed barrier. The models we introduced so far use Bernoulli as the standard example of learning a noisy concept. In the interest of technical brevity, we will actually prove the result for the case where the noise model is a Normal distribution. The reason is that the proof is more insightful for a continuous distribution and it is known in the literature [Redner, 2001; Feller, 1968] that the first passage time properties in the continuous case approximate the discrete version well.

Theorem 3. *Given a Normal distribution with unknown mean p, and the ability to sample from it, the expected number of samples a teacher needs to teach p in the NSTD protocol scales with* $O(\frac{1}{\epsilon})$ *(the variance is considered known).*

Proof. The above theorem statement is equivalent to stating that the expected first time the empirical av-

erage of a sequence of i.i.d. samples from a $D = Normal(p, 1)$ distribution hits the interval $[p-\epsilon, p+\epsilon]$ is $O(\frac{1}{\epsilon})$. Let $X_i, i = 1, 2, ...$ be i.i.d. samples from distribution D and let $S_t = \sum_{i=1..t} X_i$ be a random walk on $\mathbb{R}$ (with step values sampled from D). The empirical average at any time $t > 0$ is of course $\hat{X}_t = \frac{S_t}{t}$. Let $Y_i = X_i - p$ (thus $Y_i \sim Normal(0, 1)$) and let $W_t = \sum_{i=1..t} Y_i$. We can thus write $S_t = pt + W_t, \forall t > 0$.

Proving a bound on the expected time it takes $\hat{X}_t$ to first hit interval $[p - \epsilon, p + \epsilon]$ is equivalent to showing a bound on the expected time it takes the random walk S_t to hit the dynamic interval $[pt - \epsilon t, pt + \epsilon t]$. Let $A_t = pt + \epsilon t$ be a process that encodes the time evolution of the upper bound of the dynamic interval.

We will first focus on the expected time it takes for the random walk to first be inside the interval from the perspective of the upper bound. Let $B_t = A_t - S_t = \epsilon t - W_t = \epsilon t + W_t$ where the last equality follows from W_t being a symmetric stochastic process around 0. Since we are looking for the expected time t that A_t first becomes larger than S_t, this is equivalent to asking what is the expected first time that B_t hits the origin if it first starts on the negative side (if it starts on the positive side, this first time will be 1).

We will now approximate the discrete-time stochastic process B_t by a continuous-time process with the goal of getting a qualitative result about the expected mean time. This technique is commonly used to study first passage-time properties of discrete time random processes (see for instance the Integrate-and-Fire Neuron model in section 4.2 in [Redner, 2001]). Viewed from this perspective, $B_t = \epsilon t + W_t$ is actually the standard Brownian motion with positive drift ϵ. But it is well known that the mean first passage time over a fixed positive constant α for a Brownian motion with positive drift ϵ is governed by the **Inverse Gaussian Distribution (IG)** with parameters $IG(\frac{\alpha}{\epsilon}, \alpha^2)$ [Chhikara and Folks, 1989]. The expected value of the IG distribution is $\frac{\alpha}{\epsilon}$ and if we take $\alpha = 1$ we get that the expected first time that B_t will become larger that 1 is $\frac{1}{\epsilon}$. Since the expected time to first hit the origin if started on the negative side is naturally upper bounded by the expected time to hit 1, we get a bound on the expected time A_t needs to first 'catch up' with the random walk S_t.

Symmetrically we can show that the expected time for S_t to become larger than the lower bound of the dynamic interval (the process $pt - \epsilon r$) is also $\frac{1}{\epsilon}$. □

Figure 1a shows empirical validation of this result in the coin-flipping case for increasingly smaller values of ϵ (1000 runs, $\delta = .05$). While NTD grows quadratically in accordance with $H(\epsilon, \delta)$, the NSTD expected time grows only linearly in $\frac{1}{\epsilon}$.

4.3 k-armed Bandits

A natural extension of coin-learning is teaching a complete model in the k-armed bandit case [Fong, 1995], that is teaching the expected payout of all k arms, each of which may have a different noisy (but bounded $[0, 1]$) payout function. We note again that we are teaching the full model here, not the optimal policy. Each arm can be treated as a Bernoulli distribution that needs to be learned within ϵ with probability δ/k to ensure total failure probability at most δ . Note ϵ does not change with k because each arm corresponds to a different input parameter x (a different action). Hence for k arms, the NTD solution is to pull each arm $H(\epsilon, \delta/k)$ times, giving us an NTD bound of $\frac{k}{2\epsilon^2} ln(\frac{2k}{\delta})$. For NSTD, the teacher can again pull the arms in some ordering, but can stop pulling an arm when it has either (1) been pulled $m = H(\epsilon, \delta/k)$ times or (2) its empirical average is within $\epsilon/2$ of its true payout. The expected savings over NTD is a factor of $\frac{1}{\epsilon}$ *for each arm*, so the speedup effect is actually multiplied across the arms. Figure 1b illustrates this in the bandit setting for increasing k (1000 runs, $\epsilon = 1/45$, $\delta = .05$). The algorithms just described are labeled NTD-IND and NSTD-IND (for "individual" pulls). The growth of NTD-IND is actually $kln(k)$ but quickly diverges from the other approaches here, showing the increasingly better (than NTD-IND) expected performance for NSTD-IND.

While not applicable in RL, the complexity of teaching by pulling all of the arms in parallel will be informative in the next section, so we investigate it here. The goal is still to learn each arm's expected payout with ϵ-accuracy, but the teacher has access to an action that pulls all of the arms at once and reports their individual payouts. NTD in this case (NTD-PAR in Figure 1b) performs $H(\epsilon, \delta/k)$ parallel pulls, saving a factor of k over the individual NTD above. But in NSTD, the parallel pulls introduce a tension between the speedup from parallelizing and the previously noted speedup from being able to stop pulling an arm when its empirical mean is close to the true mean. Now if some arms are close to their empirical mean but others are not, a parallel pull may disturb the empirical means of the "learned" arms. Figure 1b shows the NSTD-PAR strategy that is forced to either perform a parallel pull or *stop*, which it only does when *all* the empirical payouts are within $\epsilon/2$ of their true payout or have been pulled $H(\epsilon, \delta/k)$ times. For small k, the sequential pulls are actually more efficient, but for a larger number of arms, the parallel pulls have a significant benefit despite the danger of "unlearning" an arm.

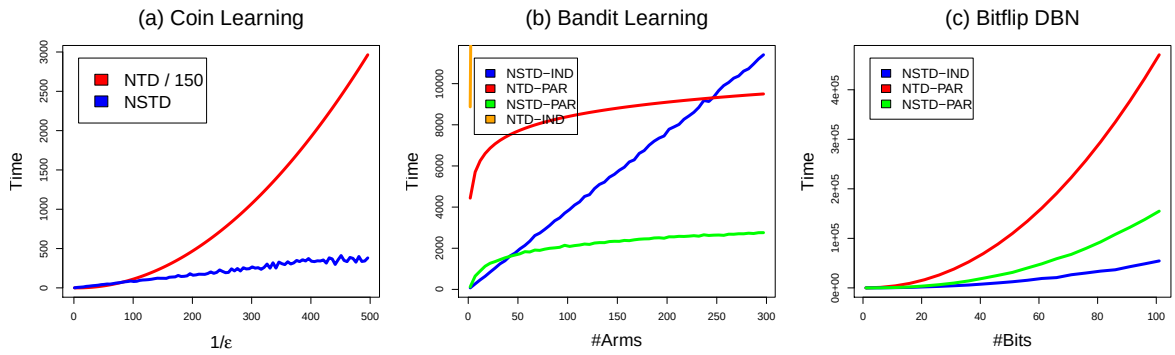

Figure 1: TD and STD comparisons for (a) coin flipping, (b) k-armed bandits and (c) the Bitflip DBN

4.4 Dynamic Bayesian Networks

We now consider Dynamic Bayesian Networks [Dean and Kanazawa, 1989], or DBNs, where multiple noisy factors are learned in parallel. This case is similar to the parallel bandit case but here because the total error (ϵ) is an aggregate of the subproblem errors, the NSTD strategy will be dramatically different. A Dynamic Bayesian Network is composed of n discrete valued factors. At every timestep, the next value for factor x_i is determined by a probability distribution $P(x_i|\rho(x_i))$ where ρ maps the factor to its k "parent factors". We assume here that $k = O(1)$ and we only consider the binary case (all factors are either 0 or 1) as the bounds generalize to ordinal values from 1 to D with extra terms including D^{k+1} (see [Li et al., 2011]).

Mapping this back to our learning protocols, the input space is all possible configurations of the DBN factors and predictions should be made on the distribution of the factors at the next timestep. As a simple example, consider the case where every variable is the parent of only one other variable. Assume that the structure is known and the DBN is *deterministic*, so all that has to be learned is the relationship between each parent value and its child value. In the traditional mistake bound setting, where the teacher has no control over the inputs, the worst case learning bound is $O(n)$, because each example after the first one could show the same parent (input) pattern as the first, except with a single bit flipped. Because of the connection between mistake bound learnability and teaching by demonstration [Walsh et al., 2010] this is the worst-case bound for teaching this type of DBN by demonstration of a static policy. However, with our dynamic teaching protocols we can do much better. Specifically, in the TD case the sample complexity is $O(1)$, because the teacher can pick the parent values. In the first example, the teacher can pick an arbitrary setting of the factors and show the result. Then all it needs to do is show the complement of this bit string in the second example. Thus, deterministic binary DBNs with $k = 1$ are teachable with 2 examples. The STD bound is the same in this case and the generalization to multiple parents adds only a constant term.

In the stochastic setting, the consequences of teaching the factor probabilities in parallel are more complicated than the deterministic case. Unlike the bandit case, the total error in predicting the next state probability is based on the aggregate error (total variation by Definition 4) of all the subproblems. So each factor needs to be predicted with ϵ/n accuracy. This means that for an NTD teacher, we need $H(\epsilon/n, \delta/n^k) = O(\frac{n^2}{\epsilon^2} kln(\frac{n}{\delta}))$ samples to learn the probabilities.

The stochastic setting is even more complicated in the NSTD case, where once again there is competition between the desire to teach factor probabilities in parallel and the desire to stop showing certain conditions once they have been taught. The parallel and individual teaching styles in the bandit case manifest themselves here in the following ways. NSTD-PAR tries to teach multiple factors at once, using the same "complement" input selection as NTD but can stop providing samples whenever *all* of the factors are $\epsilon/2n$ accurate. The worst case time for this approach is bounded by NTD's bound above but again on expectation this will usually perform better than NTD. However, if one wishes to minimize expected teaching time when there is background knowledge that says certain conditions are already known, a variant of the NSTD-IND strategy is likely better. In NSTD-IND, the teacher presents inputs with only one unknown condition for a single factor, and all other factors have their parent values set to configurations matching the background knowledge. As in the bandit case, this avoids "unteaching" but sacrifices parallelization. Once the factor outcome being taught has its empirical distribution within $\epsilon/2n$ of the true probability, the algorithm moves on to the next condition. The worst-case time for NSTD-IND is $O(\frac{n^3}{\epsilon^2} kln(\frac{n}{\delta}))$, worse than TD and NSTD-PAR, but

its expected time is only $O(\frac{n^2}{\epsilon} kln(\frac{n}{\delta}))$ since it targets individual conditions.

An empirical demonstration of these teaching strategies is shown in Figure 1c for a DBN representation of a noisy Bitflip domain [Givan et al., 2003]. The input for this DBN is simply a bit string of length n and there are two actions, one to flip bit 0 and one to *shift* each bit up (with a 0 always incoming to bit 0). However, the effect of the shift is noisy for each bit: with probability p_i the shift to bit i is successful, and otherwise the bit retains the same value it currently has. Figure 1c shows the number of steps needed to teach all of the p_i's for $\epsilon = .3$ (aggregate error) and $\delta = .05$ for the three teaching protocols described above (500 runs). NTD teaches by setting the inputs (current state) to an alternating string of 0's and 1's ending in a one, so that each bit's shift probability is observed on every step (ensuring parallel teaching). NSTD-PAR uses the same alternating bit string for every example, but stops building the collection if all of the p_i values are within $\epsilon/2n$ of their true value. NSTD-IND sets up the state to have all 1's from bit 0 up to the highest bit it has not yet taught, and then all $0's$ above that. This teaches the probability of shifting each bit one at a time with deterministic outcomes for the other bits. We see here that unlike the bandit case, NSTD-IND dominates the other strategies, even as the number of bits increases. This is because the continually shrinking accuracy requirements increase the chances of the parallel strategy unteaching a factor. However, NSTD-PAR still outperforms NTD, so in situations where no background knowledge is available (for NSTD-IND) and the teacher and learner are aware of each other, this may be the preferred strategy.

Finally, we note Bitflip also showcases the benefit of teaching versus demonstration from an optimal policy. Consider Bitflip with a reward only when all bits are 1. The optimal policy is to flip if bit 0 is a 0, otherwise shift. However, this strategy produces very few useful samples because once a bit is turned to 1 in an episode, it will never be a 0 (even if the shift fails the bit retains its current value). Even if $p_i = .5$, the expected number of useful samples in an episode for bit i is only 2, and the probability of more samples drops off exponentially. So the optimal *performance* policy will almost always take far more steps to teach the domain than any of the teaching protocols described above.

5 Teaching in an MDP

Above, we established the teachability of several RL concept classes in a supervised setting. However, we are interested in teachers acting out lessons in an MDP, where a transition function $T : X, A \mapsto Pr[X]$ governs agent movement, and therefore the teacher may not have access to all possible states at every timestep. We now extend the previously defined frameworks to the sequential setting, forcing them to handle teaching *sequences* drawn from an MDP. We then describe the teaching process in an MDP as a planning problem in its own right and present and demonstrate a heuristic solution based on our supervised learning results.

5.1 Sequential Teaching Frameworks

In sequential domains, the teacher may not be able to access all possible states at every timestep, but instead may have to take multiple steps (each of which will be seen by the learner) to reach its target teaching state. Hence, we now adapt the TD and STD definitions to consider *sequences* of states and actions rather than randomly accessed inputs and labels. More formally, we need each protocol to handle the following constrained teaching sequences.

Definition 7. *An* MDP teaching sequence $MTS(c, C, M)$ *for MDP* $M = \langle X, A, T, R, \gamma \rangle$ *and* $c : X, A \mapsto Pr[X]$ *or* $c : X, A \mapsto \Re$ *is a sequence* $\langle \langle x_0 a_0 r_0 \rangle ... \langle x_T, a_T, r_T \rangle \rangle$ *with each* $\langle x_i, a_i, r_i, x_{i+1} \rangle$ *reachable by taking action* a_i *from* x_i *in* M*, starting from* $x_0 = s_0$*. After witnessing this sequence, the* $\hat{c}$ *learned by a consistent learner must either be* c *(deterministic) or distributionally consistent (Definition 4) to* c *with high probability (stochastic concepts).*

In the definition above, c is a concept that may be part of the transition or reward function (or both) of M. For TD, instead of considering a set of instances and labels, one now needs to consider a sequence of states and actions drawn from M based on the teacher's potentially non-stationary policy π. We denote the distribution of such sequences as $MTS^{\pi}(c, C, M)$. Formally, we define Sequential Teaching Dimension (TD_S) in an MDP as:

Definition 8. *The* sequential teaching dimension $TD_S(C, M)$ *of concept class* C *being taught in MDP* M *with accuracy parameters* ϵ *and* δ *is the maximum of the minimum expected length of an MDP teaching sequence for any individual concept in the class,* $TD_S(C, M) = \max_c \min_{\pi} E[MTS^{\pi}(c, C, M)]$*, where* π *is an arbitrary, potentially non-stationary, policy (any possible teaching algorithm).*

This definition is very general and using it constructively in the full stochastic case is a topic of future work, but there are cases where the optimal dynamic teaching policy is clear. For instance, when the transition function is deterministic (including cases where we are teaching a noisy reward function), the teacher simply needs to find the shortest-length teaching sequence starting from s_0 that contains enough samples

to teach c to any consistent learner. Also, heuristic solutions for approximating optimal teaching defined in this manner (e.g. Algorithm 1) can successfully teach in both the deterministic and stochastic setting.

The conversion of Zille's STD protocol to the sequential setting is even more complicated because in STD the learner makes inferences about why the teacher is showing certain instances, but now not every instance is accessible at every step. The main intuition we can use to resolve these difficulties in the case where T is deterministic is to instead apply the recursive reasoning to the teaching sequences defined above. Intuitively, this should allow the learner to reason that a teacher is trying to teach a concept c when the teacher chooses a path that leads to a state consistent with c instead of other paths that would teach different concepts. This saves the teacher from walking the entire path. We can formalize this using the notion of an example subsequence and prefix.

Definition 9. *An* example subsequence Σ' *of example sequence* Σ *is a contiguous series of inputs and labels* $\langle x_i, y_i ... x_j ... y_j \rangle$ *for* $i \geq 0$, $j \leq T$. *A* prefix *(*$\Sigma' <_{pre} \Sigma$*) is a subsequence with* $i = 0$ *and a* suffix *is a subsequence with* $j = T$.

Using this definition, we can replace previous definitions of subsets and collections in STD and NSTD and define a SubSequence Teaching Dimension (SSTD) in a natural way for MDPs with a deterministic transition function (see the appendix).

As a concrete example of the more powerful reasoning about sequences in SSTD and NSSTD (its noisy version), consider coin learning, but instead of predicting a probability, assume the learner only needs to predict whether the coin is biased more towards heads or tails (assuming $p^* \neq 0.5$). Without loss of generality assume the coin is biased towards tails but comes up heads on the first trial. In NSTD, because the ordering of examples is hidden to the learner (Def. 3), we need to keep flipping the coin until we have observed more tails than heads. But in NSSTD we only need one more flip and then the teacher can end teaching, no matter what the outcome of the second flip (and even though the empirical distribution will not indicate a tails bias). This is because if the coin was biased heads the teacher would not have made the second flip; it would have stopped after the first heads observation. Similar reasoning can be done when predicting p^* as every choice to flip indicates p^* is *not* in the previous step's instantaneous region (see Theorem 2).

5.2 Practical Teaching in MDPs

If teaching is to be done in an MDP, the best policy will directly optimize the TD_S or $SSTD$ criteria described above. However, even for TD_S in the deterministic setting, the problem of determining the exact optimal teaching sequence may be intractable.

Theorem 4. *Determining the optimal teaching sequence for a concept in a deterministic MDP under the conditions of Definition 8 is NP-Hard.*

Proof. We can encode the graph of a Traveling Salesman Problem (TSP) with integer edge costs as a deterministic MDP with unit costs by adding in the same number of "dummy" states between cities as their distance in the original graph. Then consider teaching a reward function that is known to be 0 at every non-city state but has an unknown value at each of the cities. The shortest tour for teaching such a reward function provides a solution to the original TSP. □

This is in line with previous results on the intractability of determining teaching sets in the supervised setting [Servedio, 2001]. However, tractable approximations such as Algorithm 1 are certainly possible. There we perform two approximations: first we use a greedy approximation of the supervised (random access) teaching collection construction to find a set of instances that will teach the target concept and then greedily construct a tour of all instances in this set.

Algorithm 1 Heuristic teaching in an MDP

input: Concept $c \in C$ to be taught, MDP M with start state s_0, Learning protocol P
$TS(c, C) = \emptyset$
$R = \langle s, a, r, s' \rangle \in M$ reachable from s_0
while $TS(c, C)$ is not a teaching set for c in P **do**
  $X = \langle s, a, r, s' \rangle \in R$ and $\notin TS(c, C)$ that teaches the most parameters of c
  $TS(c, C) = \{X\} \cup TS(c, C)$
while $TS(c, C) \neq \emptyset$ **do**
  $X' =$ closest $X \in TS(c, C)$ to current state, reachable fastest with policy π
  Demonstrate π until X' is demonstrated
  $TS(c, C) = TS(c, C) \backslash X'$

In the SSTD setting, the first approximation by itself could be problematic because the inference process is based on optimality assumptions shared by the learner and teacher. If the teacher uses a suboptimal teaching sequence, then the learner can make the wrong inference. So for extending SSTD or NSSTD to the practical setting, any approximations used by the teacher to construct the teaching set or the touring policy need to be shared between the teacher and the learner, allowing them to simulate each other's behavior. The motivation behind this sharing is to engender natural teacher-student interactions by having the learner and teacher share a set of common assumptions about

one another (such as optimality or consistency in the original STD and TD).

Finally, we consider noise in the transition function for states and actions that are not part of the target concept being taught. In that case, we would ideally like to create a tour of instances with the shortest stochastic path length (in expectation), but this is certainly as hard as the deterministic touring case. However, we can modify the heuristic algorithm used above to simply find the state with the shortest stochastic path and then focus on reaching that state. This allows the heuristic to teach concepts in arbitrary MDPs.

5.3 An Example in the Taxi Domain

To demonstrate our heuristic teaching algorithm we conducted experiments with the Object-Oriented MDP encoding of a Taxi Domain [Diuk et al., 2008]. This environment consists of a square grid (5 by 5 for us) and a controllable taxi with actions {up, down, left, right}. There are also several *landmarks* in the grid, one of which initially contains a *passenger* and another of which is the passenger's *destination*. The taxi's goal is to go to the passenger, execute its *pickup* action, transport her to the destination, and then execute *dropoff*. In the OOMDP encoding of this domain, every state has a set of predicates (e.g. *Wall-ToRight*(taxi)) associated with it, and actions have parameters stipulating which objects are in its scope(e.g. *pickup*(T,P,L) for taxi, passenger and landmark). The predicates in this domain include indicators of walls and clearness in every direction from an object, as well as predicates indicating when two objects are in the same square and when the passenger is in the taxi. Also, each action has a conjunction over the variablized predicates that serves as a *pre-condition* for this action. We focus on teaching these pre-conditions.

We perform our experiments in a deterministic Taxi domain, starting with a modified TD-style conjunction teacher as the set constructor for Algorithm 1. The modification to the conjunction learner from Section 4.1 is that instead of using the most specific positive example, it may have to use one that contains irrelevant predicates (like *WallNorth* for *putDown*) because of state-space restrictions. The teacher must show more positive examples to discredit these irrelevant predicates in addition to the negative examples (action failures) to indicate the relevant variables.

To demonstrate the benefits of STD, we used an approximation of the STD behavior described in Section 4.1 that shows the most specific state it can, then shows positive examples for all of the irrelevant variables and then stops demonstrating (since the learner can infer all other variables are relevant). Table 5.3 shows the number of steps needed to fully teach the pre-conditions of several sets of actions with all others being known. The agent in all cases starts from the middle of the grid and there are 2 landmarks in the bottom-left and top-right corners.

Table 1: Teaching steps for selected action sets in taxi

Action(s)	TD	STD Approximation
pickup	20	15
pickup / putdown	23	17
movement	37	27
all	63	45

Several interesting behaviors were observed, including the teacher using the landmarks in the corners as areas to gather many positive examples (because the irrelevant predicates can be dispelled en masse there). The teacher also made use of the lack of type constraints on most of the variables to create negative instances (where the pre-conditions failed) by swapping the order of arguments to indicate specific relations were relevant. These results compare favorably to previous result on teaching taxi conditions by static-policy demonstration [Walsh et al., 2010] but static policy approaches can be made to look arbitrarily bad in this situation because they will not teach subtle aspects of the domain (like how the corners work) unless they are actually on the way to the goal. By contrast, our approach ignores the current goal and focuses on being the best teacher, not the best performer.

We also experimented with a sequential Bitflip domain (Section 4.4) where all but two of the bits (the middle and one from the end) had deterministic shift outcomes. Our experiments again showed the approximations using NSTD significantly outperforming those using NTD. The average steps to teach the 10 bit version were 362.35 (NSTD-Par), 869.61 (NSTD-IND) and 14610.41 (NTD-PAR). The parallel versions were all more efficient despite flipping every other action.

6 Conclusions

We have extended two supervised learning frameworks (TD and STD) to handle noisy observations and sequential data. These frameworks provide efficient ways to teach several RL classes, including DBNs and Bernoulli distributions. We also presented a practical heuristic algorithm for leveraging TD and STD to perform efficient teaching in an MDP and demonstrated its effectiveness in the taxi domain. Unlike previous efforts at teaching domains with a static policy, these new algorithms actually target the individual parameters of a domain in a task-independent manner, leading to agents that truly teach, rather than just show.

Abstract

In practical machine learning systems, graph based data representation has been widely used in various learning paradigms, ranging from unsupervised clustering to supervised classification. Besides those applications with natural graph or network structure data, such as social network analysis and relational learning, many other applications often involve a critical step in converting data vectors to an adjacency graph. In particular, a sparse subgraph extracted from the original graph is often required due to both theoretic and practical needs. Previous study clearly shows that the performance of different learning algorithms, e.g., clustering and classification, benefits from such sparse subgraphs with balanced node connectivity. However, the existing graph construction methods are either computationally expensive or with unsatisfactory performance. In this paper, we utilize a scalable method called auction algorithm and its parallel extension to recover a sparse yet nearly balanced subgraph with significantly reduced computational cost. Empirical study and comparison with the state-of-art approaches clearly demonstrate the superiority of the proposed method in both efficiency and accuracy.

1 INTRODUCTION

Graph based data representation treats data points as graph nodes and builds pairwise edges between these nodes which are often weighted by the similarity or correlations between the corresponding data samples. In the past decade, graph based data representation has become very popular and widely used in many machine learning algorithms due to both practical needs and theoretical advantage. First, under many practical situations, the data come in a natural way of graph representation, where the links or connections between items can be treated as directed or undirected edges. Typical examples include social networks, the Internet, and citations networks [13, 21]. Second, for the conventional vector space based data representation, a data graph can be easily generated using pre-defined similarity or correlation measurement.

Given the popularity of data graph representation, many graph based machine learning algorithms have been developed, including graph based clustering and semi-supervised learning algorithms. For instance, representative graph based clustering approaches include those formulated as a graph cut problem [16, 20]. In addition, graph has also been integrated into semi-supervised learning paradigm, resulting in a wide range of approaches, such as graph Laplacian regularization framework [2, 23, 25] and random walk based methods [1, 22]. Other popular methods include graph based ranking algorithms [17, 24]. In many real applications and systems, graph based approaches have shown empirical success, especially for those with agnostic setting and given no prior knowledge of the data distributions.

As indicated in [12, 15], constructing a suitable data graph is the vital step for ensuring the learning performance. The sparse structure of the constructed graph is desired for learning algorithms to remain efficiency to memory usage and robustness to noisy samples. Given an adjacency graph, a typical way to recover a sparse graph without losing the global structure of the data is to build a neighborhood graph. The objective is to connect each data point with its nearest neighbors and prune all other connections. However, since the nearest neighborhood method prune the edges through a greedy process, it can only produce an asymmetric graph with some adhoc symmetrization processes. As a result, the constructed neighborhood graph is often irregular and imbalanced, where

the learning performance could be significantly degraded [12]. Therefore, this drawback of nearest neighbor method motivated one to consider matching technique, such as b-matching, to build a balanced graph structure [11, 12]. Instead of achieving symmetrization by post-processing, b-matching sets the symmetry as additional constraints and directly extracts a symmetric solution. But this modification imposes much high computation and memory cost and the one of the known fast approximated solution using belief propagation has the space complexity of $O(n)$ and the time complexity $O(n^{2.5})$ [10], where n is the number of graph nodes (refer to Table 1).

Considering the trade off between computational efficiency and performance, in this paper, we propose a fast and scalable solution for constructing nearly balanced graphs using the auction algorithm proposed in [3]. In order to remain performance superiority and reduce computation cost, our method tends to extract an approximately balanced graph though preserving the regularity as much as possible. We show that this method has the space complexity $O(n)$ and time complexity $O(|\mathbf{E}| \cdot \max |a_{ij}|/\epsilon)$, where $\max |a_{ij}|/\epsilon$ is a constant determined by the data and the learning parameter ϵ. It is much less expensive than the existing regular graph construction methods, e.g. b-matching technique. In addition, the auction algorithm based graph construction is naturally parallelizable and therein the computational efficiency can be further improved using multiple processes. We provide extensive experiments and comparison study with the state-of-the-arts on both synthetic and real benchmark datasets. The experimental results clearly show that the graphs created by parallel auction algorithm (PAA) provide superior performance than neighborhood graphs for different machine learning algorithms. Although PAA graphs have slightly lower quality than b-matching graphs, we observe that PAA method reduces the computational cost by hundreds of times than b-matching method. Therefore, the PAA method is very suitable for handling large scale applications with massive data graphs.

The remainder of this paper is organized as follows. In Section 2, we give a brief introduction of related work on graph construction process. A new graph construction and sparsification method using a parallel auction algorithm is presented in Section 3. The experiments are reported in Section 4 followed by conclusions and discussions in Section 5.

2 RELATED WORKS

Although graph based machine learning methods have been extensively studied and explored, there have been limited efforts for building effective data graphs in the community. Although some recent methods use sampling techniques to approximate large scale graphs [14], it still remains as a challenging issue to efficiently construct large scale graphs with good qualities, such as sparsity and regularity. In this section, we will provide a brief introduction about related work for graph construction and then motivate our proposed method.

Given a data set $\mathbf{X}$, graph construction aims in converting the data to a weighted graph $G = \{\mathbf{X}, \mathbf{E}, \mathbf{W}\}$ where graph nodes are the samples and $\mathbf{W} \in \mathbb{R}^{n \times n}$ is a weight matrix of edges $\mathbf{E}$. As summarized in [12], two important steps for graph constructions are sparsifying the adjacency matrix $\mathbf{A} = \{a_{ij}\} \in \mathbb{R}^{n \times n}$ and assigning weights to edges. In many practical settings, the adjacency matrix is computed using a similarity function for all pairs of nodes, i.e. $a_{ij} = sim(\mathbf{x}_i, \mathbf{x}_j)$. For other applications, such as social network analysis and relational learning, the adjacency or connection matrix $\mathbf{A}$ might be given in a natural way without the above process of computing pair-wise similarity. In the second step, graph sparsification tries to recover a sparse binary matrix $\mathbf{B} = \{b_{ij}\} \in \mathbb{B}^{n \times n}$ to preserve the global structure of data using local information. The final edge matrix can be easily derived as $\mathbf{W} = \mathbf{B} \bullet \mathbf{A}$, where the symbol $\bullet$ indicates element-wise multiplication. Such an extract sparse subgraph often leads better learning performance and requires less storage and computation cost [11, 12].

The most popular method for constructing a sparse graph is the nearest neighbor (NN) approach, including different variants such as k-nearest neighbor and ϵ-nearest neighbor methods. Since ϵ-nearest neighbor often generate fragile subgraphs and does not provide satisfactory performance, kNN graph remains more popular in many applications [15]. Briefly speaking, kNN graph construction performs a greedy search process to select the edges with the most significant weights for each node, and remove all the other insignificant ones. The objective of kNN approach indeed solves the following maximization problem

$$\begin{aligned} &\max_{b_{ij}} \sum_i \sum_j b_{ij} a_{ij} \\ \text{s.t.} \quad &\sum_j b_{ij} = k, \\ &b_{ii} = 0, b_{ij} \in \{0,1\}, \forall i, j = 1, \cdots, n \quad . \end{aligned} \tag{1}$$

Since the greedy search for k nearest neighbors does not guarantee to produce symmetric $\mathbf{B}$, it usually needs some postprocessing to achieve symmetrization by $\max(\mathbf{B}, \mathbf{B}^\top)$ or $\min(\mathbf{B}, \mathbf{B}^\top)$. However, this adhoc symmetrization often leads to imbalanced connectivity for nodes, which could seriously degrade the learning

Table 1: Comparison of the time and space complexity for different graph construction approaches. Assume the input adjacency graph has n nodes and $|\mathbf{E}|$ edges. The compared methods are: Loopy Belief Propagation (LBP) [9], Sufficient Selection Belief Propagation (SSBP) [10], and the auction algorithm.

Method	Time	Space
LBP Method	$O(n\|\mathbf{E}\|)$	$O(n+\|\mathbf{E}\|)$
SSBP Method	$O(n^{2.5})$	$O(n)$
Nearest Neighbor Method	$O(n^2)$	$O(1)$
Auction Method	$O(\|\mathbf{E}\| \cdot \max\|a_{ij}\|/\epsilon)$	$O(n)$

performance, as observed in [12].

As a valuable alternative for extracting sparse graph structure, weighted b-matching technique [18] has been applied to build graph with balanced node connectivity. Similarly to the objective of kNN approach, b-matching recovers a sparse graph with the maximized edge weights. Furthermore, b-matching enforces the symmetry of connectivity through directly imposing a set of constraints $b_{ij} = b_{ji}$. Essentially, b-matching is a generalized version of the well-known linear assignment problem, which can be solved by Hungarian method with a cubic complexity $O(n^3)$ ($n = |\mathbf{X}|$) in time. Various methods have been proposed to solve b-matching problem with less memory and time cost, including the reduction based method [8] and belief propagation based approaches [9, 10], for which the computational complexity is summarized in Table 1. Although b-matching method yields clear advantage for different machine learning algorithms, including spectral clustering and semi-supervised classification [11, 12], it is a much more expensive procedure than the intuitive kNN method. Due to both time and memory constraints, the existing b-matching based graph construction is infeasible for large scale datasets.

3 AUCTION ALGORITHM FOR GRAPH CONSTRUCTION

In this section, we describe the procedure to utilize an auction algorithm to identify bn significant edges from the given bipartite graph corresponding to the adjacency matrix $\mathbf{A}$. In particular, each node is connected with at most b edges. If given an arbitrary graph, it is straightforward to convert it to a bipartite graph though creating a shadow node for each graph node and only connect the original graph nodes to the shadow nodes. In order to utilize distributed computing systems to process massive data graphs, we also describe the parallelization technique for the proposed graph construction method.

3.1 Auction Algorithm for Linear Assignment

Here, we first describe the solution for a single-edge matching problem using an auction algorithm, and then provide general extensions. For a standard maximum 1-matching problem (also known as a linear assignment problem) over a bipartite graph with a non-negative weight matrix $\mathbf{A}$, the objective can be written as:

$$\max_{\mathbf{B}} \ \mathrm{tr}(\mathbf{A}^\top \mathbf{B}) \quad \text{s.t.} \ \ \mathbf{B}\vec{1}^T = \vec{1}, \ \mathbf{B}^T\vec{1} = \vec{1}, \ \mathbf{B} \in \mathbb{B}^{n\times n}, \tag{2}$$

where $\vec{1} = (1, 1, \cdots, 1)^T$. This linear program can be interpreted as selecting a permutation matrix $\mathbf{B}$, so that after permutation of $\mathbf{A}$, the sum of entries on the diagonal is maximized. The edges corresponding to the permutation matrix $\mathbf{B}$ is as known as a matching in $\mathbf{A}$. Thus, the solution of this program can be used to sparsify $\mathbf{A}$ with constraints of regularity. To generalize the standard linear assignment problem to the objective of extracting a balanced graph where each node connects to b edges, we can simply replace $\vec{1}$ with $\vec{b} = b \cdot \vec{1}$. However, this solution for such a b-matching problem can be approximated by solving the above linear assignment problem for $b/2$ times and removing the selected edges after each iteration.

As discussed earlier, we seek fast and scalable solutions for graph sparsification due to the demand of processing large scale graphs in many domains. Conventional approach for solving Eq. 2 is based on increasing augmenting paths, which leads to low concurrency and limited scalability [3, 19]. Thus, we propose to use the auction algorithm introduced by Bertsekas in [3]. Since the constrained problem in Eq. 2 can be converted into a dual form, the auction algorithm deals with the above linear programming by solving its dual problem. In particular, we are solving the following dual problem of the original primal linear program:

$$\min_{p,\pi} \ \vec{1}^T p + \vec{1}^T \pi \quad \text{s.t.} \ \ \vec{1}p^T + \pi\vec{1}^T \geq \mathbf{A}, \tag{3}$$

where $p = (p_1, p_2, \cdots, p_n)^T$ and $\pi = (\pi_1, \pi_2, \cdots, \pi_n)^T$ are known as the dual vectors. The constraints $\vec{1}p^T + \pi\vec{1}^T \geq \mathbf{A}$ indicate the element wise relationship between the matrices $\vec{1}p^T + \pi\vec{1}^T$ and $\mathbf{A}$, i.e. $(\vec{1}p^T + \pi\vec{1}^T)_{ij} \geq a_{ij}, i, j = 1, \cdots, n$. The auction algorithm computes the dual variables through an iterative *auction* process. Intuitively, we view each row i as a buyer and each column j as an object; a_{ij} is the benefit of object j to buyer i; p_j is the price of object j (initialized to 0 at the beginning); π_i is the profit for buyer i, defined as $(a_{ij} - p_j)$, in case object j is assigned to i. The auction algorithm proceeds as follows: Each buyer i bids for an adjacent object j that offers the highest profit, i.e., $\max_{j \in \text{adj}(i)}(a_{ij} - p_j)$, where $\text{adj}(i)$ denotes the set of adjacent nodes of i. The bid is the difference between the highest profit and the second highest profit. An object j is assigned to the buyer offering the highest bid, say buyer i. Thus, row i and column j are matched and price p_j is increased by the bid. Price increment makes an object expensive for competitors, so that they can choose other objects. The above steps are repeated for all unmatched rows until every row is matched or the matching does not change.

The naive auction algorithm described above has a defect caused by *price war* [3]. When the highest and second highest profits are equal for some buyers, the bid becomes 0 and the object price remains unchanged. Therefore, buyers can indefinitely compete for the same object without increasing its price. The object will be alternately assigned to them and the auction will not progress. To overcome this issue, a small positive scalar ϵ is added to the price of an object once it is assigned to a buyer. A smaller ϵ leads to better accuracy; a greater ϵ results in an accelerated auction process.

3.2 Auction for Graph Sparsification

The auction algorithm described in Section 3.1 selects a single edge for each node while maximizing the total weight of the selected edges. For selecting b edges, there are two straightforward approaches to generalize the auction. The first approach is to perform auction multiple times. Every time the algorithm selects an edge for each node, if exists, without having two edges connect to the same node. The other approach is to select up to b edges in each iteration process, following the same criteria for edge selection. The details are discussed in below.

Note that the above algorithm does not ensure that if a node i connects to a shadow node j', node j will also connect to node i'. This can cause adverse impact on graph regularity. We propose a heuristic strategy to reduce such negative impact. When such inconsistence occurs, saying node j selects node $\tilde{i}'$ instead of node i', we compare the percentile of edge $(j, \tilde{i}')$ with respect to all incident edges of j and the percentile of (i, j') with respect to all incident edges of i. By percentile, we mean the index of the selected edge among all incident edges sorted in descending order. We accept the edge with smaller percentile while reject the other one. The intuition that we select edges according to the percentile instead of edge weight is that all incident edges for the boundary nodes in a graph can be weighed much higher than even the lightest incident edge of an internal node.

Algorithm 1 Fast Graph Construction Using Parallel Auction Algorithm

Graph partitioning: partition graph G into L disjoint subgraphs $\{G_l\}_{l=1}^L$ with weight matrices $\{\mathbf{A}_l\}_{l=1}^L$, where $\mathbf{A}_l = \{a_{ij}^l\}$

Initialization: Dual vectors $p = \vec{0}$, initial $\pi = \vec{0}$, the set of selected edges $\mathcal{M} = \emptyset$

while price keeps changing **do**

[1]. For each subgraph corresponding to the weight matrix $\mathbf{A}_l = \{a_{ij}^l\}$, compute for nodes in X_l that have not identified b edges:

$$j_1^l = \arg\max(a_{ij}^l - p_j^l),\ \forall j \in \text{adj}(i)$$

.....

$$j_{b+1}^l = \arg\max(a_{ij}^l - p_j^l),\ \forall j \in \text{adj}(i), j \neq j_1, \cdots j_b$$

[2]. Remove earlier selected edges that conflict

$$\mathcal{M} = \mathcal{M} \backslash \{(i', j_t^l) \in \mathcal{M}, \forall 1 \leq t \leq b, i' \in X_l\}$$

[3]. Add current selected edges

$$\mathcal{M} = \mathcal{M} \cup \{(i, j_t^l) \in \mathcal{M}, \forall 1 \leq t \leq b$$

[4]. Update price

$$p_{j_t^l}^l = a_{ij_t^l}^l - a_{ij_{t+1}^l}^l + p_{j_{t+1}^l}^l + \epsilon, \forall t = 1, \cdots, b$$

[5]. Synchronize price globally $p_j^l = \max_{t=1}^P p_j^t$

end while

3.3 Parallelization

In this subsection, we discuss a parallelization strategy of the auction algorithm for graph sparsification. Given the weight matrix $\mathbf{A}$ of a bipartite graph, we first partition $\mathbf{A}$ into L disjoint sub-matrices, where each sub-matrix $\mathbf{A}_l = \{a_{ij}^l\}$ is of size $n_l \times n$, $\sum_{l=1}^L n_l = n$. Therefore, sub-matrix $\mathbf{A}_l$ is the weight matrix of a bipartite subgraph G_l, which contains disjoint node sets X_l and Y_l. Although $\mathbf{A}$

Table 2: Average running time (seconds) on the synthetic bipartite and unipartite graphs using different methods for constructing sparse graphs. The graphs have nodes from 100 to 2000 and the value of b is set as 10 uniformly. The compared methods include Loopy Belief Propagation (LBP) [9], kNN, and the proposed parallel auction algorithm (PAA).

n	**Bipartite**				**Unipartite**			
	$\|\mathbf{E}\|$	LBP	kNN	PAA	$\|\mathbf{E}\|$	LBP	kNN	PAA
100	5×10^3	0.2	8×10^{-4}	4×10^{-3}	9.9×10^3	0.3	4×10^{-3}	1.1×10^{-2}
200	2×10^4	2.8	3×10^{-3}	1.5×10^{-2}	3.98×10^4	0.7	0.01	0.04
500	1.25×10^5	18.7	0.02	0.11	2.495×10^5	6.2	0.07	0.28
1000	5×10^5	37.9	0.11	0.53	9.99×10^5	23.2	0.39	1.26
2000	2×10^6	609.7	0.47	2.42	3.998×10^6	111.4	1.31	5.39

can also be partitioned by columns or into checkerboard structures [4], the above horizontal partitioning along row direction is more natural since large scale sparse graphs/matrices are often stored in the compress sparse rows format. After partitioning, we can rewrite the linear assignment problem in Eq. 2 as:

$$\begin{aligned} \max & \sum_{l=1}^{L} \sum_{i \in X_l} \sum_{j \in Y_l} a_{ij} b_{ij} \qquad (4) \\ \text{s.t.} & \sum_{j \in Y_l} b_{ij} = 1, \ \forall i \in X_l, l = 1, \cdots, L \\ & \sum_{l=1}^{L} \sum_{i \in X_l} b_{ij} = 1, \ \forall j \in Y_l, \quad b_{ij} \geq 0, \ \forall i, j. \end{aligned}$$

Eq. 4 implies a straightforward parallelization of auction algorithm for graph sparsification. In Algorithm chart 1, we summarize the major steps of parallel auction for graph sparsification. Here we set the initial values for $\vec{p}$ and $\vec{\pi}$ are both $\vec{0}$. The maximum number of edges allowed for a node is denoted by b and the set for selected edges is $\mathcal{M}$, which is initialized as an empty set $\emptyset$.

The above algorithm allows concurrent auction on a maximum of L processors, each of which handles one single bipartite subgraph. The only communication between processors occurs when synchronizing price vectors in step 5 of the above parallel algorithm. Note that the solution of the other dual variable $\vec{\pi}$ is updated implicitly, which is given by $\pi_i^l = a_{ij}^l - p_j^l$, where (i, j) is selected. The parallel auction typically accelerates computation due to the concurrent auction activities in each sub-matrix. However, it does not change the complexity. That is, in the worst case (the input graph is a chain), it is equivalent to a serial auction process.

3.4 Complexity Analysis

The time complexity for auction algorithm depends on the number of auction iterations and the workload for each iteration. In an auction process, a price of node increases at least for ϵ [3], i.e., the minimum bid increment. Since the profit for bidder i that matched with object j is given by $(a_{ij} - p_j)$, the profit becomes negative after $|a_{ij}|/\epsilon$ iterations, i.e., i will seek other objects for possibly higher profit. In each iteration, we visit at most $|\mathbf{E}|$ edges (the number typically decreases dramatically after a few iterations), so the overall complexity is $O(|\mathbf{E}| \max |a_{ij}|/\epsilon)$. During the auction process, the only information we must keep is the price of objects. There are n objects, so the space complexity is $O(n)$. Note that the space for storing the data or graph itself is not counted for evaluating space complexity. In Table 1, we summarize the time and space complexity of the proposed parallel auction algorithm based graph construction process and compare with other methods. From this analysis, it is easy to see the proposed parallel auction algorithm (PAA) based method is extremely efficient for large scale sparse graph data, which is indeed very common in real applications, such as social network and geometry analysis [7].

4 EXPERIMENTS

In this section, we provide empirical study of the proposed parallel auction algorithm (PAA) based graph construction method and compare with the-state-of-art approaches. In particular, we are interested in comparing with the belief propagation (BP) based methods [9, 10] since these method tends to generate high quality graphs with balanced node connectivity, similar as our proposed method. Note that there are two variants of the BP approach, loopy belief propagation (LBP) and a speed-up version, sufficient selection belief propagation (SSBP). However, in the empirical study, we notice that these two methods share very similar computational performance. Hence, we only report the results of LBP for comparison. In addition, we also implement the nearest neighbor search based graph construction using the standard sorting pro-

cess as another baseline. Extensive experimenters over both synthetic and real benchmark datasets are performed to evaluate the computational efficiency and performance for different learning algorithms, as discussed below.

4.1 Speed Comparison

We first evaluate the running time of different graph construction methods. Similar to the settings in [9], here we randomly generate bipartite and unipartite graphs with $100 \leq n \leq 2000$ nodes, where the weights of graph edges are independently sampled from a uniform distribution $U(0, 1)$. For bipartite graph, each of the two disjoint node sets has $n/2$ nodes. For constructing a sparse graph, the degree of each nodes of the extracted sparse graph is uniformly set for all the experiments. For instance, in kNN approach, the value of k is set as 10, and accordingly $b = 10$ for b-matching methods. For fair comparison, all the experiments are conducted on the same platform with identical hardware and software environment.

For the LBP method, we use the default parameters in the software package [1], except setting the maximum iteration as 5000. Table 2 shows the comparison of the running time for the synthetic data. It is obvious that kNN provides the most efficient graph construction method due to its fast greedy search process. However, comparing LBP and PAA, both of which tend to generate balanced graphs, PAA improves the speed of graph construction in the magnitude of 10^2. In addition, we found that the propose method has more stable running performance for different random data, while both LBP method relies more on the properties of the synthetic graph data.

4.2 Performance Comparison

Graph representation has been widely used for different machine learning algorithms, including clustering and classification. In this subsection, we present the performance comparison study of clustering and classification through using different graph construction approaches. For clustering analysis, spectral clustering has been developed and shown effective in practice [16]. In a standard spectral clustering process, there are three key steps. The first step is to construct a data graph that connects sample points. Then one has to perform eigen-decomposition over the graph Laplacian. Finally, K-means algorithm is applied to derive the final clusters. In this study, we use the toy data [12] to construct different graphs, namely kNN graph, b-matching graph, and the graph built by the parallel auction algorithm (PAA-graph). Figure 4(a)-1(d) show the original data and different graphs. Then we feed these graph into standard spectral clustering algorithm to compare the results.

Figure 2 shows the error rate for the clustering results. The number of connected edges for graph nodes

varies from 6 to 24. For all the tests, we use the same Gaussian kernel based weighting scheme with the kernel bandwidth informally set as 0.1. Clearly, kNN graph provides the worst performance and b-matching graph has the best performance. The proposed parallel auction based graph construction method has slightly worse performance than b-matching. However, it significantly increases the by the magnitude of 10^2 in practice. Figure 1(e)-1(g) shows the examples of constructed sparse graphs using different approaches. Due to the greedy search process, kNN method generates highly irregular graph and breaks the data structure by creating more cross-manifold edges. In contrast, b-matching and the proposed PAA method create more balanced graphs and have much less edges across the two clusters. When the node degree increases, it is easy to generate more cross-cluster edges. Hence, all the clustering performance of all three graph construction methods accordingly decreases.

In addition, we also compare the performance of graph based semi-supervised learning for classification tasks, i.e. classifying USPS handwritten digits [5] and face recognition [6]. In particular, we apply the method developed by Zhou et.al in [23] as the testbed for different graph construction methods. In the tests, we fix the number of node degree as 7 and use the same weighting scheme, similar to the settings used in the above clustering experiments. The number of initially given labels is varied from 4 to 20 for digits data and 3 to 18 for the face data. For each setting, we randomly run 50 independent trials and compute the average error rates of the classification results. Figure 3(a) and 3(b) show the performance curves with error bars for digits classification and face recognition, respectively. Again, b-matching approach builds the most balanced graph and therein achieves the best performance. The

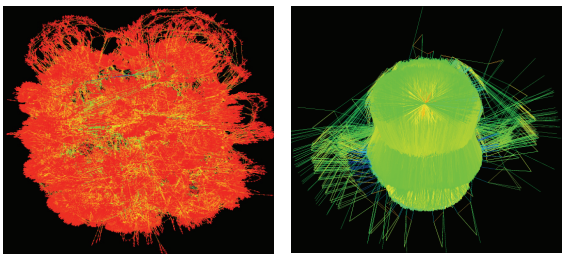
The horizontal axis indicates the number of initially given labels and the vertical axis shows the error rate of classification results.

proposed PAA method has slightly worse performance but almost as fast as kNN method, which tends to create the highly imbalanced graphs.

4.3 Evaluation of Parallel Efficiency

Since all the above experiments involve the graphs with relatively small scales, there is no extra benefit to parallelize the algorithm. However, when handling large scale data, it is very important to perform parallel process for fast graph construction. Note that the time complexity of the PAA based graph construction is linear with respect to the number of edges. This property makes the approach very suitable to the applications with large scale sparse data graphs. In order to validate the parallelization efficiency of the proposed method for such applications, here we used two real benchmark datasets about circuit simulation problems from the sparse matrix collection [7]. The first graph data "ASIC_680ks" contains 682, 712



(a) (b)

Figure 4: The visualization of the two large graph data: a) ASIC_680ks, and b) ASIC_680k.

nodes and $2,329,176$ edges (after reverse process) [2], and the second data "ASIC_680k" has $682,862$ nodes and $3,871,773$ edges (after reverse process) [3]. Figure 4 presents the visualization of these two large graphs[4]. From this figure, it is easy to see that both graphs are heavily irregular and the boundary nodes are with extremely sparse connectivity. Here we apply the proposed PAA method to recover sparse and balanced graphs from the original graph data.

Our experiments are performed using a computer cluster on which each compute node contains two 2.33 GHz Intel Xeon E5410 quadcore processors. The eight cores share 32 GB DDR2 RAM running at 800 MHz. The OS is Ubuntu 9.10 with GCC 4.10 installed. All codes were compiled with -O3 level option. We spawn parallel processes using MPICH2 to evaluate the parallel performance of the proposed PAA based graph construction method. In addition, we utilize MPICH2 so that our proposed technique can scale up to multiple compute nodes when the scale of the input graph is large enough. The graphs are partitioned evenly and launched to each process with equal number of nodes along with all the neighbor information.

For both graph data, graph construction is performed for two scenarios: $b = 2$ and $b = 4$. For those nodes with less than b edges in the original graph, all the connected edges will be preserved. We vary the number of used processes from 1 to 8, where each process is hosted by a separate core. The computational cost includes the time for generating parallel process, partitioning the graph, assigning tasks to each process, and performing the auction process (The time for loading data is not considered). Table 3 provides the running time in seconds for each tested case. From this table, it is easy to see that the proposed PAA-based graph construction method achieves lower execution time when multiple processes were used. However, the speedup is *sublinear* instead of linear because the extra time used for parallelization and communication. In general, when performing the graph construction in 8 parallel processes, the time cost will be reduced from one quarter to more than half. Especially for more complex problems (e.g., $b = 4$), the speed up is usually more significant.

Table 3: Evaluation of the parallel efficiency of the proposed PAA-based graph construction method. The numbers give the computational cost in seconds using different number of processes.

Data	**ASIC_680ks**		**ASIC_680k**	
# of processes	$b = 2$	$b = 4$	$b = 2$	$b = 4$
1	3.09	18.92	1.76	11.62
2	2.74	18.73	1.49	10.83
4	2.70	11.60	1.33	7.29
8	2.47	8.92	1.26	5.03

5 CONCLUSION

Data graph has been widely used for different machine learning and data mining algorithms. It is critical to build high quality graphs with affordable cost. Commonly, one aims in extracting sparse yet regular graph from data for both theoretic and practical advantages. Popular methods for constructing sparse graphs include nearest neighbor method and b-matching algorithm. The former is very efficient since it essentially perform greedy search to pick up the significant graph edges. However, it often generates highly imbalanced graphs with unsatisfactory performance. The later can provide fairly balanced regular graphs but suffers from extremely high computational cost.

In order to remain computational efficiency, while achieving certain properties of the extracted graph, such as sparsity and regularity, in this paper, we proposed a novel graph construction method through exploring the auction algorithm. In particular, the proposed method is almost as fast as kNN method, while maintain stratificatory regularity property. Experimental results show that the parallel auction algorithm based graph construction provides comparable performance to the b-matching algorithm, but improves the speed in the magnitude of 10^2. Finally, we also provide the empirical study of the parallelization efficiency over large data sets with up to 680K nodes. One of our future direction is to extend the proposed graph construction to semi-supervised and supervised scenarios, where partial label information are given to help improve accuracy of the auction process.

Abstract

We introduce a new cluster-cumulant expansion (CCE) based on the fixed points of iterative belief propagation (IBP). This expansion is similar in spirit to the loop-series (LS) recently introduced in [1]. However, in contrast to the latter, the CCE enjoys the following important qualities: 1) it is defined for arbitrary state spaces 2) it is easily extended to fixed points of generalized belief propagation (GBP), 3) disconnected groups of variables will not contribute to the CCE and 4) the accuracy of the expansion empirically improves upon that of the LS. The CCE is based on the same Möbius transform as the Kikuchi approximation, but unlike GBP does not require storing the beliefs of the GBP-clusters nor does it suffer from convergence issues during belief updating.

1 Introduction

Graphical models play a central role in knowledge representation and reasoning across a broad spectrum of scientific disciplines, in which probabilistic queries, or *inference* must be performed. A classic goal is to calculate the *partition function*, or sum over all possible configurations of the model; this task is central to many problems, such as computing the probability of observed data ("probability of evidence"), learning from data, and model comparisons.

Exact inference in these systems is typically NP-hard, motivating the need for efficient and accurate approximations. One of the most successful algorithms is *iterative belief propagation* (IBP) [7], which approximates the marginal probabilities of the distribution via an iterative, message-passing procedure. IBP can also be interpreted as a variational optimization, in which the messages and their approximate marginals, or beliefs, minimize a particular free energy approximation called the Bethe approximation [11, 3]. IBP is approximate on graphs with cycles, but is often empirically very accurate.

The wide success of IBP has also led to several techniques for improving its estimate quality. Generalized belief propagation (GBP) performs IBP-like updates on a set of *regions*, consisting of collections of variables. However, region selection is often difficult, and can even lead to convergence problems and degraded estimates [10]. An alternative is to use "series corrections" to the partition function such as the loop series and its generalizations, which compute modifications to the estimate provided by a given fixed point of IBP [1]. Such series expansions can be used to provide "any-time" algorithms that initialize to the IBP estimate and eventually converge to the exact solution.

In this paper we propose an alternative series correction to IBP estimates based on a cluster cumulant expansion (CCE). We show that the CCE has several benefits over the loop series representation, including more accurate partial estimates and more efficient aggregation of terms. We also show that our CCE representation is closely related to GBP, and that it can naturally be extended to GBP fixed points. We show the effectiveness of our approach empirically on several classes of graphical models.

2 Background

Let $X = \{X_i\}$ be a collection of random variables, each of which takes on values in a finite alphabet, $X_i = x_i \in \mathcal{X}$. For convenience, in the sequel we will not distinguish between the random variable X_i and its instantiation x_i. Suppose that the distribution on X factors into a product of real-valued, positive functions $\{\psi_f : f \in F\}$, each defined over a subset f of the variables:

$$p(\mathbf{x}) = \frac{1}{Z_\psi}\psi(\mathbf{x}) = \frac{1}{Z_\psi}\prod_{f\in F}\psi_f(x_f)$$

where $x_f = \{x_i \,|\, i \in f\}$ represents the arguments of factor ψ_f, and Z_ψ is the partition function, $Z_\psi = \sum_x \psi(\mathbf{x})$, which serves to normalize the distribution. We denote by F_i the set of factors that have x_i in their argument. A *factor graph* represents this factorization using a bipartite graph,

in which each factor (represented by a square) is connected to the variables (circles) in its argument. See Figure 1-Left.

2.1 Iterative Belief Propagation

With each factor or variable node in the factor graph (FG) we will associate a belief, denoted with $b_f(x_f)$ and $b_i(x_i)$ respectively. Iterative (or Loopy) Belief Propagation (IBP) is a message passing algorithm on the factor graph that attempts to make these beliefs consistent with each other. In particular, at a fixed point of IBP we require

$$\sum_{x_f \backslash x_i} b_f(x_f) = b_i(x_i) \tag{1}$$

for every pair of factor and variables nodes that are connected in the factor graph. IBP expresses these beliefs in terms of a set of messages m_{fi}:

$$\begin{aligned} b_i(x_i) &\propto \prod_{f \in F_i} m_{fi}(x_i) \\ b_f(x_f) &\propto \psi_f(x_f) \prod_{i \in f} \prod_{g \in F_i \backslash f} m_{gi}(x_i) \end{aligned} \tag{2}$$

and updates the messages iterative to achieve Eqn. (1):

$$m_{fi}^{\text{new}}(x_i) \leftarrow \delta(x_i) m_{fi}^{\text{old}}(x_i), \quad \delta(x_i) \doteq \frac{\sum_{x_f \backslash x_i} b_f(x_f)}{b_i(x_i)}$$

If the factor graph contains no cycles, at convergence the beliefs exactly equal the marginal probabilities of $p(\mathbf{x})$.

[11] showed that IBP fixed points correspond to stationary points of the Bethe variational free energy $\mathcal{F}$, giving an approximation to the log-partition function:

$$\begin{aligned} \log \hat{Z}_{BP} &= -\mathcal{F}(\{\psi_f\}, \{b_f, b_i\}) \\ &= \sum_{f \in F} \mathbb{E}_{b_f}[\log \psi_f] + \sum_{f \in F} \mathbb{H}(b_f) + \sum_{i \in V} (1 - |F_i|) \mathbb{H}(b_i) \end{aligned} \tag{3}$$

where V is the set of variables, $\mathbb{E}_{b_f}$ denotes the expectation under b_f and $\mathbb{H}(b_f) = -\sum_x b(x_f) \log b(x_f)$ is its entropy.

We may view the IBP updates as a *reparameterization* of the original distribution [9]. In particular, if we apply the message update from factor f to variable i, according to Eqn. (2) we change $b_i(x_i) \leftarrow b_i(x_i)\delta(x_i)$ and also a total of $|F_i|-1$ factor beliefs $b_g(x_g) \leftarrow b_g(x_g)\delta(x_i)$ with $g \in F_i \backslash f$ (see Figure 1-Left). As a result, the expression

$$\frac{1}{Z_b} b(\mathbf{x}) = \frac{1}{Z_b} \prod_{f \in F} b_f(x_f) \prod_{i \in V} b_i(x_i)^{1-|F_i|} \tag{4}$$

remains invariant under message updating, where Z_b is the partition function of the reparameterization $b(\mathbf{x})$. Moreover, if we initialize all messages to 1, we immediately see that Eqn. (4) is also equal to $\frac{1}{Z_\psi}\psi(\mathbf{x})$.

Since $\psi(\mathbf{x})$ and $b(\mathbf{x})$ correspond to the same normalized distribution $p(\mathbf{x})$, they differ by a constant multiplicative factor. Using (3) and noting that $\mathcal{F}(\{b\}, \{b_f, b_i\}) = 0$ shows that this factor is exactly $\hat{Z}_{BP}$, and so

$$Z_\psi = \hat{Z}_{BP} \cdot Z_b \tag{5}$$

This shows that the true partition function Z_ψ can be computed from IBP's estimate $\hat{Z}_{BP}$ and the reparameterization's normalization constant, Z_b.

2.2 Generalized Belief Propagation

Generalized BP, or GBP [11], generalizes (3) to include higher-order interactions than the original factors of the model. In GBP, one identifies a set of *regions* $\mathcal{R}$, in which each region $\alpha \in \mathcal{R}$ is defined to be a subset of the factors, $\alpha \subseteq F$. Each region is also given a "counting number" c_α, and messages are passed between regions; a data structure called a *region graph* is used to organize the message passing process. The GBP estimate of the partition function is

$$\log \hat{Z}_{GBP} = \sum_{f \in F} \mathbb{E}_b[\log \psi_f] + \sum_{\alpha \in \mathcal{R}} c_\alpha \mathbb{H}(b_\alpha). \tag{6}$$

BP on the factor graph constitutes a special case of GBP, in which the regions $\mathcal{R} = F \cup V$ and counting numbers $c_f = 1$ and $c_i = 1 - |F_i|$. Regions form a partial ordering defined by their set inclusion; the *ancestors* of region α are $an(\alpha) = \{\gamma \in \mathcal{R} | x_\alpha \subset x_\gamma\}$ and its *descendants* are $de(\alpha) = \{\beta \in \mathcal{R} | x_\alpha \supset x_\beta\}$, where x_α is the set of variables in region α.

The counting numbers should satisfy some basic properties; in [11], a RG is considered *valid* or *1-balanced* if

$$\sum_{\alpha \in R(f)} c_\alpha = 1 \; \forall \, f \qquad \sum_{\alpha \in R(i)} c_\alpha = 1 \; \forall \, i$$

where $R(f)$, $R(i)$ are those regions that contain factor f and variable i, respectively.

Validity can be ensured by assigning each factor f to a single outer region, setting $c_\alpha = 1$ for outer regions (i.e. regions with no parents) and recursively for inner regions as:

$$c_\alpha = 1 - \sum_{\beta \in an(\alpha)} c_\beta. \tag{7}$$

The GBP message updates can again be interpreted as reparameterization updates on the region graph. Any two regions that are connected through a directed edge will exchange messages from parent to child region. We write the beliefs in terms of the potentials and messages to α and its descendants, $\Delta_\alpha = \alpha \cup de(\alpha)$,

$$b_\alpha(x_\alpha) = \frac{1}{Z_\alpha} \prod_{f \in \alpha} \psi_f(x_f) \prod_{\substack{\gamma \in \{an(\Delta_\alpha) \backslash \Delta_\alpha\} \\ \beta \in \Delta_\alpha}} m_{\gamma\beta}(x_\beta)$$

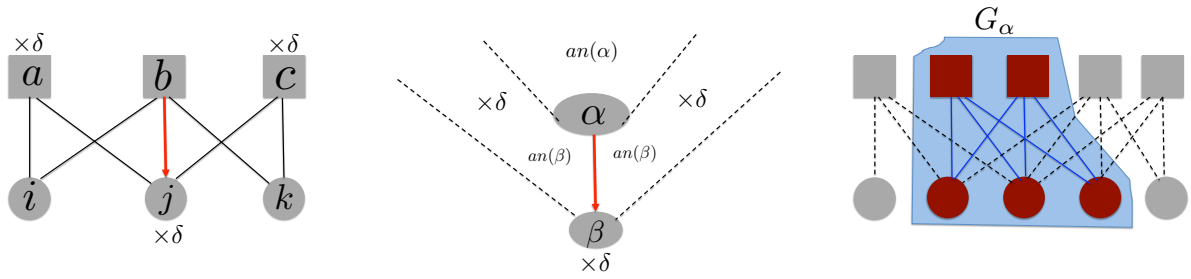

Figure 1: **Left:** A reparameterization update on a factor graph. **Middle:** A region graph GBP reparameterization update. **Right:** Factor subgraph G_α corresponding to a cluster-cumulant.

and write a fixed-point message update as,

$$m^{\text{new}}_{\alpha\beta}(x_\beta) \leftarrow \delta(x_\beta) m^{\text{old}}_{\alpha\beta}(x_\beta) = \frac{\sum_{x_\alpha \setminus x_\beta} b_\alpha(x_\alpha)}{b_\beta(x_\beta)} m^{\text{old}}_{\alpha\beta}(x_\beta)$$

In words, to compute the belief at region α we collect messages from all regions that are either ancestors or ancestors of descendants of that region, and that flow into α or its descendants. Those messages that originate in α or its descendants are not used.

It is now not difficult to see that these updates constitute a reparameterization. Namely, if we update a message $m_{\alpha\beta}$, the update factor δ is multiplied into the expressions for b_β and all its ancestors, except b_α and all its ancestors. Using the expression for the counting numbers (7) we thus see that we accumulate a total number of terms,

$$c_{\text{total}} = [c_\beta + \sum_{\gamma \in an(\beta)} c_\gamma] - [c_\alpha + \sum_{\delta \in an(\alpha)} c_\delta] = 0$$

where we used that $c_\beta = 1 - \sum_{\gamma' \in an(\beta)} c_{\gamma'}$ and similarly for c_α. This is illustrated in Figure 1-Middle.

As a result, the following expression will stay invariant under the GBP updates:

$$\frac{1}{Z_\psi} \prod_f \psi_f(x_f) = \frac{1}{Z_b} \prod_\alpha b_\alpha(x_\alpha)^{c_\alpha} \tag{8}$$

We can now use similar arguments as in Section 2.1 to show that $Z_\psi = \hat{Z}_{GBP} \cdot Z_b$ again holds.

2.3 The Loop Series Expansion

The loop series [1, 8, 2] expresses Z_b as a finite series expansion of terms related to the generalized loops of the graph. Starting from Eqn. (4) we rewrite the terms:

$$\frac{b_f(x_f)}{\prod_{i \in f} b_i(x_i)} = 1 + \frac{b_f(x_f) - \prod_{i \in f} b_i(x_i)}{\prod_{i \in f} b_i(x_i)} = 1 + U_f(x_f)$$

where U_f is like a covariance in that it measures dependence among the variables $x_i, i \in f$. We can then write

$$Z_b = \mathbb{E}_{\tilde{b}}\Big[\prod_{f \in F} (1 + U_f)\Big] \quad \text{where} \quad \tilde{b}(\mathbf{x}) = \prod_i b_i(x_i).$$

Expanding the product gives one term for each element in the power set of F. If we expect the individual terms U_f to be small, it makes sense to organize this series (for example) in order of increasing number of U_f terms, and truncate it once some computational limit is reached. Each term corresponds to a subset $\alpha \subseteq F$, and thus to a subgraph of the factor graph. One can show that if this subgraph contains any factor f that is *not* part of a loop (a.k.a. part of a dangling tree), then the corresponding term will be zero.

To make the connection with the formulation of [1], we must assume a binary alphabet $x_i \in (0, 1)$. Following [8] we can re-express,

$$\frac{b_f(x_f) - \prod_{i \in V_f} b_i(x_i)}{\prod_{i \in V_f} b_i(x_i)} = \sum_{v \subseteq V_f, |v| \geq 2} \beta_v \prod_{i \in v} (x_i - \mathbb{E}[x_i])$$

$$\beta_v = \frac{\mathbb{E}[\prod_{i \in v}(x_i - \mathbb{E}[x_i])}{\prod_{j \in v} \mathbb{V}(x_j)} \tag{9}$$

where $\mathbb{V}(x)$ denotes the variance of x. In the process we have created even more terms than the powerset of all factors because each factor itself is now a sum over all its subsets of variables with cardinality larger than one. The total set of terms is in one-to-one correspondence with all the "generalized loops" of the factor graph (graphs where every variable and factor node have degree at least two). The advantage for the binary case is that the final expansion can now be written in terms of expectations of the form $\mathbb{E}[(x_i - \mathbb{E}[x_i])^d]$ which admit closed form expressions in terms of the beliefs b_i obtained from IBP at its fixed point. We refer to [1, 8] for further details.

3 The Cluster-Cumulant Expansion

We now develop an alternative expansion of the log-partition function which we call the cluster-cumulant expansion (CCE). As with the loop series, we begin analysis at a fixed point of IBP; we will later relate our expansion to GBP and extend its definition to include GBP fixed points.

The CCE is defined over an arbitrary collection of subsets of factors which we will denote with α. We define

a partial ordering on this set through subset inclusion, i.e. $\alpha \leq \beta$ iff $\alpha \subseteq \beta$ and $\alpha < \beta$ iff $\alpha \subset \beta$. We will denote this poset with Ω. We also define a factor subgraph, $G_\alpha = \{i, f | i \in V_\alpha, f \in \alpha, \alpha \in \Omega\}$ where V_α corresponds to the set for variables that occur in the arguments of the factors $f \in \alpha$. An example of such a factor subgraph is provided in Figure 1-Right. Finally we will define the partial probability distribution over this factor subgraph as P_α and the corresponding partial log partition function, $\log Z_\alpha$ as its log normalization constant:

$$P_\alpha(x_\alpha) = \frac{1}{Z_\alpha} \prod_{i \in V_\alpha} b_i(x_i) \prod_{f \in \alpha} \frac{b_f(x_f)}{\prod_{i \in V_f} b_i(x_i)} \tag{10}$$

$$\log Z_\alpha = \log \sum_{x_\alpha} \prod_{i \in V_\alpha} b_i(x_i) \prod_{f \in \alpha} \frac{b_f(x_f)}{\prod_{i \in V_f} b_i(x_i)} \tag{11}$$

We first observe that if we choose $\alpha = F$ (the set of all factors) then $\log Z_F$ is the exact log partition function $\log Z_b$. We now show that $\log Z_\alpha = 0$ when the corresponding factor subgraph G_α is a tree:

THEOREM **1.** *If the factor subgraph G_α is* singly connected*, then* $\log Z_\alpha = 0$.

Proof. When G_α is a tree, the expression (10) represents the exact joint probability distribution expressed in terms of its marginals with $Z_\alpha = 1$. Thus the result follows. □

As a corollary we observe that $\log Z_\alpha$ vanishes if α consists of a single factor f. The theorem also allows us to remove all "dangling trees" from any factor subgraph by marginalizing out the variables that correspond to the dangling tree. We will thus define the "core" of a factor subgraph as the part of the factor subgraph that remains after all dangling trees have been removed (see also [2]).

We are now ready to define the cluster-cumulants (CCs). The idea is to decompose each partial log partition function as a sum of cluster-cumulant contributions from clusters in the same or lower levels of the partially ordered set $\alpha \in \Omega$. In this manner, we expect that the lowest order CCs generate the largest contribution and that higher order CCs subsequently represent increasingly small corrections. The definition of the CCs is provided by the expression [5, 4]

$$\log Z_\alpha = \sum_{\beta \leq \alpha} C_\beta \tag{12}$$

This relation can be inverted using a Möbius transform,

$$C_\alpha = \sum_{\beta \leq \alpha} \mu_{\beta,\alpha} \log Z_\beta \tag{13}$$

where we define the Möbius numbers as,

$$\mu_{\alpha,\alpha} = 1 \quad \text{and} \quad \mu_{\gamma,\alpha} = -\sum_{\beta : \gamma < \beta \leq \alpha} \mu_{\beta,\alpha} \quad \text{if } \gamma < \alpha.$$

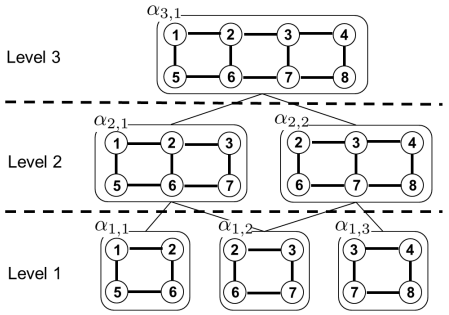

Figure 2: A poset for a pairwise MRF on a 1×3 grid. Truncating this poset at level 1 would include clusters over the faces of the grid. Truncating at level 2 would add clusters $\alpha_{2,1}$ and $\alpha_{2,2}$.

To approximate $\log Z \approx \log Z_\ell$ we truncate the cumulant series by only including clusters $\alpha \in \Omega_\ell$ up to some level ℓ in the poset:

$$\log Z_\ell = \sum_{\alpha \in \Omega_\ell} C_\alpha = \sum_{\alpha \in \Omega_\ell} \sum_{\beta \leq \alpha} \mu_{\beta,\alpha} \log Z_\beta \tag{14}$$

$$= \sum_{\beta \in \Omega_\ell} \sum_{\alpha \in \Omega_\ell} \mu_{\beta,\alpha} \mathbb{I}[\beta \leq \alpha] \log Z_\beta \doteq \sum_{\beta \in \Omega_\ell} \kappa_\beta \log Z_\beta$$

where $\mathbb{I}[\cdot]$ is the indicator function. Moreover, $\kappa_\beta \doteq \sum_{\alpha \in \Omega_\ell} \mu_{\beta,\alpha} \mathbb{I}[\beta \leq \alpha]$ can be computed recursively as

$$\kappa_\beta = 1 - \sum_{\alpha \in an(\beta)} \kappa_\alpha \tag{15}$$

with $an(\beta)$ the ancestors of cluster β in the Hasse diagram corresponding to the poset and with $\kappa_\alpha = 1$ for the clusters at the highest level of Ω_ℓ (i.e. the clusters with no parents) [6]. It is important to realize that this truncation is *not* equivalent to simply including all partial log partitions from the the highest level in the poset, i.e. $\log Z_\ell = \sum_{\alpha \in \Omega_\ell} C_\alpha \neq \sum_{\alpha \in \Omega_\ell} \log Z_\alpha$.

Figure 2 illustrates the computation of $\log Z_\ell$ on a simple pairwise MRF. On this 1×3 grid, the approximation truncated at level 2 is $\log Z_2 = \log Z_{\alpha_{2,1}} + \log Z_{\alpha_{2,2}} - \log Z_{\alpha_{1,2}}$. The computation of each partial log partition function requires exact inference on the partial factor subgraph. Thus, the time complexity for an approximation including c clusters is $O(c|V| \exp(w))$, where w is the largest induced width of the c clusters. However, the space complexity of the truncated approximation is $O(|V| \exp(w))$ since we need only retain $\log Z_\alpha$ for each cluster.

This expansion is similar to the expansion of the free energy (or the entropy) in the cluster variation method of GBP (see Section 2.2). However, there clusters serve as regions between which messages are exchanged during the execution of GBP. In contrast, in this paper CCs are calculated after IBP has converged in order to compute corrections.

The cumulant definition in Eqn. (13) immediately shows that cumulants of singly connected subgraphs vanish:

THEOREM **2.** *If the factor subgraph G_α is* singly connected*, then the cluster-cumulant satisfies $C_\alpha = 0$.*

Proof. From Eqn. (13) we see that a cumulant can be written as a linear combination of $\log Z_\alpha$ and $\log Z_\beta,\ \beta < \alpha$. Using Theorem 1 together with the facts that every subgraph of a tree is a smaller tree (or a forest of trees) and that at the lowest level of the poset we have $C_\alpha = \log Z_\alpha$, the result follows by induction. □

Unlike the terms in the loop series [1] (see Section 2.3), cluster-cumulants corresponding to *disconnected* subgraphs also vanish, even if the disconnected components are not singly connected.

THEOREM **3.** *If the factor subgraph G_α is* disconnected*, then the cluster-cumulant satisfies $C_\alpha = 0$.*

Proof. If the graph G_α is disconnected, its probability P_α factorizes: $P_\alpha = P_{\alpha_A} P_{\alpha_B}$. Then, the partial partition function decomposes as $\log Z_\alpha = \log Z_{\alpha_A} + \log Z_{\alpha_B}$ which by Eqn. (12) we rewrite as $\log Z_\alpha = \sum_{\beta_A \le \alpha_A} C_{\beta_A} + \sum_{\beta_B \le \alpha_B} C_{\beta_B}$. Again by Eqn. (12) we have

$$\begin{aligned} C_\alpha &= \log Z_\alpha - \sum_{\beta<\alpha} C_\beta \\ &= \sum_{\beta_A \le \alpha_A} C_{\beta_A} + \sum_{\beta_B \le \alpha_B} C_{\beta_B} - \sum_{\beta<\alpha} C_\beta. \end{aligned}$$

Clusters $\beta < \alpha$ in the poset fall into one of three categories: either $C_\beta \le C_{\alpha_A}$, or $C_\beta \le C_{\alpha_B}$, or $[(C_\beta > C_{\alpha_A}) \wedge (C_\beta > C_{\alpha_B}) \wedge (C_\beta < C_\alpha)]$. We now proceed by induction. Cumulants in the first two categories will cancel in the expression for C_α. Sufficiently small clusters will have no cumulants in the third category, and so must be zero. For larger clusters, cumulants in the third category correspond to smaller clusters that must also be disconnected, which by the inductive argument must vanish. The result follows. □

This property is special to the cumulant expansion and holds even though the partial log-partition function $\log Z_\alpha$ for the disconnected region does *not* vanish. Apart from reducing the number of terms that must be considered, this property also suggests (by continuity of the cumulants as a function of their factor parameters) that cumulants with nearly-independent components must also be small. Thus, we expect significant contributions from tight, highly correlated sets of variables and factors, but small contributions from clusters with components that are almost independent.

To emphasize this point, consider a cluster-cumulant corresponding to a subgraph G_α that has one uniform factor $\psi_f(x_f) = 1$. Moreover, assume that the cluster $\tilde{\alpha}$ given by removing this factor from α is also in the poset. This creates a situation where cluster α is ranked higher in the poset than $\tilde{\alpha}$, i.e., $\alpha > \tilde{\alpha}$, yet their partial partition functions must be the same: $\log Z_\alpha = \log Z_{\tilde{\alpha}}$. In this case, $C_\alpha = 0$:

THEOREM **4.** *Consider a poset Ω that includes a factor f with unit potential $\psi_f(x_f) = 1$, and a cluster α that contains factor f. Assume that there is also a cluster $\tilde{\alpha} < \alpha$ containing the same factors as α except f, i.e. $\tilde{\alpha} = \alpha \backslash f$. Then, $C_\alpha = 0$.*

Proof. For both clusters $\{\alpha, \tilde{\alpha} | \alpha > \tilde{\alpha}\}$ we must have the same partial partition function, $\log Z_\alpha = \log Z_{\tilde{\alpha}}$. Hence, from Eqn. (12) we have $\sum_{\beta \le \alpha} C_\beta = \sum_{\tilde{\beta} \le \tilde{\alpha}} C_{\tilde{\beta}}$. Since $\alpha > \tilde{\alpha}$ it follows that $\sum_{\beta \le \alpha} C_\beta = \sum_{\tilde{\beta} \le \tilde{\alpha}} C_{\tilde{\beta}} + \sum_{\gamma > \tilde{\alpha}, \gamma \le \alpha} C_\gamma$. However, since $\tilde{\alpha}$ is defined to have exactly one factor fewer than α we have that $\sum_{\gamma > \tilde{\alpha}, \gamma \le \alpha} C_\gamma = C_\alpha$. Combining these expressions we have $C_\alpha = 0$. □

The significance of Theorem 4 is illustrated by imagining a situation where $\psi_f(x_f) \approx 1$. By the continuity argument, we expect $C_\alpha \approx 0$ if the cluster $\tilde{\alpha}$ with factor f removed is in the poset. Hence, a cluster-cumulant will only significantly differ from zero if it introduces new dependencies that were not already captured by lower order cumulants. This result strengthens the interpretation of CCE as an expansion in terms of orders of statistical dependency.

These considerations suggest a way to build posets that are likely to deliver good truncated series approximations of the log-partition function. We first choose a collection of clusters which may be overlapping, but none are a subset of any other cluster. These clusters should be chosen so that 1) they are not disconnected and 2) they have no dangling trees. Moreover, tightly coupled clusters with strong interdependencies are preferred over ones with weak dependence. We then generate all intersections, intersections of intersections, etc., to construct our poset. Finally we compute their partial log partition functions and combine them using Eqn. (14).

4 CCE for Region Graphs

We now extend the cluster-cumulant expansion to region graphs; see Section 2.2 and [11] for background on region graphs. The CCE will be build on top of an existing region graph. We will call the existing region graph "calibrated" (abbreviated CRG) if the GBP fixed point equations have converged.[1] We will add new "uncalibrated" regions to the region graph during the expansion (see Figure 3-Left). Any new region will become a parent of all the existing regions that it contains. We then define the region subgraph $G_\alpha = G_{\Delta_\alpha}$ to be the collection of *calibrated* regions and parent-child relations restricted to α and its descendants. Note that G_α includes only regions in the calibrated part of the region subgraph, i.e., below the dashed line in Figure 3-Left.

[1] We only consider CCEs on calibrated region graphs; although an expansion can be established for uncalibrated RGs, Theorem 2 will not hold (increasing the number of non-zero cumulants) and terms may not fall off quickly, leading to poor approximations.

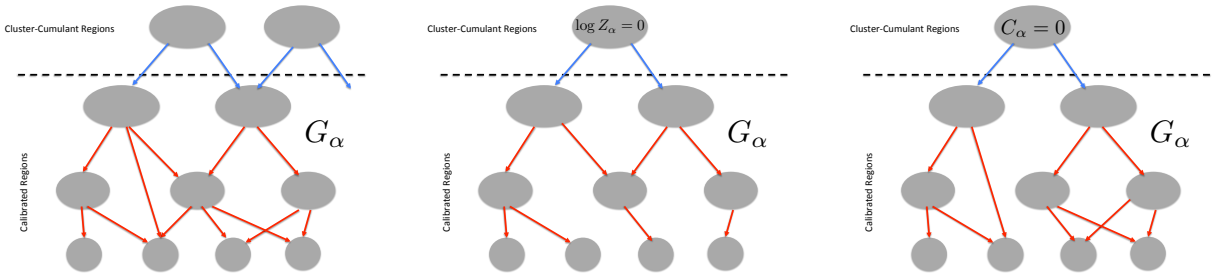

Figure 3: **Left:** Cluster-cumulant extension of the calibrated region graph. **Middle:** A tree-structured RG for which $\log Z_\alpha = 0$. **Right:** Illustration of a disconnected RG for which $C_\alpha = 0$.

We define counting numbers c_β^α for regions β in G_α by

$$c_\beta^\alpha = 1 - \sum_{\gamma \in (G_\alpha \cap an(\beta))} c_\gamma^\alpha$$

Note that a counting number c_β^α can vanish for some regions in G_α even though their counting number c_β in the original region graph did not vanish. Regions with $c_\beta^\alpha = 0$ will not contribute to $\log Z_\alpha$ and can be excluded from G_α.

The partial log-partition function for this region is,

$$\log Z_\alpha = \log \sum_{x_\alpha} \prod_{\beta \subseteq \alpha} b_\beta(x_\beta)^{c_\beta^\alpha} \tag{16}$$

To generate cumulants we again use Eqn. (13). The truncated cumulant series is the sum of these cumulants up to some level in the poset. More convieniently, we can instead use Eqn. (14) to express the series in terms of partial log partition functions. Note that this will require counting numbers κ_α that should not be confused with the counting numbers c_α above. In particular, the c_α are computed strictly in terms of the calibrated part of the region graph (e.g., the regions right below the dashed line in Figure 3-Left have $c_\alpha = 1$), while the κ_α are computed strictly in terms of the cluster-cumulants (e.g., the regions at the highest level in the extended region graph have $\kappa_\alpha = 1$).

As with the IBP expansion, $\log Z_\alpha$ vanishes for a region subgraph G_α that is singly connected (after only regions with $c_\beta^\alpha \neq 0$ have been retained):

THEOREM **5.** *If a region subgraph G_α consisting of regions in the CRG that are descendants of α and that have counting numbers $c_\beta^\alpha \neq 0$ is* singly connected*, then the partial log partition function and the cumulant satisfy* $\log Z_\alpha = 0$, $C_\alpha = 0$.

Proof. Since the marginals on G_α are calibrated (due to the reparameterization property of GBP) and because G_α is singly connected, we have $Z_\alpha = 1$. Since according to Eqn. (13) cumulants are linear combinations of log-partition functions over subsets and since all subsets must also be singly connected (or disconnected), the cumulant for a singly connected region must also vanish. □

This idea is illustrated in Figure 3-Middle. More generally, for any region subgraph we can remove "dangling trees" for the purpose of computing the CCE. (Note that this removal may change the counting numbers of regions connecting the core to the dangling trees.) To see this, follow an elimination order from the tree's leaf regions to the core. Since it is just message passing on the (hyper) tree and since the tree was already at a fixed point of GBP, the marginalization result will be equivalent to removing those regions.

Analogous to the factor graph case, cluster-cumulants defined on a region subgraph with two or more disconnected components vanish. The proof is identical to the one given for Theorem 3, and so we simply state the result:

THEOREM **6.** *If a region subgraph G_α consisting of regions in the CRG that are descendants of α and that have counting numbers $c_\beta^\alpha \neq 0$ is* disconnected*, then the cluster-cumulant satisfies $C_\alpha = 0$.*

This is illustrated in Figure 3-Right. Note again that the partial log partition function may not vanish; rather, it will equal the sum of two (or more) terms whose contributions are already included in the lower order cumulants.

In building our CCE, it is clear that we should avoid CCs that correspond to either disconnected or singly connected region subgraphs. (However, if we happen to include them, no harm is done to the approximation; their contribution will be zero). More generally, Theorem 4 remains valid for region graphs, suggesting to define CCs over tightly connected groups of regions that are expected to exhibit strong dependencies beyond what are already modeled by the calibrated region graph. This still leaves considerable freedom to design a good CCE. The experiments in Section 5 will provide further guidance in his respect.

We end this section with a different perspective of what is accomplished with the CCE. Starting with Eqn. (5) we can write

$$\begin{aligned} \log Z_\psi &= \log \hat{Z}_{BP} + \log Z_b \\ &= -\sum_{\alpha \in \mathcal{R}_{\text{calibrated}}} c_\alpha \mathcal{F}_\alpha - \sum_{\alpha' \in \mathcal{R}_{\text{uncalibrated}}} \kappa_{\alpha'} F_{\alpha'} \end{aligned} \tag{17}$$

where $\mathcal{R}_{\text{calibrated}}$ and $\mathcal{R}_{\text{uncalibrated}}$ are calibrated and uncalibrated regions and $F_\alpha = -\log Z_\alpha$. The first term is the standard decomposition of the variational free energy for region graphs (see e.g. [11]) and the second term is the cluster cumulant expansion. This expression highlights the fact that CCE can be considered a correction to the variational free energy. Moreover, it suggests a procedure where increasingly many regions are moved from the uncalibrated part of the region graph to the calibrated part of the region graph. We leave exploration of these ideas for the future.

5 Experiments

We conducted a variety of experiments to study the CCE. Since the CCE is defined on a collection of clusters, we first describe the cluster choices used in our experiments. This description primarily refers to clusters that are sets of factors, i.e., for CCE on a factor graph. CCE on a region graph considers clusters that are sets of calibrated regions. In the sequel a k-cluster is a collection of k factors (or regions).

We considered two different collections of clusters in our experiments. We first considered the poset Ω_{all} containing all pairs of factors, all triplets of factors, and so forth. Enumerating factors in this manner quickly becomes unmanageable, so the expansion must be truncated. We will use Ω^l_{all} to denote truncating the poset at level l, where for example Ω^4_{all} denotes the series truncated after all quintuplets of factors have been included.

The second collection of factors considered come from the Truncated Loop Series (TLS) algorithm of [2]. The TLS algorithm finds a subset of all generalized loops in a factor graph. It does so by first finding a set of S simple loops (i.e., cycles in the factor graph with degree 2) and then *merges* these simple loops to create a set of generalized loops (i.e., cycles with degree ≥ 2). In the TLS algorithm, a generalized loop is formed from two simple loops l and l' by finding a path in the factor graph from some factor or variable in l to some factor or variable in l'. Since many paths may connect two simple loops, the set of generalized loops is restricted to paths of at most length M.

The authors of [2] provide code that enumerates a set of generalized loops l_1,...,l_N and computes the LS approximation to $\log Z$ after every loop. In [2], the set of loops are placed in descending order by the magnitude of their contributions, $|U_l|$ (see 2.3 for details). To make the TLS algorithm an "anytime" algorithm, we do not post-process the set of loops and instead report the LS approximation on the order in which the loops are discovered. A sequence α_1,...,α_N of clusters can be constructed from a sequence of loops $l_1, .., l_N$, where α_i is the set of factors in generalized loop l_i [2]. In the experiments that follow 'LS (TLS)' denotes the Loop Series approximation on the (unsorted) sequence of loops from the TLS algorithm and 'CCE (TLS)' is the CC approximation on the unsorted sequence of loops.

When adding clusters to the CCE, it is important to note that the collection of clusters may become imbalanced in that the approximation in Eqn. (14) does not include all intersections (and intersections of intersections etc.) of all clusters, which leads to over-counting in the CCE. While adding clusters bottom up along the poset Ω_{all} guarantees a balanced CCE, this is not always true for the TLS sequence leading to suboptimal results. We thus emphasize that we include CCE (TLS) results for the sake of comparison, but that it is not the expansion that we recommend for the CCE.

We ran experiments on synthetic Markov Network (MN) instances as well as benchmark instances from the UAI-2008 solver competition. In all experiments, we take the absolute difference of true and approximate log-partition functions $|\log Z - \log \hat{Z}|$ as our error measure. We stop BP and GBP when $L_\infty(b_p(\mathbf{x}_c), b_c(\mathbf{x}_c)) < 1e^{-8}$, where $b_c(\mathbf{x}_c)$ is the belief at a child region c, $b_p(\mathbf{x}_c)$ is the marginal belief of parent region p on variables $\mathbf{x}_c$ and L_∞ is the maximum absolute difference between the two beliefs.

5.1 Grids

We first tested pairwise MNs defined on 10×10 grids. Each grid instance has unary potentials of the form $f_i(x_i) = [\exp(h_i);\ \exp(-h_i)]$ and pairwise potentials of the form:

$$f_{ij}(x_i, x_j) \quad = \quad \begin{bmatrix} \exp(w_{ij}) & \exp(-w_{ij}) \\ \exp(-w_{ij}) & \exp(w_{ij}) \end{bmatrix}$$

The values of h_i and w_{ij} were drawn from $\mathcal{N}(0, \sigma_i^2)$ and $\mathcal{N}(0, \sigma_{ij}^2)$ distributions, respectively. To study the behavior of the CCE at various interaction strengths, we fixed $\sigma_i = 0.1$ and varied σ_{ij} from 0.1 to 1. Reported errors are averages across 25 instances at each setting, and error bars indicate the standard error.

Figure 4 compares the different series approximations on grids. Following [2], the TLS algorithm was run on the 10×10 grid instances with $S = 1000$ and $M = 10$.

'CCE (BP)' is the CC approximation given a sequence of terms efficiently enumerated in Ω^{15}_{all}. All pairs and triplets of factors on a pairwise grid have zero contribution and can be ignored. The only 4-clusters with non-zero contribution are the 81 faces of the 10×10 grid. To fill out the remaining levels of Ω^{15}_{all}, we enumerate pairs, triplets and quadruplets of connected faces (sharing a vertex or edge), since the CC for two disconnected faces in the grid is zero.

'CCE (GBP)' is the CCE on a region graph. GBP was run on a region graph with outer regions equal to the faces of the grid. In this case, all pairs and triplets of faces give zero contributions and can be ignored. Each 3×3 subgraph in the grid is comprised of 4 faces forming a cycle. We take all

[2] Since many generalized loops are defined over the same set of factors, we consider only the unique sets of factors.

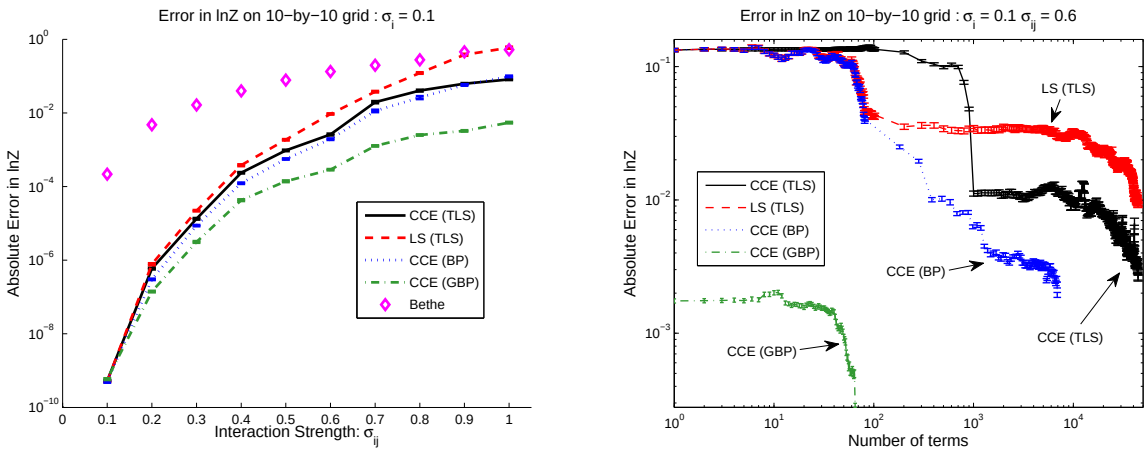

Figure 4: **Left:** Comparison of the 4 series approximations on 10×10 grids at a variety of interaction strengths. **Right:** $Error_Z$ versus the number of terms in each approximation, for $\sigma_{ij} = 0.6$.

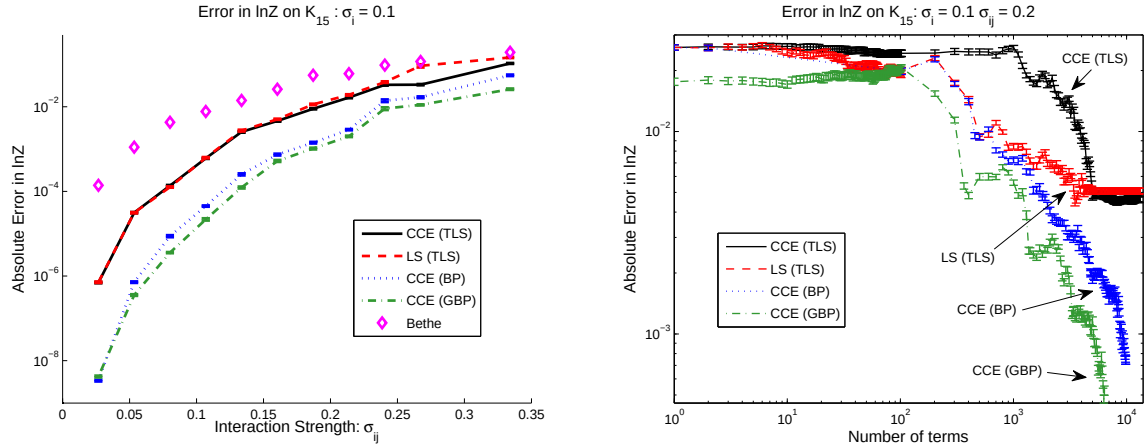

Figure 5: **Left:** Comparison of the 4 series approximations on complete MNs of 15 variables at different coupling levels. **Right:** $Error_Z$ as a function of the number of terms in each series.

64 of these to be the clusters in the 'CCE (GBP)' approximation. Importantly, the intersection of any two such clusters will be a cluster on either a disconnected or acyclic subgraph (having a zero contribution) implying that the whole collection of clusters remains balanced.

Figure 4-Left compares the series approximations at a variety of coupling levels. The error reported is w.r.t. the final $\log Z$ approximation of each series. All the approximations offer a substantial error reduction over the Bethe approximation for instances with weak interactions. As interaction strength is increased, the relative improvement of each series declines. At the strongest coupling level, the error in the LS approaches the Bethe approximation error, while CCE remains an order of magnitude better.

Figure 4-Right shows a trace of the error as a function of the number of terms included. Each LS term can be computed very efficiently for binary MNs, while each CCE term requires inference on a set of factors (or regions). Thus, comparing the series on the the number of terms may seem to unfairly favor the CC approximations. However, the LS requires enumerating generalized loops in the MN which is more expensive than enumerating clusters.

5.2 Complete Graphs

We also experimented on pairwise MNs over a complete graph of 15 variables. Here 'CCE (BP)' is the CC approximation given an efficient enumeration of terms in Ω^{14}_{all}. Since all pairs of factors are acyclic (and have zero contribution), we begin by considering all cycles of length 3, which is equivalent to all embedded K_3 subgraphs. We then proceed with adding all K_4, all K_5 and finally all K_6 subgraphs to the CCE. Note that this enumeration is efficient in that it skips certain contributions, such as cycles over 4 variables because their contribution will be included when we add the corresponding K_4 subgraph.

'CCE (GBP)' enumerates in a similar fashion. GBP is run on a region graph formed using the "star" construction – outer regions equal to all cycles of length 3 passing through vertex 0. We then enumerate all complete graphs K_4, K_5 and K_6 containing vertex 0. The set of K_4 containing ver-

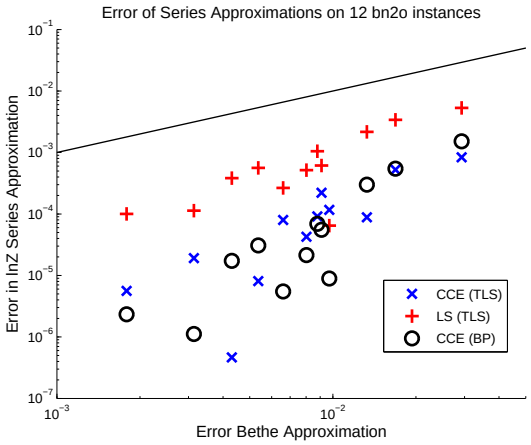

Figure 7: Scatter plot of $Error_Z$ for each series approximation versus error in the Bethe approximation. Points below the line are improvements upon IBP.

tex 0 is only a subset of all the K_4's embedded in the MN. However, enumerating embedded complete graphs in this fashion ensures that the collection of clusters remains balanced.

Figure 5 compares the four series approximations across a variety of interaction strengths. In these experiments the TLS algorithm was run with $S = 5000$ and $M = 10$. On complete graphs, the CC and LS approximations behave similarly when using terms from the TLS algorithm. The CCE as described above is much more accurate. This is because while the TLS algorithm enumerates > 10K loops, the loops contain at most 5 factors while the CCE up to K_6 covers 15 factors.

5.3 UAI-2008 Benchmarks

In addition to the synthetic instances, we evaluated each of the series approximations on instances from the 2008-UAI solver competition. We selected 12 bn2o instances and 27 promedas instances that were solvable by our Junction Tree implementation. The promedas instances have a very sparse graph structure and contain between 400-1000 factors. As a result, enumerating all clusters in Ω^l_{all} is costly and yields few non-zero terms even for small l. Thus, for the promedas instances we only compare the LS and CC approximations on the loops found by the TLS algorithm. Figure 6 shows the error of the CC and LS approximations versus the Bethe approximation. Points below the diagonal line indicate improvement over the Bethe approximation. The TLS algorithm was run on all 27 instances with $S = 100$ and $M = 10$. These results are consistent with [2] in that if the TLS algorithm finds most of the generalized loops in an instance, the error is reduced by several orders of magnitude, while if a small set of all generalized loops are found, the series approximations offer no improvement.

Unlike the promedas instances, the bn2o instances have densely connected graph structures and contain far fewer factors. These instance are thus better suited to enumeration along Ω_{all}. Figure 7 compares the error of the 4 series approximations to the error of the Bethe approximation. The TLS algorithm was run with $S = 10$K and $M = 10$, producing more than 10K generalized loops. 'CCE (BP)' was run on the set of clusters in Ω^4_{all}.

6 Conclusion

We have introduced a new cluster-cumulant expansion based on the fixed points of either BP or GBP. The expansion was inspired by the LS of [1] but has certain advantages over the latter. First, terms corresponding to disconnected clusters vanish. More generally, only tightly coupled groups of variables are expected to make significant contributions, which can be used to significantly cut down on the number clusters that need to be considered. Second, while the LS was only developed for binary variables, the CCE is defined on arbitrary alphabets. Third, the CCE has a natural extension to GBP on region graphs. Finally, the accuracy of the CCE expansion improves upon the LS.

The CCE represents a very natural extension of the Kikuchi approximation as it is based on the same type of expansion. But unlike GBP on a region graph, the CCE does not suffer from convergence issues and does not require storing beliefs during message passing. This makes it a useful "anytime" tool to improve results obtained form GBP. It also suggests new algorithms that move regions from the CCE to regions used in GBP. The question of which regions should be included in the GBP + CCE approximation and whether a region should be included in GBP or be handled by the CCE are left for future investigation.

Self-Confirming Price Prediction Strategies for Simultaneous One-Shot Auctions

Abstract

Bidding in simultaneous auctions is challenging because an agent's value for a good in one auction may depend on the uncertain outcome of other auctions: the so-called *exposure problem*. Given the gap in understanding of general simultaneous auction games, previous works have tackled this problem with heuristic strategies that employ probabilistic price predictions. We define a concept of *self-confirming prices*, and show that within an independent private value model, Bayes-Nash equilibrium can be fully characterized as a profile of optimal price-prediction strategies with self-confirming predictions. We exhibit practical procedures to compute approximately optimal bids given a probabilistic price prediction, and near self-confirming price predictions given a price-prediction strategy. An extensive empirical game-theoretic analysis demonstrates that self-confirming price-prediction strategies are effective in simultaneous auction games with both complementary and substitutable preference structures.

1 Introduction

One of the most attractive features of automated trading is the ability to monitor and participate in many markets simultaneously. Compared to human traders, software agents can take in data from multiple sources at very high throughput rates. In principle, software agents can also process massive quantities of information relevant to trading decisions in short time spans. In practice, however, dealing with multiple markets poses one of the greatest strategic challenges for automated trading. When markets interact, a strategy for bidding in one market must consider the implications of and ramifications for what happens in others.

Markets are *interdependent* when an agent's preference for the outcome in one depends on results of others. For instance, when value for one good is increased by obtaining another, the goods are *complements*. Dealing with multiple markets under complementary preferences presents an agent with the classic *exposure problem*: before it can obtain a valuable bundle, the agent must risk getting stuck with a strict subset of the goods, which it may not have wanted at the prevailing prices. Exposure is a potential issue for *substitute* goods as well, as the agent risks obtaining goods it does not want given that it obtains others.

The pitfall of exposure is a primary motivation for combinatorial auctions [Cramton et al., 2005], where the mechanism takes responsibility for allocating goods respecting agents' expressed interdependencies. Combinatorial auctions are often infeasible, however, due to nonexistence of an entity with the authority and capability to coordinate markets of independent origin. Consequently, interdependent markets are inevitable. Nonetheless, there is at present very little fundamental understanding of agent bidding strategies for these markets. Specifically, how should an agent's bidding strategy address the exposure problem?

We address this question in what is arguably the most basic form of interdependent markets: simultaneous one-shot sealed-bid (SimOSSB) auctions. Despite the simplicity of this mechanism and the practical importance of the exposure issue, there is little available guidance in the auction theory literature on the strategic problem of how to bid in SimOSSB auctions. We aim to fill this gap by providing computationally feasible methods for constructing bidding strategies for the SimOSSB-auction environment, which we justify with both theory and evidence from simulation-based analysis. Specifically, we (i) characterize Bayes-Nash equilibria of SimOSSB auctions as best responses to price predictions (§3); (ii) provide bounds on approximate Bayes-Nash equilibria in terms of the accuracy of price predictions and the degree of optimality of responses (§4); (iii) introduce methods to construct bidding strategies that respect the equilibrium form (§5,6); and (iv) demonstrate through a comprehensive empirical game-theoretic analysis the efficacy of these strategies compared to a wide variety of heuristics from the literature (§7).

2 Previous Work

Theoretical results about general simultaneous auction games are few and far between. The leading auction theory textbook [Krishna, 2010] treats sequential but not simultaneous auctions, and most of the literature that addresses simultaneity does so only in the context of ascending [Peters and Severinov, 2006] or multi-unit auctions.

In the first work to derive an equilibrium of a simultaneous-auction game, Engelbrecht-Wiggans and Weber [1979] tackle an example with perfect substitutes, where each agent is restricted to bid on at most two items. Their analysis was performed in the large-limit of auctions and agents, and exhibited a mixed equilibrium where the agents diversify their bids even though the items are indistinguishable. Krishna and Rosenthal [1996] studied a second-price setup with two categories of bidders: local bidders who have value for a single item, and global bidders who have superadditive values for multiple items. The authors characterize an equilibrium that is symmetric with respect to the global bidders, and show, somewhat surprisingly, that an increase in the number of bidders often leads to less aggressive bidding. Rosenthal and Wang [1996] tackled a first-price setup, assuming synergies and common values. Szentes and Rosenthal [2003] studied two-bidder auctions with three identical objects and complete information.

Recently, Rabinovich et al. [2011] generalized fictitious play to incomplete information games with finite actions and applied their technique to a class of simultaneous second-price auctions. They computed approximate equilibria in environments with utilities expressible as linear functions over a one-dimensional type space.

Complementing these theoretical treatments, researchers have designed trading strategies applicable to simultaneous auctions, which address the exposure problem through heuristic means. In the Trading Agent Competition (TAC) Travel game [Wellman et al., 2007], agents face an exposure problem for hotels—they must obtain a room each night for the client or the whole trip is infeasible. Experience from TAC and other domains has demonstrated the importance of *price prediction* for bidding in interdependent markets [Wellman et al., 2004]. Given probabilistic predictions of prices across markets, agents can manage exposure risk, choosing bids that trade off the profits and losses of the possible bundles of goods they stand to win.

Greenwald and Boyan [2004] framed the problem of bidding across interdependent markets given probabilistic price predictions. Follow-on work [Greenwald et al., 2009, Wellman et al., 2007] formalized this bidding problem in decision-theoretic terms and established properties of optimal bidding assuming that bids do not affect other-agent behaviors. Further experimental comparison was performed by Greenwald et al. [2010]. These works introduced a taxonomy of heuristic bidding strategies [Wellman, 2011], which we employ here.

Self-confirming price-prediction (SCPP) bidding strategies were first explored in the context of simultaneous ascending auctions (SimAAs) [Cramton, 2005]. For the SimAA environment, SCPP strategies were found to be highly effective at tackling the exposure problem [Wellman et al., 2008]. To our knowledge, no other general price-prediction methods have been proposed for SimOSSB auctions, other than learning from historical observations.

3 Price-Prediction Strategies and Equilibrium

We consider a market with m goods, $\mathcal{X} = \{1, \ldots, m\}$, and n agents. Agent i's value for a bundle $X \in 2^{\mathcal{X}}$ is given by $v_i(X)$, where $v_i(X) \in [0, \bar{V}]$. We assume free disposal: if $X \subseteq X'$, then $v_i(X) \leq v_i(X')$. The m goods are allocated to the agents via SimOSSB auctions, one per good. That the mechanism is simultaneous means that each agent i submits a bid vector $\boldsymbol{b}_i = (b_i^1, \ldots, b_i^m) \in \mathbb{R}_+^m$ before a specified closing hour. That the auctions are one-shot means that all auctions compute and report their results upon the closing hour. That the bids are sealed means that agents have no information about the bids of other auction participants until the outcome is revealed.

The *second-price sealed-bid* (SPSB) auction is an OSSB auction in which the winning bidder pays the second-highest bid rather than its own (highest) bid. The environments studied in our empirical game-theoretic analysis below employ the SPSB mechanism. For simplicity of description we focus on SPSB throughout, although our theoretical results hold as well for first-price sealed-bid auctions, or indeed any auction mechanism where the outcome to agent i (whether it gets the good and the price it pays) is a function of i's own bid and the highest other-agent bid.

Our investigation employs the familiar *independent private values* (IPV) model (see, for example, [Krishna, 2010]), where each agent i's values are drawn independently from a probability distribution that is common knowledge. Under IPV, it is a dominant strategy for an agent to bid its true value in a single SPSB auction. This result does not generalize to simultaneous SPSB auctions, however, unless the agent's value over bundles happens to be additive. When agents' values for different goods interdepend (e.g., through complementarity or substitutability), bidding truthfully in simultaneous auctions is not even an option, as the value for an individual good is not well-defined.

To deal effectively with interdependent markets, an agent's bid in each auction must reflect its beliefs about the outcomes of others. We consider beliefs in the form of *predictions* about the prices at which the agent might obtain goods in the respective auctions. Bidding strategies that are

explicitly cast as functions of some input price prediction are termed *price-prediction (PP) strategies*.

We denote by $p_j \in \mathbb{R}_+$ a *price* for good j. The vector $\boldsymbol{p} = \langle p_1, \ldots, p_m \rangle$ associates a price with each good. We represent price predictions as probability distributions over the joint price space. We use the symbol Π for such predictions in the form of cumulative probability distributions,

$$\Pi_{\boldsymbol{p}}(\boldsymbol{q}) = \Pr(\boldsymbol{p} \leq \boldsymbol{q}), \tag{1}$$

where $\boldsymbol{p} \leq \boldsymbol{q}$ holds iff $p_j \leq q_j$ for all j. We generally omit the subscript $\boldsymbol{p}$ as understood.

We have previously argued [Wellman et al., 2007] that price prediction is a key element of agent architecture for complex trading environments. Here, we support a stronger claim for the case of SimOSSB auctions: given IPV, *PP strategies are necessary and sufficient for optimal bidding*.

Let $w(\boldsymbol{b}, \boldsymbol{q}) = \{j \mid b^j > q_j\}$ denote the set of goods an agent would win by bidding $\boldsymbol{b}$ when the highest other-agent bids are $\boldsymbol{q}$.[1] Agent i's utility for a bid given others' bids can thus be written as

$$u_i(\boldsymbol{b}, \boldsymbol{q}) = v_i(w(\boldsymbol{b}, \boldsymbol{q})) - \sum_{j \in w(\boldsymbol{b}, \boldsymbol{q})} q_j. \tag{2}$$

Definition 1 (Optimal PP Bidders)**.** An *optimal PP bidding strategy* $s^*(\Pi)$ submits bids that maximize expected utility given a price prediction Π,

$$s^*(\Pi) \in \arg\max_{\boldsymbol{b}} \mathbb{E}_{\boldsymbol{q} \sim \Pi}[u_i(\boldsymbol{b}, \boldsymbol{q})]. \tag{3}$$

In games of incomplete information, agent i's strategy produces actions (here, bids) as a function of i's type. Under IPV, knowing other agents' values tells agent i nothing about its own value. The distribution of outcomes given i's bid $\boldsymbol{b}_i$ depends only on $\boldsymbol{b}_i$ and the marginal distribution of other-agent bids. Agent i's expected utility is thus conditionally independent of other-agent valuations given their bids [Wellman et al., 2011]. In particular, i's best response to a profile of other-agent strategies depends only on the distribution of their bids [Rabinovich et al., 2011].

Let b^{k*}_{-i} denote the highest bid submitted for good k by an agent other than i. Since agent i's utility depends only on what it wins and what it pays, the distribution of *highest* other-agent bids (i.e., the distribution of b^{k*}_{-i}) is a sufficient statistic for the other-agent bid distributions. This distribution can be expressed in the form of a price prediction (1).

Therefore, a best response to other-agent bidding strategies takes the form of an optimal PP bidding strategy (3), where the input PP is the distribution of highest other-agent bids induced by those other-agent strategies. Since a Bayes-Nash equilibrium (BNE) is a profile of mutual best-response strategies, any profile of optimal PP strategies, where the PP for each equals the distribution of highest bids induced by the other agents' optimal PP strategies, constitutes a BNE. Moreover, any BNE can be characterized as a profile of optimal PP strategies, or mixtures thereof.

Theorem 1. *Suppose a SimOSSB auction game, with independent private values, where the outcome of each auction to agent i depends only on i's bid and the highest other-agent bid in that auction. Then the strategy profile $\boldsymbol{s} = (s_i, s_{-i})$ is a Bayes-Nash equilibrium if and only if, for all i, s_i is equivalent to an optimal PP bidding strategy with input $\Pi_i(\boldsymbol{q}) = \Pr((b^{1*}_{-i}, \ldots, b^{m*}_{-i}) \leq \boldsymbol{q} \mid s_{-i})$, or equivalent to a mixture of such optimal PP strategies.*

Price predictions that support strategic equilibrium are themselves in a form of equilibrium. The bidding strategies employ price predictions that are actually borne out as correct (i.e., the distributions generated by the strategies are as predicted) assuming that everyone follows the given strategies. This situation can be viewed as a form of *rationalizable conjectural equilibrium* (RCE) [Rubinstein and Wolinsky, 1994], where each agent's conjecture is about the distribution of highest other-agent bids. In this instance, the RCE is also a BNE, since the conjecture provides sufficient information to determine a best response.

An auction game with IPV is *symmetric* if all agents have the same probability distribution over valuations. In earlier work on simultaneous ascending auctions [Wellman et al., 2008], we considered the symmetric IPV case and referred to price predictions in this kind of equilibrium relationship as *self-confirming*. Let Γ be an instance of a symmetric IPV SimOSSB auction game, and s a bidding strategy that employs price predictions (whether optimally or not).

Definition 2 (Self-Confirming Price Prediction (SCPP))**.** The prediction Π is *self-confirming* for PP strategy s in Γ iff Π is equal to the distribution of the highest other-agent prices $(b^{1*}_{-i}, \ldots, b^{m*}_{-i})$ when all agents play $s(\Pi)$.

The following theorem specializes Theorem 1 for the symmetric case, employing the language of SCPPs.

Theorem 2. *In symmetric IPV SimOSSB auctions, a symmetric pure BNE comprises optimal PP bidders employing self-confirming price predictions. Hence, existence of pure symmetric BNE in such games entails existence of self-confirming price predictions.*

In summary, for SimOSSB auctions under IPV, we can restrict attention to optimal PP strategies employing price predictions that are in equilibrium with one another (which for the symmetric case, means SCPPs). In the remainder of this paper, we demonstrate that PP strategies are amenable to effective approximation, are a convenient abstraction on

[1] In the case of ties, the winner is chosen uniformly from among the high bidders. Our analysis ignores ties, which are rare given our setup of real-valued bids and rich valuation functions. Our theoretical results require that the highest other-agent bid is a sufficient statistic for outcome, which is true as long as one's bid does not tie for best with *two or more* other bidders.

which to design and implement trading strategies, and exhibit a high degree of robustness across environments.

4 Approximate Price Prediction

We have shown that an optimal PP strategy is a best response to the strategies of other agents if price predictions Π exactly reflect the other-agent bid distributions. Since it is unrealistic to expect perfect price prediction, we examine the consequences of employing PP strategies that use inaccurate price predictions Π'.

We quantify the inaccuracy of Π' in two ways. The first is a multivariate form of the *Kolmogorov-Smirnov (KS) statistic*: $KS(\Pi, \Pi') \equiv \sup_{\boldsymbol{q}} |\Pi(\boldsymbol{q}) - \Pi'(\boldsymbol{q})|$. Second, we define the *bundle probability distance*, $BP(\Pi, \Pi', \boldsymbol{b})$, with respect to a bid $\boldsymbol{b}$: $\sum_{X \subseteq \mathcal{X}} |\Pr_{\boldsymbol{q} \sim \Pi}(w(\boldsymbol{b}, \boldsymbol{q}) = X) - \Pr_{\boldsymbol{q} \sim \Pi'}(w(\boldsymbol{b}, \boldsymbol{q}) = X)|/2$.

We first bound the difference between perceived and actual expected utility when incorrectly using Π' instead of Π. Let us denote the payment for $\boldsymbol{b}$ given highest other-agent bids $\boldsymbol{q}$ by $\psi(\boldsymbol{b}, \boldsymbol{q})$, so that for SPSB we have $\psi(\boldsymbol{b}, \boldsymbol{q}) = \sum_{j \in w(\boldsymbol{b}, \boldsymbol{q})} q_j$. Overall expected utility is the difference between expected value of winnings and payment:

$$\mathbb{E}_{\boldsymbol{q}}[u_i(\boldsymbol{b}, \boldsymbol{q})] = \mathbb{E}_{\boldsymbol{q}}[v_i(w(\boldsymbol{b}, \boldsymbol{q}))] - \mathbb{E}_{\boldsymbol{q}}[\psi(\boldsymbol{b}, \boldsymbol{q})]. \quad (4)$$

To bound the difference between perceived and actual expected utility, we separately consider winnings and payment. The following bounds the amount a bidder can underestimate its expected payment by using Π'.

Lemma 3. *Let $\delta_{KS} = KS(\Pi, \Pi')$ and $\|\boldsymbol{b}\|_1 \equiv \sum_{j=1}^{m} b^j$. Then for all $\boldsymbol{b}$,*

$$\mathbb{E}_{\boldsymbol{q} \sim \Pi}[\psi(\boldsymbol{b}, \boldsymbol{q})] \leq \mathbb{E}_{\boldsymbol{q} \sim \Pi'}[\psi(\boldsymbol{b}, \boldsymbol{q})] + 2\delta_{KS}(\|\boldsymbol{b}\|_1), \quad (5)$$

Proof. See Appendix A.1 in the online supplement. □

We similarly bound the amount a bidder can overestimate its expected value of winnings by using Π'. A variant distribution Π can degrade expected value of winnings only by decreasing the probability of winning valuable bundles. By constraining BP distance, we can ensure, for any set of bundles, that the total probability of winning a bundle from that set at $\boldsymbol{b}$ decreases by at most δ_{BP}. This means that the expected value of winnings can suffer by at most $\delta_{BP}\bar{V}$.

Lemma 4. *Let $\delta_{BP} = BP(\Pi, \Pi', \boldsymbol{b})$. Then*

$$\mathbb{E}_{\boldsymbol{q} \sim \Pi}[v_i(w(\boldsymbol{b}, \boldsymbol{q}))] \geq \mathbb{E}_{\boldsymbol{q} \sim \Pi'}[v_i(w(\boldsymbol{b}, \boldsymbol{q}))] - \delta_{BP}\bar{V}. \quad (6)$$

Combining the lemmas, we have the following bound.

Theorem 5. *Let $\delta_{KS} = KS(\Pi, \Pi')$ and $\delta_{BP} = BP(\Pi, \Pi', \boldsymbol{b})$. Then for all i,*

$$\mathbb{E}_{\boldsymbol{q} \sim \Pi}[u_i(\boldsymbol{b}, \boldsymbol{q})] \geq \mathbb{E}_{\boldsymbol{q} \sim \Pi'}[u_i(\boldsymbol{b}, \boldsymbol{q})] - \delta_{BP}\bar{V} - 2\delta_{KS}\|\boldsymbol{b}\|_1.$$

We can use these bounds to limit how far an optimal PP strategy with inaccurate price predictions Π' can be from equilibrium. Let us denote by $\bar{b}$ the maximum payment, that is, the L_1-norm of the greatest possible bid vector. The value of $\bar{b}$ is bounded above by $m\bar{V}$ for any rational bidding strategy under any valuation distribution, but typically it will be far less than that.

Theorem 6. *Suppose that for all agents i, strategy $\hat{s}_i$ is a best response to other-agent highest-bid distribution $\hat{\Pi}_{-i}$, and that $\Pi_{\hat{s}_{-i}}$ is the other-agent bid distribution actually induced by $\hat{s}_{-i}$. If for all i, $KS(\hat{\Pi}_{-i}, \Pi_{\hat{s}_{-i}}) \leq \delta_{KS}$, and for all $\boldsymbol{b}$, $BP(\hat{\Pi}_{-i}, \Pi_{\hat{s}_{-i}}, \boldsymbol{b}) \leq \delta_{BP}$, then $\hat{\boldsymbol{s}}$ constitutes an ϵ-Bayes-Nash equilibrium, for $\epsilon = 2\delta_{BP}\bar{V} + 4\delta_{KS}\bar{b}$.*

Proof. See online Appendix A.2. □

5 Heuristic PP Bidding Strategies

Having shown that optimal PP bidding strategies are theoretically ideal in that they comprise a BNE, we turn our attention to practical PP bidding strategies. Building on prior work [Wellman et al., 2007, Chapter 5], we explore a broad range of heuristic bidding strategies. The most salient of these are described here.

5.1 Marginal Values and Optimal Bundles

Interdependence dictates that the value of any individual good must be assessed relative to a bundle of goods. This idea is captured by the notion of *marginal value*.

Definition 3 (Marginal Value)**.** Agent i's marginal value, $\mu_i(x, X)$, for good x with respect to a fixed bundle of other goods X is given by: $\mu_i(x, X) \equiv v_i(X \cup \{x\}) - v_i(X)$.

Given a fixed vector of prices, $\boldsymbol{p} = \langle p_1, \ldots, p_m \rangle$, let $\sigma_i(X, \boldsymbol{p})$ denote agent i's surplus from obtaining the set of goods X at those prices:

$$\sigma_i(X, \boldsymbol{p}) \equiv v_i(X) - \sum_{j | x_j \in X} p_j. \quad (7)$$

Definition 4 (Acquisition [Boyan and Greenwald, 2001])**.** Given price vector $\boldsymbol{p}$, the *acquisition problem* selects an optimal bundle of goods to acquire: $X^* = \text{ACQ}_i(\boldsymbol{p}) \equiv \arg\max_{X \subseteq \mathcal{X}} \sigma_i(X, \boldsymbol{p})$.

Faced with perfect point price predictions, an optimal bidding strategy would be to compute $X^* = \text{ACQ}_i(\boldsymbol{p})$ and then to buy precisely those goods in X^*. By definition, this strategy yields the optimal surplus at these prices: $\sigma_i^*(\boldsymbol{p}) \equiv \sigma_i(\text{ACQ}_i(\boldsymbol{p}), \boldsymbol{p})$.

To assess goods with respect to (typically imperfect) point price predictions, we extend the concept of marginal value. Let $\boldsymbol{p}[p_j \leftarrow q]$ be a version of the price vector $\boldsymbol{p}$ with

the jth element revised as indicated: $\boldsymbol{p}[p_j \leftarrow q] = \langle p_1, \ldots, p_{j-1}, q, p_{j+1}, \ldots, p_m \rangle$.

Definition 5 (Marginal Value at Prices)**.** Agent i's *marginal value* $\mu_i(x_j, \boldsymbol{p})$ for good x_j at prices $\boldsymbol{p}$ is given by: $\mu_i(x_j, \boldsymbol{p}) \equiv \sigma_i^*(\boldsymbol{p}[p_j \leftarrow 0]) - \sigma_i^*(\boldsymbol{p}[p_j \leftarrow \infty])$.

Here, $\sigma_i^*(\boldsymbol{p}[p_j \leftarrow 0])$ represents the optimal surplus at the given prices, assuming good x_j is free. Similarly, $\sigma_i^*(\boldsymbol{p}[p_j \leftarrow \infty])$ represents the optimal surplus at the given prices, if x_j were unavailable. The difference is precisely the marginal value of good x_j with respect to the prices of other goods. Note that Definition 5 generalizes Definition 3, under the interpretation that goods in X have zero price, and all other goods have infinite price.

StraightMV The heuristic strategy StraightMV employs this concept directly, and simply bids marginal value for all goods: $\mathsf{StraightMV}_j = \mu(x_j, \boldsymbol{p})$.

5.2 Bidding with Price Distributions

A point price estimate fails to convey the uncertainty inherent in future prices. Probability distributions over prices provide a more general representation, expressing degrees of belief over the possible prices that might obtain.

The *expected value method* [Birge and Louveaux, 1997] approximates a stochastic optimization by collapsing probability distributions into point estimates through expectation. Let $\hat{\boldsymbol{p}}_\Pi = \langle \hat{p}_1, \ldots, \hat{p}_m \rangle$, where $\hat{p}_j = \mathbb{E}_{\boldsymbol{p} \sim \Pi}[p_j]$ is the expectation of p_j under given price prediction Π.

Any bidding strategy defined for point price predictions can be adapted to take as input distribution price predictions through this expected value method, simply by using $\hat{\boldsymbol{p}}_\Pi$ for the point price prediction. For example, we define StraightMU as the strategy that takes as input a distribution prediction, and bids as StraightMV at the mean prices. "MU" stands for "marginal utility", but its usage here is simply to distinguish the name from its corresponding point strategy ending with "MV".

We implemented two approaches to calculating $\hat{\boldsymbol{p}}_\Pi$. The first samples from Π, and the second computes the exact expectation of a piecewise approximation of Π. For the sampling method, accuracy depends on the number of samples k drawn; thus we indicate a version of the strategy by appending "k" to the name. For example, StraightMU8 takes the mean of eight samples from Π, and employs StraightMV with that average price vector as input.

AverageMU Whereas StraightMU bids the marginal value of the expected price, the PP strategy AverageMU bids the expected marginal value: $\mathsf{AverageMU}_j = \mathbb{E}_{\boldsymbol{p} \sim \Pi}[\mu(x_j, \boldsymbol{p})]$. Our implementation samples from the price distribution, calculates marginal values for each sample, and averages the results.

5.3 Explicit Optimization

Finally, we consider strategies that explicitly attempt to optimize bids given a distribution price prediction, as do the optimal PP bidders introduced above (Definition 1).

BidEval One heuristic optimization approach is to generate candidate bid vectors, and evaluate them according to the price prediction. The BidEval strategy uses other bidding heuristics to propose candidates, and estimates each candidate's performance by computing its expected utility given the price prediction. It then selects the candidate bid vector with the greatest expected utility. There are many variations of BidEval, defined by:

- *the method used to generate candidates.* When this method is a named bidding strategy, we indicate this in parentheses; for instance, BidEval(SMU8) generates candidates using StraightMU8. Strategy BidEvalMix employs a mix of previously described bidding strategies to generate candidates.
- *number of candidates generated.* Methods based on sampling naturally produce a diverse set of candidates. For example, each invocation of StraightMU8 employs a new draw of eight samples from Π to estimate $\hat{\boldsymbol{p}}_\Pi$, thus we generally obtain different bids.
- whether the candidates are evaluated by exact computation on a piecewise version of Π, or by sampling. If by sampling, then how many samples are used.

LocalBid The LocalBid strategy (see Alg. 1) employs a local search method in pursuit of optimal bids. Starting with an initial bid vector proposed by another heuristic strategy, LocalBid makes incremental improvements to that bid vector for a configurable number of iterations. Those incremental improvements are made good-by-good, treating all other goods' bids as fixed. Assuming bids for all goods except j are fixed, the agent effectively faces a single auction for good j, with the winnings for other goods determined probabilistically. For a single SPSB auction, it is a dominant strategy to bid one's expected marginal value for good j, which is given by $\mathbb{E}_{\boldsymbol{p} \sim \Pi}[v(w(\boldsymbol{b}, \boldsymbol{p}) \cup \{j\}) - v(w(\boldsymbol{b}, \boldsymbol{p}) \setminus \{j\})]$, under these circumstances.

Algorithm 1 LocalBid

Input: prediction Π, heuristic strategy s, #iterations K
Output: bid vector $\boldsymbol{b}$

```
Initialize b ← s(Π)
for k = 1 to K do
  for j = 1 to m do
    b^j ← E_{p∼Π}[v(w(b, p) ∪ {j}) − v(w(b, p) \ {j})]
return b
```

LocalBid is an iterative improvement algorithm: the expected utility of $\boldsymbol{b}$ is nondecreasing with each update. Further, if LocalBid converges, it returns a bid vector that is

consistent (unlike AverageMU), in the sense that each element of the vector is the average marginal value for its corresponding good given the rest of the bid.

In an empirical comparison of bid optimization algorithms, we found that the LocalBid method was highly effective. In one representative environment, LocalBid achieved 98.8% optimality (see Figure 1), whereas a version of BidEval produced bids with expected value 94.5% of optimal. In that same environment, the bids generated by AverageMU64 were 66.1% as profitable as the optimal bid.

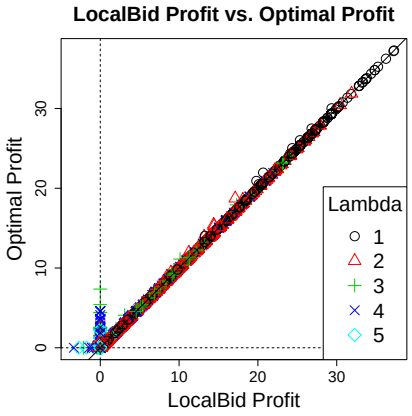

Figure 1: Expected profit for LocalBid versus optimal, for 5000 sample valuations in SimSPSB environment U[5,5]. Points above the diagonal are suboptimal instances.

6 Self-Confirming Price Predictions

Now that we have a suite of strategies that employ price predictions, we turn to the question of how to generate such predictions. We propose here to employ *self-confirming price predictions* (SCPPs) (Definition 2), originally introduced and evaluated in the context of simultaneous ascending auctions [Osepayshvili et al., 2005]. A high-level description of our iterative procedure for computing self-confirming price predictions is shown in Alg. 2.

Algorithm 2 Self-Confirming Price Search

Input: PP strategy PP, parameters F^0, L, G, κ_t, τ
Output: price prediction F
  Initialize $F \leftarrow F^0$
  for $t = 1$ to L **do**
    $F' \leftarrow$ outcome of G runs with all playing $\mathsf{PP}(F)$
    if $KS_{marg}(F, F') < \tau$ **then**
      return F
    $F \leftarrow \kappa_t F' + (1 - \kappa_t)F$
  return F

We extend the flexibility of the existing SCPP-derivation procedure by considering two interpretations of the "outcome" prices resulting from each instance of the game. In one, the resulting price is the actual transaction price of the good (price), as in the earlier SimAA study. In the second, we take the highest other-agent bid (HB) as the result.

To measure the difference between distributions at successive iterations, we adopt the Kolmogorov-Smirnov statistic. Since we maintain our prediction in terms of marginal distributions, our comparison takes the maximum of the KS statistic separately for each good: $KS_{marg}(F, F') \equiv \max_j KS(F_j, F'_j)$.

Our initial prediction F^0 considers all integer prices in the feasible range equally likely. At each iteration, we run G instances of game Γ, with all agents playing the distribution-prediction strategy $\mathsf{PP}(F)$. We tally the prices resulting from each instance, and update the price prediction as a weighted average of this tally F' and the previous prediction F. When $KS_{marg}(F, F')$ falls below threshold, we halt and return F. Or, if this distance never falls below threshold, then the procedure terminates and returns the result after L iterations.

Although not guaranteed to converge, we found that for the heuristics of the previous section the iterative procedure generally produced approximately marginally self-confirming distribution predictions. For example, in one environment with a range of strategies we ran the procedure with $G = 10^6$ and $L = 100$, achieving an accuracy $KS_{marg} < 0.01$ in all cases. Due to space constraints, we relegate a full description and evaluation of this procedure to the extended version of this paper.

7 Empirical Game-Theoretic Analysis

The heuristic strategies introduced in §5 represent plausible but not generally optimal approaches to bidding in simultaneous auctions. Even the strategies based on explicit optimization (§5.3) fall short of ideal due to inaccuracy in price prediction and non-exhaustive search of bid candidates. To evaluate the performance of these strategies, we conducted an extensive computational study, simulating thousands of strategy profiles—millions of times each—in five different simultaneous SPSB environments. Analysis of the game model induced from simulation data provides evidence for the efficacy and robustness of approximately optimal PP strategies across these environments.

7.1 Approach

The methodology of applying game-theoretic reasoning to simulation-induced game models is called *empirical game-theoretic analysis* (EGTA) [Wellman, 2006]. In EGTA, we simulate profiles of an enumerated strategy set playing a game, and estimate a normal-form game from the observed payoffs. The result is a simulation-induced game model, called the *empirical game*. By applying standard game-theoretic solution concepts to the empirical game,

we can draw conclusions about the strategic properties of the strategies and profiles evaluated. Although the strategy space in the empirical game is necessarily a severely restricted subset of the original, by including a broad set of strategies representing leading ideas from the literature, we can produce relevant evidence bearing on the relative quality of heuristic strategies in the simulated environments.

Our EGTA study of SimSPSB followed these steps.

1. Define an environment: numbers of goods and agents, and valuation distributions.
2. Specify a set of heuristic strategies. For PP strategies, this includes deriving self-confirming distribution price predictions to be input to these strategies, based on the environment defined in Step 1. The full set of strategies included in our EGTA study is described in online Appendix B.
3. Simulate select profiles among these strategies, sampling from the valuation distributions for each simulation instance (at least one million per profile, most profiles two million or more). Calculate mean payoffs for each strategy in each profile.
4. Analyze the empirical game defined by these mean payoffs to identify Nash equilibria, dominance relationships, regret values, and other analytic constructs.

In actuality, Steps 2–4 were applied in an iterative and interleaved manner, with intermediate analysis results informing the selection of strategies to explore and profiles to sample. The exploration and sample selection were guided manually, generally driven by the objective of confirming or refuting equilibrium candidates among the profiles already evaluated. The process for each environment was terminated when all of the following conditions were met: (1) a broadly representative set of heuristic strategies were covered, (2) all symmetric mixed profiles evaluated were either confirmed or refuted as equilibria, and (3) all strategies showing relative success in at least one environment were evaluated against the equilibria in all other environments. Overall, the analysis commanded some tens of CPU-years over a roughly six-month period.

7.2 Environments

We evaluated five simultaneous SPSB environments, involving 3–8 agents bidding on 5 or 6 goods. The environments span two qualitatively different valuation distributions, from highly complementary to highly substitutable. Both of these assume IPV and symmetry, so that each agent receives a private valuation drawn independently from the same distribution.

7.2.1 Scheduling Valuations

The first valuation distribution we employ in this study is based on a model of *market-based scheduling* [Reeves et al., 2005]. Goods represent time slots of availability for some resource: for example, a machine, a meeting room, a vehicle, or a skilled laborer. Agents have tasks, which require this resource for some duration of time to complete.

Specifically, the goods $\mathcal{X} = \{x_1, \ldots, x_m\}$ comprise a set of m time slots available to be scheduled. Agent i's task requires λ_i time slots to accomplish, and the agent values a set of time slots according to when they enable completion of the task. If agent i acquires λ_i time slots by time t, it obtains value V_i^t. Completion value with respect to time is a nonincreasing function: for all i, if $t < t'$ then $V_i^t \geq V_i^{t'}$. If it fails to obtain λ_i slots, the agent accrues no value ($V_i^\infty = 0$). Let $X \subseteq \mathcal{X}$ denote a set of slots. The expression $|\{x_j \in X \mid j \leq t\}|$ represents the number of these that are for time t or earlier. The overall valuation function for agent i is $v_i(X) = V_i^{T(X,\lambda_i)}$, where

$$T(X, \lambda) = \min\left(\{t \text{ s.t. } |\{x_j \in X \mid j \leq t\}| \geq \lambda\} \cup \{\infty\}\right)$$

is the earliest time by which X contains at least λ slots.

For each agent, a task length λ_i is drawn uniformly over the integers $\{1, \ldots, m\}$. Values associated with task completion times are drawn uniformly over $\{1, \ldots, 50\}$, then pruned to impose monotonicity [Reeves et al., 2005]. The valuations induced by this scheduling scenario exhibit strong complementarity among goods. When $\lambda > 1$, the agent gets no value at all for goods in a bundle of fewer than λ. On the other hand, there is some degree of substitutability across goods when there may be multiple ways of acquiring a bundle of the required size.

We denote environments using this valuation by $U[m, n]$, with m and n the numbers of goods and agents, and "U" indicating the uniform distribution over task lengths.

7.2.2 Homogeneous-Good Valuations

The second valuation distribution expresses the polar opposite of complementarity: goods are perfect substitutes, in that agents cannot distinguish one from another. Agents' marginal values for units of this good are weakly decreasing. Specifically, valuation is a function of the number of goods obtained, constructed as follows. Agent i's value for obtaining exactly one good, $v_i(\{1\})$, is drawn uniformly over $\{0, \ldots, 127\}$. Its value for obtaining two, $v_i(\{1, 2\})$, is then drawn from $\{v_i(\{1\}), v_i(\{1\}) + 1, \ldots, 2v_i(\{1\})\}$. In other words, its marginal value for the second good is uniform over $\{0, \ldots, v_i(\{1\})\}$. Subsequent marginal values are similarly constrained not to increase. Its marginal value for the kth good is uniform over $\{0, \ldots, v_i(\{1, \ldots, k-1\}) - v_i(\{1, \ldots, k-2\})\}$.

We denote environments using this valuation by $H[m, n]$,

with "H" an indicator for homogeneity.

7.3 Regret

We evaluate the stability of a strategy profile by *regret*, the maximal gain a player could achieve by deviating from the profile. Formally, let $\Gamma = \{n, S, u(\cdot)\}$ be a symmetric normal-form game with n players, strategy space S (the same for each player, since the game is symmetric), and payoff function $u : S \times S^{n-1} \to \mathbb{R}$. The expression $u(s_i, s_{-i})$ represents the payoff to playing strategy s_i in a profile where the other players play strategies $s_{-i} \in S^{n-1}$.

Definition 6 (Regret)**.** The *regret* $\epsilon(\boldsymbol{s})$ of a strategy profile $\boldsymbol{s} = (s_1, \ldots, s_n)$ is given by

$$\epsilon(\boldsymbol{s}) = \max_i \max_{s'_i \in S} \left(u(s'_i, s_{-i}) - u(s_i, s_{-i})\right).$$

A Nash equilibrium profile has zero regret, and more generally regret provides a measure of approximation to Nash equilibrium. Using this regret definition, profile $\boldsymbol{s}$ is an $\epsilon(\boldsymbol{s})$-Nash equilibrium.

Regret is a property of profiles. Evaluation of a particular strategy is inherently relative to a context of strategies played by other agents. Jordan et al. [2007] proposed ranking strategies according to their performance when other agents are playing an equilibrium.

Definition 7 (NE regret [Jordan, 2010])**.** Let $\boldsymbol{s}^{NE}$ be a Nash equilibrium of game Γ. The regret of strategy $s_i \in S$ relative to $\boldsymbol{s}^{NE}$, $u(s_i^{NE}, s_{-i}^{NE}) - u(s_i, s_{-i}^{NE})$, is an *NE regret* of s_i in Γ.

NE regret represents the loss experienced by an agent for deviating to a specified strategy from a Nash equilibrium of a game. The rationale for this measure comes from the judgment that all else equal, Nash equilibria provide a compelling strategic context for evaluating a given strategy. For games with multiple NE, a given strategy may have multiple NE-regret values.

7.4 Results

Table 1 summarizes the extent of simulation coverage of the five SPSB environments investigated.[2] The empirical games comprise 600–14,000 profiles, over 29–34 strategies. Evaluated profiles constitute a small fraction (as little as 0.03%) of the entire profile space over these strategies. Nevertheless, these are sufficient to confirm symmetric Nash equilibria for each game. Whereas it is impossible to rule out additional equilibria without exhaustive evaluation, we have either confirmed or refuted every evaluated symmetric mixed profile (i.e., every subset of strategies for which all profiles are evaluated). Since this includes every strategy in conjunction with those most effective in other contexts, we doubt that there are any other small-support symmetric equilibria, and expect few if any alternative symmetric equilibria among the explored strategies.

Table 1: Strategies and profiles simulated for the environments addressed in our EGTA study.

Environment	# Strategies	# Profiles	% Profiles
$U[6,4]$	34	1165	1.76
$U[5,5]$	30	5219	1.88
$U[5,8]$	29	9096	0.03
$H[5,3]$	32	608	10.16
$H[5,5]$	34	13197	2.62

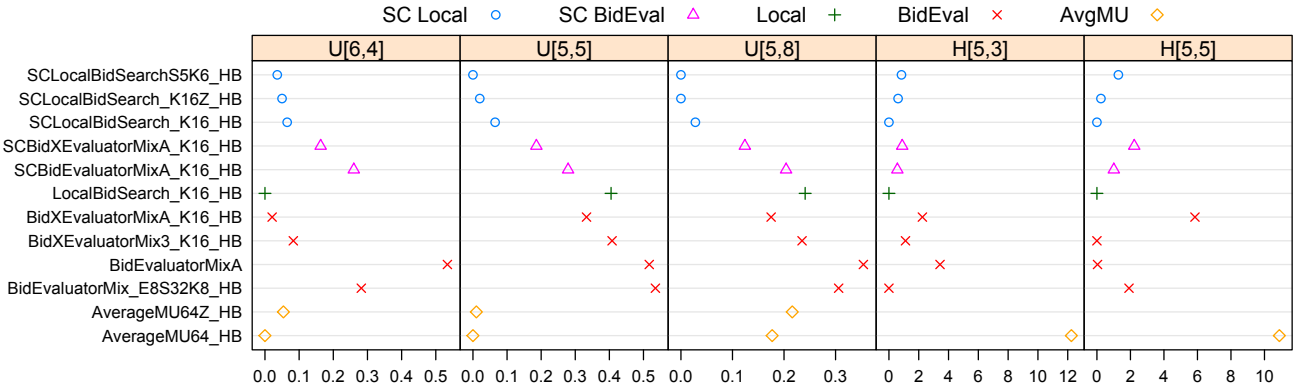
As it happens, our process identified exactly one symmetric mixed-strategy NE in each game. Of the 44 distinct strategies explored across environments, only seven were supported in equilibrium in any environment. Variants of SCLocalBid, a strategy that explicitly optimizes with respect to self-confirming prices, predominate in equilibrium in four out of five environments. LocalBid and the BidEvalMix strategies also explicitly optimize, but with respect to price predictions that are self-confirming for different strategies (see Appendix B). AverageMU64_HB performs remarkably well in the "U" environments, and is the sole non-optimizing heuristic to appear in equilibria.

Whether a strategy is in equilibrium or not is a crude binary classification of merit. We measure relative degrees of effectiveness by NE regret (Definition 7), as reported in Table 2. The table depicts the NE-regret values for 12 top strategies: all those ranked fourth or better in at least one environment. The values are indicated on a horizontal scale for each game environment, ranging from zero (indicating the strategy is in the support of equilibrium) to the highest NE regret value among the listed strategies. We also verified via a bootstrap technique that the results are statistically robust: for each identified equilibrium the one-tailed 90% confidence bound on regret is at the far left end (1% of the range) of the NE regret scale shown.

These results provide solid support for the SCLocalBid strategy. For the one environment it fails to participate in equilibrium, its NE regret is still quite low, thus we find it to be a strong all-around strategy. This situation contrasts starkly with prior findings for bidding in simultaneous ascending auctions [Wellman et al., 2008], where the best strategies for complementary (scheduling valuation) environments were awful in substitutes (homogeneous good)

[2]The extended version includes an online data supplement with full payoff data for the empirical games. The results we report here subsume those of a preliminary study [Yoon and Wellman, 2011]. That study set the groundwork for the current investigation by developing the infrastructure for simulation and derivation of self-confirming price predictions, and tuning parameters (e.g., number of evaluating samples) for several of the strategies. However, the preliminary results reflected sparser coverage of relevant profiles and a weaker overall set of strategy candidates.

Table 2: NE regret for top strategies across five environments.



environments, and vice versa. The fact that SCLocalBid performs so well aligns with our key theoretical finding, in support of optimal PP bidders with self-confirming price predictions. As the LocalBid search method is most effective in optimizing bids, it is consistent with our theory to find that both examples of strategies in this class are leaders among explicit optimizing strategies.

All the remaining top strategies are in the BidEval class (also explicit optimizers), except for AverageMU64. In contrast to the others, however, AverageMU64's quality is limited to one of the valuation distributions—the strategy performs poorly in homogeneous-good environments. This observation is consistent with the results reported by Boyan and Greenwald [2001], where an example environment with perfect substitutes was contrived to demonstrate the shortcomings of marginal-utility-based bidding. Given such examples, it is perhaps unsurprising that the heuristic strategies based on marginal value have a difficult time competing with explicit optimizers. If anything it is the observed success of AverageMU64 that is striking, but this outcome is consistent with past experimental results in an environment that exhibits substantial complementarity [Stone et al., 2003]. Still, compared to optimal PP bidders, AverageMU lacks robustness across valuation classes.

Finally, all the top strategies but one employ the highest-bid (HB) statistic in deriving self-confirming price distributions, as opposed to the actual transaction price. This, too, is aligned with what the theory would dictate. The lone exception in Table 2 is BidEvaluatorMixA, which performed impressively in one of the homogenous-good environments but not so well in the rest.

8 Conclusion

Our theoretical and experimental findings point to two key ingredients for developing effective bidding strategies for SimOSSB auctions with independent private values. The first is an algorithm for computing approximately optimal bid vectors given a probabilistic price prediction. We have found that a simple local search approach (LocalBid) achieves a high fraction of optimality, and that this translates into superior performance in strategic simulations (§7). The second ingredient is a method for computing self-confirming price predictions for a given price-prediction bidding strategy and a specification of a simultaneous-auction environment. We have found a simple iterative estimation procedure (§6) to be effective at finding price distributions that are approximately marginally self-confirming for a range of strategies and environments.

Our theoretical results say that if these ingredients can achieve their tasks perfectly, we have a solution (i.e., a Bayes-Nash equilibrium) to the corresponding simultaneous auction game. Approximations to the ideal in these ingredients yield approximate game solutions. Our computational experiments indicate that following this approach produces results that are as good or better than any other general method proposed for bidding in SimOSSB auctions. The evidence takes the form of a comprehensive empirical game-theoretic analysis, covering both complementary and substitutable valuation classes and a broad swath of heuristic strategies from the literature.

There is still room for improvement in our proposed methods, as well as opportunity to subject our conclusions to further empirical scrutiny. More sophisticated stochastic search techniques may improve upon our best bid optimization algorithms, and allow them to scale to larger environments with more complex valuations. Similarly, we do not consider our simple iterative method to be a last word on finding self-confirming price distributions. In particular, we expect that substantial improvement could be obtained by accounting for some joint dependencies in price predictions. Finally, further testing against alternative proposals or in alternative environments would go some way to bolstering or refuting our positive conclusions.

Abstract

Many latent (factorized) models have been proposed for recommendation tasks like collaborative filtering and for ranking tasks like document or image retrieval and annotation. Common to all those methods is that during inference the items are scored independently by their similarity to the query in the latent embedding space. The structure of the ranked list (i.e. considering the set of items returned as a whole) is not taken into account. This can be a problem because the set of top predictions can be either too diverse (contain results that contradict each other) or are not diverse enough. In this paper we introduce a method for learning latent structured rankings that improves over existing methods by providing the right blend of predictions at the top of the ranked list. Particular emphasis is put on making this method scalable. Empirical results on large scale image annotation and music recommendation tasks show improvements over existing approaches.

1 INTRODUCTION

Traditional latent ranking models score the ith item $d_i \in \mathbb{R}^D$ given a query $q \in \mathbb{R}^D$ using the following scoring function:

$$f(q, d_i) = q^\top W d_i = q^\top U^\top V d_i, \quad (1)$$

where $W = U^\top V$ has a low rank parameterization, and hence $q^\top U^\top$ can be thought of as the latent representation of the query and Vd_i is equivalently the latent representation for the item. The latent space is n-dimensional, where $n \ll D$, hence U and V are $n \times D$ dimensional matrices. This formulation covers a battery of different algorithms and applications.

For example, in the task of collaborative filtering, one is required to rank items according to their similarity to the user, and methods which learn latent representations of both users and items have proven very effective. In particular, Singular Value Decomposition (SVD) (Billsus and Pazzani, 1998; Bell *et al.*, 2009) and Non-negative Matrix Factorization (NMF) (Lee and Seung, 2001) are two standard methods that at inference time use equation (1), although the methods to learn the actual parameters U and V themselves are different. In the task of document retrieval, on the other hand, one is required to rank text documents given a text query. The classical method Latent Semantic Indexing (LSI) (Deerwester *et al.*, 1990) is an unsupervised approach that learns from documents only, but still has the form of equation (1) at test time. More recently, supervised methods have been proposed that learn the latent representation from (query, document) relevance pairs, e.g. the method Polynomial Semantic Indexing (SSI) (Bai *et al.*, 2009). Finally, for multiclass classification tasks, particularly when involving thousands of possible labels, latent models have also proven to be very useful, e.g. the WSABIE model achieves state-of-the-art results on large-scale image (Weston *et al.*, 2011) and music (Weston *et al.*, 2012) annotation tasks. Moreover, all these models not only perform well but are also efficient in terms of computation time and memory usage.

Scoring a single item as in equation (1) is not the end goal of the tasks described above. Typically for recomendation and retrieval tasks we are interested in ranking the items. This is achieved by, after scoring each individual item using $f(q, d_i)$, sorting the scores, largest first, to produce a ranked list. Further, typically only the top few results are then presented to the user, it is thus critical that the method used performs well for those items. However, one potential flaw in the models described above is that scoring items individually as in eq. (1) does not fully take into account the joint set of items at the top of the list (even when optimizing top-of-the-ranked-list type loss functions).

The central hypothesis of this paper is that latent ranking methods could be improved if one were to take into account the structure of the ranked list during inference. In particular this would allow the model to make sure there is the right amount of consistency and diversity in the predictions.

Let us suppose for a given query that some of the predictions at the top of the ranked list are accurate and some are inaccurate. A model that improves the consistency of the predictions might improve overall accuracy. A structured ranking model that predicts items dependent on both the query *and* other items at the top of the ranked list can achieve such a goal. To give a concrete example, in a music recommendation task you might not want to recommend both "heavy metal" and "60s folk" in the same top k list. In that case, a structured model which encodes item-item similarities as well as query-item similarities could learn this by representing those two items with very different latent embedding vectors such that their pairwise item-item contribution is a large negative value, penalizing both items appearing in the top k. Note that a structured ranking model can do this despite the possibility that both items are a good match to the query, so an unstructured model would find this difficult to achieve.

Conversely, if improved results are gained from encouraging the top ranked items to be a rather diverse set for a particular query, then a structured model can learn to predict that instead. For example in the task of document retrieval, for ambiguous queries like "jaguar", which may refer either to a *Panthera* or to the car manufacturer, diversity should be encouraged. The goal of a structured ranker is to learn the optimal tradeoff between consistency and diversity on a case-by-case (per query) basis. As latent parameters are being learnt for each query type this is indeed possible.

In this work we propose a latent modeling algorithm that attempts to do exactly what we describe above. Our model learns to predict a ranked list that takes into account the structure of the top ranked items by learning query-item and item-item components. Inference then tries to find the maximally scoring set of documents. It should be noted that while there has been strong interest in building structured ranking models recently (Bakir *et al.*, 2007), to our knowledge this is the first approach of this type to do so for latent models. Further, the design of our algorithm is also particularly tuned to work on large scale datasets which are the common case for latent models, e.g. in collaborative filtering and large scale annotation and ranking tasks. We provide empirical results on two such large scale datasets, on a music recommendation task, and an image annotation task, that show our structured method brings accuracy improvements over the same method without structure as well as other standard baselines. We also provide some analysis of why we think this is happening.

The rest of the paper is as follows. Section 2 describes our method, Latent Structured Ranking (LaSR). Section 3 discusses previous work and connects them to our method. Section 4 describes our empirical results and finally Section 5 concludes.

2 METHOD

Given a query $q \in \mathcal{Q}$ our task is to rank a set of documents or items $\mathcal{D}$. That is, we are interested in outputting (and scoring) a permutation $\bar{d}$ of the set $\mathcal{D}$, where $\bar{d}_j$ is the jth item in the predicted ranked list. Our ultimate goal will be to design models which take into account not just individual document scores but the (learned) relative similarities of documents in different positions as well.

2.1 SCORING PERMUTATIONS BY SCORING INDIVIDUAL ITEMS

Let us begin by proposing methods for using the standard latent model of eq. (1) to score permutations. We need a method for transforming the scores for single documents into scores for permutations. Such transformations have been studied in several previous works, notably (Le and Smola, 2007). They show that finding maximally scoring permutations from single documents can be cast as a linear assignment problem, solvable in polynomial time with the Hungarian algorithm.

For the vanilla model we propose here, however, we can use a simple parameterization which allows for inference by sorting. For any given permutation we assign a score as follows:

$$f_{vanilla}(q, \bar{d}) = \sum_{i=1}^{|\bar{d}|} w_i (q^\top U^\top V \bar{d}_i), \qquad (2)$$

where for each position i in the permutation, we associate a weight w_i, where w_i can be any weights such that $w_1 > w_2 > \cdots > w_{|\bar{d}|} \geq 0$. For example, one can just set $w_i = \frac{1}{i}$. Inference using this model is then performed by calculating:

$$F_{vanilla}(q) = \text{argmax}_{\bar{d}'}[f_{vanilla}(q, \bar{d}')].$$

In this case, computing the best-scoring assignment is simply a matter of sorting documents by their scores from eq. (1). To see this note that the score of any unsorted pair can be increased by sorting, since the positional weights w_i are fixed and decreasing.

2.2 LATENT STRUCTURED RANKING

The fundamental hypothesis of this paper is that including knowledge about the structure of the rankings at inference time will improve the overall set of ranked items. That is, we want to define a model where the score of a document $\bar{d}_i$ does not only depend on the query q but also on the other items and their respective positions as well. What is more, we would prefer a model that places more weight on the top items in a permutation (indeed, this is reflected by common ranking losses like MAP and precision@k).

This leads us to propose the following class of Latent Structured Ranking (LaSR) models:

$$f_{lsr}(q, \bar{d}) = \sum_{i=1}^{|\bar{d}|} w_i (q^\top U^\top V \bar{d}_i) + \sum_{i,j=1}^{|\bar{d}|} w_i w_j (\bar{d}_i^\top S^\top S \bar{d}_j) \ . \tag{3}$$

In addition to the parameters of eq. (2), we now introduce the additional parameter S. S takes into account the structure of the predicted ranked list. $S^\top S$ is a low rank matrix of item-item similarities where S is a $n \times D$ matrix, just like U and V, and must also be learnt by the model using training data.

2.3 CHOICE OF THE w_i PARAMETERS

The weights w are crucial to the usefulness of the matrix in the second term of eq. (3). If $w_i = 1$ for all i then the entire second term would always be the same no matter what choice of ranking $\bar{d}$ one chooses. If the position weights w_i are decreasing, however, then the structural term S is particularly meaningful at the top of the list.

As suggested before in Section 2.1 we could choose $w_i = \frac{1}{i}$. In that case the items that are at the top of the predicted ranked list dominate the overall score from the second term. In particular, the pairwise item-item similarities between items in the top-ranked positions play a role in the overall choice of the entire ranked list $\bar{d}$. Our model can hence learn the consistency vs. diversity tradeoff within the top k we are interested in.

However, if one knows in advance the number of items one wishes to show to the user (i.e. the top k) then one could choose directly to only take into account those predictions:

$$w_i = 1/i, \quad \text{if } i \leq k, \quad \text{and 0 otherwise.} \tag{4}$$

As we will see this also has some computational advantages due to its sparsity, and will in fact be our method of choice in the algorithm we propose.

2.4 MODEL INFERENCE

At test time for a given query we need to compute:

$$F_{lsr}(q) = \text{argmax}_{\bar{d}'}[f_{lsr}(q, \bar{d}')]. \tag{5}$$

Just as inference in the vanilla model can be cast as a linear assignment problem, inference in the LaSR model can be cast as a quadratic assignment problem (Lacoste-Julien *et al.*, 2006). This is known to be NP hard, so we must approximate it. In this section, we briefly discuss several alternatives.

- Linear programming relaxation: Since we know we can cast our problem as quadratic assignment, we could consider directly using the linear programming relaxation suggested by (Lacoste-Julien *et al.*, 2006). In our experiments, however, we have tens of thousands of labels. Solving even this relaxed LP per query is computationally infeasible for problems of this size. We note that WSABIE's (Weston *et al.*, 2011) sampling-based technique is an attempt to overcome even linear time inference for this problem.

- Greedy structured search: we could also consider a greedy approach to approximately optimizing eq. (5) as follows: (i) pick the document $\bar{d}_1 \in \mathcal{D}$ that maximizes:

$$f_{greedy}(q, \bar{d}_1) = w_1 (q U^\top V \bar{d}_1) + (w_1)^2 (\bar{d}_1^\top S^\top S \bar{d}_1) \tag{6}$$

  and then fix that document as the top ranked prediction. (ii) Find the second best document dependent on the first, by maximizing (for $N = 2$):

$$f_{greedy}(q, \bar{d}_N) = w_N (q U^\top V \bar{d}_N) q + \sum_{i=1}^{N} w_i w_N (\bar{d}_i^\top S^\top S \bar{d}_N).$$

  Finally, (iii) repeat the above, greedily adding one more document each iteration by considering the above equation for $N = 3, \ldots, k$ up to the number of desired items to be presented to the user.

  This method has complexity $O(k^2 |\mathcal{D}|)$. Its biggest drawback is that the highest-scoring document is chosen using the vanilla model. Even if we could improve our score by choosing a different document, taking into account the pairwise scores with other permutation elements, this algorithm will not take advantage of it. Another way to look at this is, precision@1 would be no better than using the vanilla model of eq. (1).

  The greedy procedure also permits beam search variants. Using a beam of M candidates this gives

a complexity of $O(Mk^2|\mathcal{D}|)$. This is tractable at test time, but the problem is that during (online) learning one would have to run this algorithm per query, which we believe is still too slow for the cases we consider here.

- Iterative search: Motivated by the defects in greedy search and LP relaxation, we propose one last, iterative method. This method is analogous to inference by iterated conditional modes in graphical models (Besag, 1986). (i) On iteration $t = 0$ predict with an unstructured model (i.e. do not use the second term involving S):

$$f_{iter:t=0}(q, \bar{d}) = \sum_{i=1}^{|\bar{d}|} w_i (qU^\top V \bar{d}_i). \quad (7)$$

As mentioned before, computing the best ranking $\bar{d}$ just involves sorting the scores $qU^\top V d_i$ and ordering the documents, largest first. Utilizing the sparse choice of $w_i = 1/i$, if $i \leq k$, and 0 otherwise described in Section 2.3 we do not have to sort the entire set, but are only required to find the top k which can be done in $O(|\mathcal{D}| \log k)$ time using a heap. Let us denote the predicted ranked list as $\bar{d}^0$ and in general on each iteration t we are going to make predictions $\bar{d}^t$. (ii) On subsequent iterations, we maximize the following scoring function:

$$f_{iter:t>0}(q, \bar{d}) = \sum_{i=1}^{|\bar{d}|} w_i (qU^\top V \bar{d}_i) + \sum_{i,j=1}^{|\bar{d}|} w_i w_j (\bar{d}_i^\top S^\top S \bar{d}_j^{t-1}). \quad (8)$$

As $\bar{d}^{t-1}$ is now fixed on iteration t, the per-document d_i scores

$$(qU^\top V \bar{d}_i) + \sum_{j=1}^{|\bar{d}|} w_j (\bar{d}_i^\top S^\top S \bar{d}_j^{t-1}) \quad (9)$$

are now independent of each other. Hence, they can be calculated individually and, as before, can be sorted or the top k can be found, dependent on the choice of w. If we use the sparse w of eq. (4) (which we recommend) then the per-document scores are also faster to compute as we only require:

$$(qU^\top V \bar{d}_i) + \sum_{j=1}^{k} w_j (\bar{d}_i^\top S^\top S \bar{d}_j^{t-1}).$$

Overall this procedure then has complexity $O(Tk|\mathcal{D}|)$ when running for T steps. While this does not look at first glance to be any faster than the greedy or beam search methods at testing time, it has important advantages at training time as we will see in the next section.

2.5 LEARNING

We are interested in learning a *ranking* function where the top k retrieved items are of particular interest as they will be presented to the user. We wish to optimize all the parameters of our model jointly for that goal. As the datasets we intend to target are large scale, stochastic gradient descent (SGD) training seems a viable option. However, during training we cannot afford to perform full inference during each update step as otherwise training will be too slow. A standard loss function that already addresses that issue for the unstructured case which is often used for retrieval is the margin ranking criterion (Herbrich *et al.*, 2000; Joachims, 2002). In particular, it was also used for learning factorized document retrieval models in Bai *et al.* (2009). The loss can be written as:

$$err_{AUC} = \sum_{i=1}^{m} \sum_{d^- \neq d_i} \max(0, 1 - f(q_i, d_i) + f(q_i, d^-)). \quad (10)$$

For each training example $i = 1, \ldots, m$, the positive item d_i is compared to all possible negative items $d^- \neq d_i$, and one assigns to each pair a cost if the negative item is larger or within a "margin" of 1 from the positive item. These costs are called *pairwise violations*. Note that all pairwise violations are considered equally if they have the same margin violation, independent of their position in the list. For this reason the margin ranking loss might not optimize the top k very accurately as it cares about the average rank.

For the standard (unstructured) latent model case, the problem of optimizing the top of the rank list has also recently been addressed using sampling techniques (Weston *et al.*, 2011) in the so-called WARP (Weighted Approximately Ranked Pairwise) loss. Let us first write the predictions of our model for all items in the database as a vector $\bar{f}(q)$ where the i^{th} element is $\bar{f}_i(q) = f(q, d_i)$. One then considers a class of ranking error functions:

$$err_{WARP} = \sum_{i=1}^{m} L(rank_{d_i}(\bar{f}(q_i))) \quad (11)$$

where $rank_{d_i}(\bar{f}(q_i))$ is the margin-based rank of the labeled item given in the i^{th} training example:

$$rank_{d_i}(\bar{f}(q)) = \sum_{j \neq i} \theta(1 + \bar{f}_j(q) \geq \bar{f}_i(q)) \quad (12)$$

where θ is the indicator function, and $L(\cdot)$ transforms this rank into a loss:

$$L(r) = \sum_{i=1}^{r} \alpha_i, \text{ with } \alpha_1 \geq \alpha_2 \geq \cdots \geq 0. \quad (13)$$

The main idea here is to *weight* the pairwise violations depending on their position in the ranked list. Different choices of α define different weights (importance) of the relative position of the positive examples in the ranked list. In particular it was shown that by choosing $\alpha_i = 1/i$ a smooth weighting over positions is given, where most weight is given to the top position, with rapidly decaying weight for lower positions. This is useful when one wants to optimize precision at k for a variety of different values of k at once Usunier *et al.* (2009). (Note that choosing $\alpha_i = 1$ for all i we have the same AUC optimization as equation (10)).

We can optimize this function by SGD following the authors of Weston *et al.* (2011), that is samples are drawn at random, and a gradient step is made for each draw. Due to the cost of computing the exact rank in (11) it is approximated by sampling. That is, for a given positive label, one draws negative labels until a violating pair is found, and then approximates the rank with

$$rank_d(\bar{f}(q)) \approx \left\lfloor \frac{|\mathcal{D}| - 1}{N} \right\rfloor$$

where $\lfloor . \rfloor$ is the floor function, $|\mathcal{D}|$ is the number of items in the database and N is the number of trials in the sampling step. Intuitively, if we need to sample more negative items before we find a violator then the rank of the true item is likely to be small (it is likely to be at the top of the list, as few negatives are above it).

This procedure for optimizing the top of the ranked list is very efficient, but it has a disadvantage with respect to structured learning: we cannot simply sample and score items any longer as we need to somehow score entire permutations. In particular, it is not directly applicable to several of the structured prediction approaches like LP, greedy or beam search. That is because we cannot compute the score of $\bar{f}_i$ independently because they depend on the ranking of all documents, which then makes the sampling scheme invalid. However, for (a variant of) the iterative algorithm which we described in the previous section the WARP (or AUC) technique can still be used.

The method is as follows. In the first iteration the model scores in eq. (7) are independent and so we can train using the WARP (or AUC) loss. We then have to compute $\bar{d}^0$ (the ranking of items) for each training example for use in the next iteration. Note that using the sparse w of eq. (4) this is $O(\mathcal{D} \log k)$ to compute, and storage is also only a $|\mathcal{D}| \times k$ matrix of top items. After computing $\bar{d}^0$, in the second iteration we are again left with independent scoring functions $\bar{f}_i$ as long as we make one final modification, instead

Algorithm 1 LASR training algorithm

Input: Training pairs $\{(q_i, d_i)\}_{i=1,\ldots,l}$.
Initialize model parameters U_t, V_t and S_t (we use mean 0, standard deviation $\frac{1}{\sqrt{d}}$) for each t.
for $t = 0, \ldots, T$ **do**
  repeat
    if $t = 0$ **then**
      $f(q, d) = qU_0^\top V_0 d$.
    else
      $f(q, d) = qU_t^\top V_t d + \sum_{j=1}^{k} w_j d^\top S_t^\top S_t \bar{d}_j^{t-1}$
    end if
    Pick a random training pair (q, d^+).
    Compute $f(q, d^+)$.
    Set $N = 0$.
    repeat
      Pick a random document $d^- \in \mathcal{D}, d \neq d_i$.
      Compute $f(q, d^-)$.
      $N = N + 1$.
    until $f(q^+, d^+) < f(q^+, d^-) + 1$ or $N \geq |\mathcal{D}| - 1$
    if $f(q^+, d^+) < f(q^+, d^-) + 1$ **then**
      Make a gradient step to minimize:
      $L(\left\lfloor \frac{|\mathcal{D}|-1}{N} \right\rfloor) \max(1 - f(q^+, d^+) + f(q^+, d^-), 0)$.
      Project weights to enforce constraints,
      i.e. if $||U_{ti}|| > C$ then $U_{ti} \leftarrow (CU_{ti})/||U_{ti}||$,
        $i = 1, \ldots, D$ (and likewise for V_t and S_t).
    end if
  until validation error does not improve.
  For each training example, compute the top k ranking documents $\bar{d}_i^t, \quad i = 1, \ldots, k$ for iteration t using $f(q, d)$ defined above.
end for

of using eq. (8) we instead use:

$$\begin{aligned} f_{iter:t>0}(q, \bar{d}) &= \sum_{i=1}^{|\bar{d}|} w_i (qU_t^\top V_t \bar{d}_i) \\ &+ \sum_{i,j=1}^{|\bar{d}|} w_i w_j (\bar{d}_i^\top S_t^\top S_t \bar{d}_j^{t-1}). \quad (14) \end{aligned}$$

on iteration t, where U_t, V_t and S_t are separate matrices for each iteration. This decouples the learning at each iteration. Essentially, we are using a cascade-like architecture of t models trained one after the other. Note that if a global optimum is reached for each t then the solution should always be the same or improve over step $t - 1$, as one could pick the weights that give exactly the same solution as for step $t - 1$.

So far, the one thing we have failed to mention is regularization during learning. One can regularize the parameters by preferring smaller weights. We constrain them using $||S_{ti}|| \leq C$, $||U_{ti}|| \leq C$, $||V_{ti}|| \leq C$, $i = 1, \ldots, |\mathcal{D}|$. During SGD one projects the parameters back on to the constraints at each step, following

the same procedure used in several other works, e.g. Weston *et al.* (2011); Bai *et al.* (2009). We can optimize hyperparameters of the model such as C and the learning rate for SGD using a validation set.

Overall, our preferred version of Latent Structured Ranking that combines all these design decisions is given in Algorithm 1.

3 PRIOR WORK

In the introduction we already mentioned several latent ranking methods: SVD (Billsus and Pazzani, 1998; Bell *et al.*, 2009), NMF (Lee and Seung, 2001), LSI (Deerwester *et al.*, 1990), PSI (Bai *et al.*, 2009) and WSABIE (Weston *et al.*, 2011). We should mention that many other methods exist as well, in particular probabilistic methods like pLSA (Hofmann, 1999) and LDA (Blei *et al.*, 2003). None of those methods, whether they are supervised or unsupervised, take into the structure of the ranked list as we do in this work, and we will use several of them as baselines in our experiments.

There has been a great deal of recent work on structured output learning (Bakir *et al.*, 2007), particularly for linear or kernel SVMs (which are not latent embedding methods). In methods like Conditional Random Fields (Lafferty *et al.*, 2001), SVM-struct (Tsochantaridis *et al.*, 2004) LaSO (Daumé III and Marcu, 2005) and SEARN (Daumé *et al.*, 2009) one learns to predict an output which has structure, e.g. for sequence labeling, parse tree prediction and so on. Predicting ranked lists can also be seen in this framework. In particular LaSO (Daumé III and Marcu, 2005) is a general approach that considers approximate inference using methods like greedy approximation or beam search that we mentioned in Section 2.4. As we said before, due to the large number of items we are ranking many of those approaches are infeasible. In our method, scalability is achieved using a cascade-like training setup, and in this regard is related to (Weiss *et al.*, 2010). However, unlike that work, we do not use it to prune the set of items considered for ranking, we use it to consider pairwise item similarities.

The problem of scoring entire permutations for ranking is well-known and has been investigated by many authors (Yue *et al.*, 2007a,b; Le and Smola, 2007; Xia *et al.*, 2008). These works have primarily focused on on using knowledge of the structure (in this case the predicted positions in the ranked list) in order to optimize the right metric, e.g. MAP or precision@k. In that sense, methods like WSABIE which uses the WARP loss already use structure in the same way. In our work we also optimize top-of-the-ranked-list metrics by using WARP, but in addition we also use the ranking structure to make predictions dependent on the query and the other predicted items during inference by encoding this in the model itself. That is, in our work we explicitly seek to use (and learn) inter-document similarity measures.

There has been work on taking into account inter-document similarities during ranking. The most famous and prominent idea is pseudo-relevance feedback via query expansion (Rocchio, 1971). Pseudo-relevance works by doing normal retrieval (e.g. using cosine similarity in a vector space model), to find an initial set of most relevant documents, and then assuming that the top k ranked documents are relevant, and performing retrieval again by adjusing the cosine similarity based on previously retrieved documents. In a sense, LaSR is also a pseudo-relevance feedback technique, but where inter-document similarities are learned to minimize ranking loss.

More recently, some authors have investigated incorporating inter-document similarity during ranking. Qin *et al.* (2008) have investigated incorporating a fixed document-document similarity feature in ranking. In their work, however, they did not score permutations. Instead, each document was associated with a relevance score and the authors treated learning as a structured regression problem. For a situation with implicit feedback, Raman *et al.* (2012) investigate an inference technique similar to our greedy algorithm. Volkovs and Zemel (2009) also explored listwise ranking using pairwise document interactions in a probabilistic setup. To the best of our knowledge, however, none of these methods investigate a learned inter-document similarity (i.e. latent parameters for that goal), which is the most powerful feature of LaSR.

4 EXPERIMENTS

We considered two large scale tasks to test our proposed method. The first is a music recommendation task with over 170,000 artists (possible queries or items) and 5 million training pairs. The second is a task of large scale image annotation with over 15,000 labels and 7 million training examples.

4.1 MUSIC RECOMMENDATION TASK

The first task we conducted experiments on is a large scale music recommendation task. Given a query (seed) artist, one has to recommend to the user other artists that go well together with this artist if one were listening to both in succession, which is the main step in playlisting and artist page recommendation on sites like `last.fm`, `music.google.com` and programs such as iTunes and `http://the.echonest.com/`.

Table 1: Recommendation Results on the music recommendation task. We report for recall at 5, 10, 30 and 50 for our method and several baselines.

Method	R@5	R@10	R@30	R@50
NMF	3.76%	6.38%	13.3%	17.8%
SVD	4.01%	6.93%	13.9%	18.5%
LaSR $(t = 0)$	5.60%	9.49%	18.9%	24.8%
LaSR $(t = 1)$	6.65%	10.73%	20.1%	26.7%
LaSR $(t = 2)$	6.93%	10.95%	20.3%	26.5%

Table 2: Changing the embedding size on the music recommendation task. We report R@5 for various dimensions n.

Method $n =$	25	50	100	200
NMF	2.82%	3.76%	3.57%	4.82%
SVD	3.61%	4.01%	4.53%	5.28%
LaSR $(t = 0)$	5.23%	5.60%	6.24%	6.42%

We used the "Last.fm Dataset - 1K users" dataset available from `http://www.dtic.upf.edu/~ocelma/MusicRecommendationDataset/lastfm-1K.html`. This dataset contains (user, timestamp, artist, song) tuples collected from the Last.fm (`www.lastfm.com`) API, representing the listening history (until May 5th, 2009) for 992 users and 176,948 artists. Two consecutively played artists by the same user are considered as a (query, item) pair. Hence, both q_i and d_i are $D = 176,948$ sparse vectors with one non-zero value (a one) indicating which artist they are. One in every five days (so that the data is disjoint) were left aside for testing, and the remaining data was used for training and validation. Overall this gave 5,408,975 training pairs, 500,000 validation pairs (for hyperparameter tuning) and 1,434,568 test pairs.

We compare our Latent Structured Ranking approach to the same approach *without* structure by only performing one iteration of Algorithm 1. We used $k = 20$ for eq. (4). We also compare to two standard methods of providing latent recommendations, Singular Value Decomposition (SVD) and Non-negative Matrix Factorization (NMF). For SVD the Matlab implementation is used, and for NMF the implementation at `http://www.csie.ntu.edu.tw/~cjlin/nmf/` is used.

Main Results We report results comparing NMF, SVD and our method, Latent Structured Ranking (LaSR) in Table 1. For every test set (query, item) pair we rank the document set $\mathcal{D}$ according to the query and record the position of the item in the ranked list. We then measure the recall at 5, 10, 30 and 50. (Note that because there is only one item in the pair, precision at k is equal to recall@k divided by k.) We then average the results over all pairs. For all methods the latent dimension $n = 50$. For LaSR, we give results for iterations $t = 0, \ldots, 2$, where $t = 0$ does not use the structure. LaSR with $t = 0$ already outperforms SVD and NMF. LaSR optimizes the top of the ranked list at training time (via the WARP loss), whereas SVD and NMF do not, which explains why it can perform better here on top-of-the-list metrics. We tested LaSR $t = 0$ using the AUC loss (10) instead of WARP (11) to check this hypothesis and we obtained a recall at 5, 10, 30 and 50 of 3.56%, 6.32%, 14.8% and 20.3% respectively which are slightly worse, than, but similar to SVD, thus confirming our hypothesis. For LaSR with $t = 1$ and $t = 2$ our method takes into account the structure of the ranked list at inference time, $t = 1$ outperforms iteration $t = 0$ that does not use the structure. Further slight gains are obtained with another iteration $(t = 2)$.

Changing the Embedding Dimension The results so far were all with latent dimension $n = 50$. It could be argued that LaSR with $t > 0$ has more capacity (more parameters) than competing methods, and those methods could have more capacity by increasing their dimension n. We therefore report results for various embedding sizes $(n = 10, 25, 50, 100)$ in Table 2. The results show that LaSR $(t = 0)$ consistently outperforms SVD and NMF for all the dimensions tried, but even with 200 dimensions, the methods that do not use structure (SVD, NMF and LaSR $t = 0$) are still outperformed by LaSR that does use structure $(t > 0)$ even with $n = 50$ dimensions.

Analysis of Predictions We give two example queries and the top ranked results for LaSR with and without use of structure ($(t = 0)$ and $(t = 1)$) in Table 3. The left-hand query is a popular artist "Bob Dylan". LaSR $(t = 0)$ performs worse than $(t = 1)$ with "Wilco" in positon 1 - the pair ("Bob Dylan","Wilco") only appears 10 times in the test set, whereas ("Bob Dylan", "The Beatles") appears 40 times, and LaSR $(t = 1)$ puts the latter in the top position. In general $t = 1$ improves the top ranked items over $t = 0$, removing or demoting weak choices, and promoting some better choices. For example, "Sonic Youth" which is a poor match is demoted out of the top 20. The second query is a less popular artist "Plaid" who make electronic music. Adding structure to LaSR again improves the results in this case by boosting relatively more popular bands like "Orbital" and "$\mu - ziq$", and relatively more related bands like "Four-Tet" and "Squarepusher", whilst demoting some lesser known bands.

Table 3: Music Recommendation results for our method LaSR with ($t = 1$) and without ($t = 0$) using the structure. We show top ranked results for a popular query, "Bob Dylan" (folk rock music) and a less popular query "Plaid" (electronic music). Total numbers of train and test pairs for given artist pairs are in square brackets, and totals for all artists shown are given in the last row. Artists where the two methods differ are labeled with an asterisk. Adding structure improves the results, e.g. unrelated bands like "Sonic Youth" are demoted in the "Bob Dylan" query, and relatively more popular bands like Orbital and $\mu-$ziq and more related bands like Four-Tet and Squarepusher are boosted for the "Plaid" query.

Table 4: Image Annotation Results comparing Wsabie with LaSR. The top 10 labels of each method is shown, the correct label (if predicted) is shown in bold. In many cases LaSR can be seen to improve on Wsabie by demoting bad predictions e.g. war paint, soccer ball, segway, denture, rottweiler, reindeer, tv-antenna, leopard frog (one example from each of the first 8 images). In the last 3 images neither method predicts the right label (armrest, night snake and heifer) but LaSR seems slightly better (e.g. more cat, snake and cow predictions).

Input Image	Wsabie	LaSR

Algorithm	r@1	r@5	r@10	MAP	MR
One-vs-Rest	2.83%	8.48%	13.2%	0.065	667
Rank SVM	5.35%	14.1%	19.3%	0.102	804
WSABIE	8.39%	19.6%	26.3%	0.144	626
LaSR ($t = 1$)	9.45%	22.1%	29.1%	0.161	523

4.2 IMAGE ANNOTATION TASK

ImageNet (Deng *et al.*, 2009) (`http://www.image-net.org/`) is a large scale image database organized according to WordNet (Fellbaum, 1998). WordNet is a graph of linguistic terms, where each concept node consists of a word or word phrase, and the concepts are organized within a hierarchical structure. ImageNet is a growing image dataset that attaches quality-controlled human-verified images to these concepts by collecting images from web search engines and then employing annotators to verify whether the images are good matches for those concepts, and discarding them if they are not. For many nouns, hundreds or even thousands of images are labeled. We can use this dataset to test image annotation algorithms. We split the data into train and test and try to learn to predict the label (annotation) given the image. For our experiments, we downloaded the "Spring 2010" release which consists of 9 million images and 15,589 possible concepts (this is a different set to (Weston *et al.*, 2011) but our baseline results largely agree). We split the data into 80% for training, 10% for validation and 10% for testing.

Following (Weston *et al.*, 2011) we employ a feature representation of the images which is an ensemble of several representations which is known to perform better than any single representation within the set (see e.g. (Makadia *et al.*, 2008)). We thus combined multiple feature representations which are the concatenation of various spatial (Grauman and Darrell, 2007) and multiscale color and texton histograms (Leung and Malik, 1999) for a total of about 5×10^5 dimensions. The descriptors are somewhat sparse, with about 50,000 non-zero weights per image. Some of the constituent histograms are normalized and some are not. We then perform Kernel PCA (Schoelkopf *et al.*, 1999) on the combined feature representation using the intersection kernel (Barla *et al.*, 2003) to produce a 1024 dimensional input vector for training.

We compare our proposed approach to several baselines: one-versus-rest large margin classifiers (One-vs-Rest) of the form $f_i(x) = w_i^\top x$ trained online to perform classification over the 15,589 classes, or the same models trained with a ranking loss instead, which we refer to as RANK SVM, as it is an online version of the pairwise multiclass (ranking) loss of (Weston and Watkins, 1999; Crammer and Singer, 2002). Finally, we compare to WSABIE a (unstructured) latent ranking method which has yielded state-of-the-art performance on this task. For all methods, hyperparameters are chosen via the validation set.

Results The overall results are given in Table 5. One-vs-Rest performs relatively poorly (2.83% recall@1), perhaps because there are so many classes (over 15,000) that the classifiers are not well calibrated to each other (as they are trained independently). The multiclass ranking loss of Rank SVM performs much better (5.35% recall@1) but is still outperformed by WSABIE (8.39% recall@1). WSABIE uses the WARP loss to optimize the top of the ranked list and its good performance can be explained by the suitability of this loss function for measure like recall@k. LaSR with $t = 0$ is essentially identical to WSABIE in this case and so we use that model as our "base learner" for iteration 0. LaSR ($t = 1$), that does use structure, outperforms WSABIE with a recall@1 of 9.45%.

Some example annotations are given in Table 4. LaSR seems to provide more consistent results than WSABIE on several queries (with less bad predictions in the top k) which improves the overall results, whilst maintaining the right level of diversity on others.

5 CONCLUSION

In this paper we introduced a method for learning a latent variable model that takes into account the structure of the predicted ranked list of items given the query. The approach is quite general and can potentially be applied to recommendation, annotation, classification and information retrieval tasks. These problems often involve millions of examples or more, both in terms of the number of training pairs and the number of items to be ranked. Hence, many otherwise straight-forward approaches to structured prediction approaches might not be applicable in these cases. The method we proposed is scalable to these tasks.

Future work could apply latent structured ranking to more applications, for example in text document retrieval. Moreover, it would be interesting to explore using other algorithms as the "base algorithm" which we add the structured predictions to. In this work, we used the approach of (Weston *et al.*, 2011) as our base algorithm, but it might also be possible to make structured ranking versions of algorithms like Non-negative matrix factorization, Latent Semantic Indexing or Singular Value Decomposition as well.

Non-Convex Rank Minimization via an Empirical Bayesian Approach

David Wipf
Visual Computing Group, Microsoft Research Asia
davidwipf@gmail.com

Abstract

In many applications that require matrix solutions of minimal rank, the underlying cost function is non-convex leading to an intractable, NP-hard optimization problem. Consequently, the convex nuclear norm is frequently used as a surrogate penalty term for matrix rank. The problem is that in many practical scenarios there is no longer any guarantee that we can correctly estimate generative low-rank matrices of interest, theoretical special cases notwithstanding. Consequently, this paper proposes an alternative empirical Bayesian procedure build upon a variational approximation that, unlike the nuclear norm, retains the same globally minimizing point estimate as the rank function under many useful constraints. However, locally minimizing solutions are largely smoothed away via marginalization, allowing the algorithm to succeed when standard convex relaxations completely fail. While the proposed methodology is generally applicable to a wide range of low-rank applications, we focus our attention on the robust principal component analysis problem (RPCA), which involves estimating an unknown low-rank matrix with unknown sparse corruptions. Theoretical and empirical evidence are presented to show that our method is potentially superior to related MAP-based approaches, for which the convex principle component pursuit (PCP) algorithm (Candès et al., 2011) can be viewed as a special case.

1 INTRODUCTION

Recently there has been a surge of interest in finding low-rank decompositions of matrix-valued data subject to some problem-specific constraints (Babacan et al., 2011; Candès & Recht, 2008; Candès et al., 2011; Chandrasekaran et al., 2011; Ding et al., 2011). While the methodology proposed herein is applicable to a wide range of low-rank applications, we will focus our attention on the robust principal component analysis problem (RPCA) described in Candès et al. (2011). We begin with the observation model

$$Y = X + S + E, \tag{1}$$

where $Y \in \mathbb{R}^{m\times n}$ is an observed data matrix, X is an unknown low-rank component, S is a sparse corruption matrix, and E is diffuse noise, with iid elements distributed as $N(0, \lambda)$. Without loss of generality, we will assume throughout that $n \geq m$. To estimate X and S given Y, one possibility is to solve

$$\min_{X,S} \frac{1}{\lambda}\|Y - X - S\|_{\mathcal{F}}^2 + n\text{Rank}\,[X] + \|S\|_0, \tag{2}$$

where $\|S\|_0$ denotes the matrix ℓ_0 norm of S, or a count of the nonzero elements in S. The reason for the factor of n is to ensure that the rank and sparsity terms are properly balanced, meaning that both terms range from 0 to nm, which reflects our balanced uncertainty regarding their relative contributions to Y. Unfortunately, solving (2) is problematic because the objective function is both discontinuous and non-convex. In general, the only way to guarantee that the global minimum is found is to conduct an exhaustive combinatorial search, which is intractable in all but the simplest cases.

The most common alternative, sometimes called principle component pursuit (PCP) (Candès et al., 2011), is to replace (2) with a convex surrogate such as

$$\min_{X,S} \frac{1}{\lambda}\|Y - X - S\|_{\mathcal{F}}^2 + \sqrt{n}\|X\|_* + \|S\|_1, \tag{3}$$

where $\|X\|_*$ denotes the nuclear norm of X (or the sum of its singular values). Note that the scale factor from (2) has been changed from n to $\sqrt{n}$; this is an

artifact of the relaxation mechanism balancing the nuclear and ℓ_1 norms.[1] A variety of recent theoretical results stipulate when solutions of (3), particularly in the limiting case where $\lambda \to 0$ (reflecting the assumption that $E = 0$), will produce reliable estimates of X and S (Candès et al., 2011; Chandrasekaran et al., 2011). However, in practice these results have marginal value since they are based upon strong, typically unverifiable assumptions on the support of S and the structure of X. In general, the allowable support of S may be prohibitively small and unstructured (possibly random); related assumptions are required for the rank and structure of X. Thus there potentially remains a sizable gap between what can be achieved by minimizing the 'ideal' cost function (2) and the convex relaxation (3).

In Section 2, as a motivational tool we discuss a simple non-convex scheme based on a variational majorization-minimization approach for locally minimizing (2). Then in Section 3 we reinterpret this method as *maximum a posteriori* (MAP) estimation and use this perspective to design an alternative empirical Bayesian algorithm that avoids the major shortcomings of MAP estimation. Section 4 investigates analytical properties of this empirical Bayesian alternative with respect to globally and locally minimizing solutions. Later in Section 5 we compare a state-of-the-art PCP algorithm with the proposed approach on simulated data as well as a photometric stereo problem.

2 NON-CONVEX MAJORIZATION-MINIMIZATION

One possible alternative to (3) is to replace (2) with a non-convex yet smooth approximation that can at least be locally minimized. In the sparse estimation literature, one common substitution for the ℓ_0 norm is the Gaussian entropy measure $\sum_i \log |s_i|$, which may also sometimes include a small regularizer to avoid taking the log of zero.[2] This can be justified (in part) by the fact that

$$\sum_i \log |s_i| \equiv \lim_{p \to 0} \frac{1}{p} \sum_i \left(|s_i|^p - 1 \right) \propto \|\boldsymbol{s}\|_0. \quad (4)$$

An analogous approximation suggests replacing the rank penalty with $\log |XX^T|$ as has been suggested for related rank minimization problems (Mohan & Fazel, 2010), since $\log |XX^T| = \sum_i \log \sigma_i$, where σ_i are the singular values of XX^T. This leads to the alternative cost function

$$\min_{X,S} \frac{1}{\lambda} \|Y - X - S\|_{\mathcal{F}}^2 + n \log |XX^T| + 2 \sum_{i,j} \log |s_{ij}|. \quad (5)$$

Optimization of (5) can be accomplished by a straightforward majorization-minimization approach based upon variational bounds on the non-convex penalty terms (Jordan et al., 1999). For example, because $\log |s|$ is a concave function of s^2, it can be expressed using duality theory (Boyd & Vandenberghe, 2004) as the minimum of a particular set of upper-bounding lines:

$$\log s^2 = \min_{\gamma \geq 0} \frac{s^2}{\gamma} + \log \gamma - 1. \quad (6)$$

Here γ is a non-negative variational parameter controlling the slope. Therefore, for any fixed γ we have a strict, convex upper-bound on the concave log function. Likewise, for the rank term we can use the analogous representation (Mohan & Fazel, 2010)

$$n \log \left| XX^T \right| = \min_{\Psi \succeq 0} \text{Trace} \left[XX^T \Psi^{-1} \right] + n \log |\Psi| + C, \quad (7)$$

where C is an irrelevant constant and Ψ is a positive semi-definite matrix of variational parameters.[3] Combining these bounds we obtain an equivalent optimization problem

$$\min_{X,S,\Gamma \geq 0, \Psi \succeq 0} \frac{1}{\lambda} \|Y - X - S\|_{\mathcal{F}}^2 + \sum_{ij} \left(\frac{s_{ij}^2}{\gamma_{ij}} + \log \gamma_{ij} \right) + \text{Trace} \left[XX^T \Psi^{-1} \right] + n \log |\Psi|, \quad (8)$$

where Γ is a matrix of non-negative elements composed of the variational parameters corresponding to each s_{ij}. With Γ and Ψ fixed, (8) is quadratic in X and S and can be minimized in closed form via

$$\begin{aligned} \boldsymbol{x}_j &\rightarrow \Psi \left(\Psi + \bar{\Gamma}_j \right)^{-1} \boldsymbol{y}_j, \\ \boldsymbol{s}_j &\rightarrow \bar{\Gamma}_j \left(\Psi + \bar{\Gamma}_j \right)^{-1} \boldsymbol{y}_j, \ \ \forall j \end{aligned} \quad (9)$$

where $\boldsymbol{y}_j$, $\boldsymbol{x}_j$, and $\boldsymbol{s}_j$ represent the j-th columns of Y, X, and S respectively and $\bar{\Gamma}_j$ is a diagonal matrix formed from the j-th column of Γ. Likewise, with X and S fixed, Γ and Ψ can also be obtained in closed form using the updates

$$\begin{aligned} \Psi &\rightarrow \frac{1}{n} XX^T \\ \gamma_{ij} &\rightarrow s_{ij}^2, \ \ \forall i, j. \end{aligned} \quad (10)$$

While local minimization of (5) is clear cut, finding global solutions can still be highly problematic just as

[1] Actually, different scaling factors can be adopted to reflect different assumptions about the relative contributions of low-rank and sparse terms. But we assume throughout that no such knowledge is available.

[2] Algorithms and analysis follow through much the same regardless.

[3] If X is full rank, then Ψ must be positive definite.

before. Whenever any coefficient of S goes to zero, or whenever the rank of X is reduced, we are necessarily at a local minimum with respect to this quantity such that we can never increase the rank or a zero-valued coefficient magnitude in search of the global optimum. (This point will be examined in further detail in Section 4.) Thus the algorithm may quickly converge to one of a combinatorial number of local solutions.

3 VARIATIONAL EMPIRICAL BAYESIAN ALGORITHM

From a Bayesian perspective we can formulate (5) as a MAP estimation problem based on the distributions

$$\begin{aligned} p(Y|X,S) &\propto \exp\left[-\frac{1}{2\lambda}\|Y-X-S\|_{\mathcal{F}}^2\right] \\ p(X) &\propto \frac{1}{|XX^T|^{n/2}} \\ p(S) &\propto \prod_{i,j}\frac{1}{|s_{ij}|}. \end{aligned} \tag{11}$$

It is then transparent that solving

$$\max_{X,S} p(X,S|Y) \equiv \max_{X,S} p(Y|X,S)p(X)p(S) \tag{12}$$

is equivalent to solving (5) after an inconsequential $-2\log(\cdot)$ transformation. But as implied above, this strategy is problematic because the effective posterior is characterized by numerous spurious peaks rendering MAP estimation intractable. A more desirable approach would ignore most of these peaks and focus only on regions with significant posterior mass, regions that hopefully also include the posterior mode. One way to accomplish this involves using the bounds from (6) and (7) to construct a simple approximate posterior that reflects the mass of the original $p(X,S|Y)$ sans spurious peaks. We approach this task as follows.

From (6) and (7)) we can infer that

$$p(S) \propto \max_{\Gamma\succeq 0}\hat{p}(S;\Gamma) \tag{13}$$

$$p(X) \propto \max_{\Psi\succeq 0}\hat{p}(X;\Psi) \tag{14}$$

where

$$\begin{aligned} \hat{p}(S;\Gamma) &\triangleq \exp\left[-\frac{1}{2}\sum_{ij}\left(\frac{s_{ij}^2}{\gamma_{ij}}+\log\gamma_{ij}\right)\right] \\ \hat{p}(X;\Psi) &\triangleq \exp\left[-\frac{1}{2}\text{Trace}\left[XX^T\Psi^{-1}\right]-\frac{n}{2}\log|\Psi|\right], \end{aligned} \tag{15}$$

which can be viewed as unnormalized approximate priors offering strict lower bounds on $p(S)$ and $p(X)$. We also then obtain a tractable posterior approximation given by

$$\hat{p}(X,S|Y;\Gamma,\Psi) \triangleq \frac{p(Y|S,X)\hat{p}(S;\Gamma)\hat{p}(X;\Psi)}{\int p(Y|S,X)\hat{p}(S;\Gamma)\hat{p}(X;\Psi)dSdX}. \tag{16}$$

Here $\hat{p}(X,S|Y;\Gamma,\Psi)$ is a Gaussian distribution with closed-form first and second moments, e.g., the means of S and X are actually given by the righthand sides of (9). The question remains how to choose Γ and Ψ. With the goal of reflecting the mass of the true distribution $p(Y,X,S)$, we adopt the approach from Wipf et al. (2011) and attempt to solve

$$\min_{\Psi,\Gamma}\int |p(Y,X,S)-p(Y|S,X)\hat{p}(S;\Gamma)\hat{p}(X;\Psi)|\,dXdS \tag{17}$$

$$= \min_{\Psi,\Gamma}\int p(Y|S,X)\,|p(X)p(S)-\hat{p}(S;\Gamma)\hat{p}(X;\Psi)|\,dXdS. \tag{18}$$

The basic idea here is that we only care that the approximate priors match the true ones in regions where the likelihood function $p(Y|X,S)$ is significant; in other regions the mismatch is more or less irrelevant. Moreover, by virtue of the strict lower variational bound, (18) reduces to

$$\max_{\Psi,\Gamma}\int p(Y|S,X)\hat{p}(S;\Gamma)\hat{p}(X;\Psi)dXdS \equiv \min_{\Psi,\Gamma}\mathcal{L}(\Psi,\Gamma) \tag{19}$$

where

$$\mathcal{L}(\Psi,\Gamma) \triangleq \sum_{j=1}^{n}\left[\boldsymbol{y}_j^T\Sigma_{y_j}^{-1}\boldsymbol{y}_j+\log\left|\Sigma_{y_j}\right|\right] \tag{20}$$

with

$$\Sigma_{y_j} \triangleq \Psi+\bar{\Gamma}_j+\lambda I. \tag{21}$$

This Σ_{y_j} can be viewed as the covariance of the j-th column of Y given fixed values of Ψ and Γ. To recap then, we need now minimize $\mathcal{L}(\Psi,\Gamma)$ with respect to Ψ and Γ, and then plug these estimates into (16) giving the approximate posterior. The mean of this distribution (see below) can then be used as a point estimate for X and S. This process is sometimes referred to as *empirical Bayes* because we are using the data to guide our search for an optimal prior distribution (Berger, 1985; Tipping, 2001).

3.1 UPDATE RULE DERIVATIONS

It turns out that minimization of (20) can be accomplished concurrently with computation of the posterior mean leading to simple, efficient update rules. While (20) is non-convex, we can use a majorization-minimization approach analogous to that used for MAP estimation. For this purpose, we utilize simplifying upper bounds on both terms of the cost function as

has been done for related sparse estimation problems Wipf & Nagarajan (2010).

First, the data-dependent term is concave with respect to Ψ^{-1} and Γ^{-1} and hence can be expressed as a minimization over (Ψ^{-1}, Γ^{-1})-dependent hyperplanes. With some linear algebra, it can be shown that

$$\boldsymbol{y}_j^T \Sigma_{y_j}^{-1} \boldsymbol{y}_j = \min_{\boldsymbol{x}_j, \boldsymbol{s}_j} \frac{1}{\lambda} \|\boldsymbol{y}_j - \boldsymbol{x}_j - \boldsymbol{s}_j\|_{\mathcal{F}}^2 + \boldsymbol{x}_j^T \Psi^{-1} \boldsymbol{x}_j + \sum_i \frac{s_{ij}^2}{\gamma_{ij}} \tag{22}$$

for all j. With a slight abuse of notation, we adopt $X = [\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n]$ and $S = [\boldsymbol{s}_1, \ldots, \boldsymbol{s}_n]$ as the variational parameters in (22) because they end up playing the same role as the unknown low-rank and sparse coefficients and provide a direct link to the MAP estimates. Additionally, the $\boldsymbol{x}_j$ and $\boldsymbol{s}_j$ which minimize (22) turn out to be equivalent to the posterior means of (16) given Ψ and Γ and will serve as our point estimates.

Secondly, for the log-det term, we first use the determinant identity

$$\log \left| \Psi + \bar{\Gamma}_j + \lambda I \right| = \log |\Psi| + \log \left| \bar{\Gamma}_j \right| + \log |A_j| + C, \tag{23}$$

where

$$A_j \triangleq \lambda^{-1} \begin{bmatrix} I & I \\ I & I \end{bmatrix} + \begin{bmatrix} \Psi^{-1} & \mathbf{0} \\ \mathbf{0} & \bar{\Gamma}_j^{-1} \end{bmatrix} \tag{24}$$

and C is an irrelevant constant. The term $\log |A_j|$ is jointly concave in both Ψ^{-1} and $\bar{\Gamma}_j^{-1}$ and thus can be bounded in a similar fashion as (22), although a closed-form solution is no longer available. (Other decompositions lead to different bounds and different candidate update rules.) Here we use

$$\log |A_j| = \min_{U_j, V_j \succeq 0} \text{Trace} \left[U_j^T \Psi^{-1} + V_j^T \bar{\Gamma}_j^{-1} \right] - h^*(U_j, V_j) \tag{25}$$

where $h^*(U_j, V_j)$ is the concave conjugate function of $\log |A_j|$ with respect to Ψ^{-1} and $\bar{\Gamma}_i^{-1}$. Note that while $h^*(U_j, V_j)$ has no closed-form solution, the minimizing values of U_j and V_j can be computed in closed-form via

$$U_j = \frac{\partial \log |A_j|}{\partial \Psi^{-1}}, \qquad V_j = \frac{\partial \log |A_j|}{\partial \bar{\Gamma}_j^{-1}}. \tag{26}$$

When we drop the minimizations over the variational parameters $\boldsymbol{x}_j$, $\boldsymbol{s}_j$, U_j, and V_j for all j, we arrive at a convenient family of upper bounds on the cost function $\mathcal{L}(\Psi, \Gamma)$. Given some estimate of Ψ and Γ, we can evaluate all variational parameters in closed form (see below). Likewise, given all of the variational parameters we can solve directly for Ψ and Γ because now $\mathcal{L}(\Psi, \Gamma)$ has been conveniently decoupled and we need only compute

$$\min_{\Psi \succeq 0} \sum_j \left(\boldsymbol{x}_j^T \Psi^{-1} \boldsymbol{x}_j + \text{Trace} \left[U_j^T \Psi^{-1} \right] \right) + n \log |\Psi| \tag{27}$$

and

$$\min_{\gamma_{ij} \geq 0} \frac{s_{ij}^2}{\gamma_{ij}} + \frac{[V_j]_{ii}}{\gamma_{ij}} + \log \gamma_{ij}, \quad \forall i, j. \tag{28}$$

We summarize the overall procedure next.

3.2 ALGORITHM SUMMARY

1. Compute $\kappa \triangleq \frac{1}{nm} \|Y\|_{\mathcal{F}}^2$
2. Initialize $\Psi^{(0)} \rightarrow \kappa I$, and $\bar{\Gamma}_j^{(0)} \rightarrow \kappa I$ for all j.
3. For the $(k+1)$-th iteration, compute the optimal $\boldsymbol{x}_j$ and $\boldsymbol{s}_j$ via

$$\boldsymbol{x}_j^{(k+1)} \rightarrow \Psi^{(k)} \left(\Psi^{(k)} + \bar{\Gamma}_j^{(k)} + \lambda I \right)^{-1} \boldsymbol{y}_j$$

$$\boldsymbol{s}_j^{(k+1)} \rightarrow \bar{\Gamma}^{(k)} \left(\Psi^{(k)} + \bar{\Gamma}_j^{(k)} + \lambda I \right)^{-1} \boldsymbol{y}_j \tag{29}$$

4. Likewise, compute the optimal U_j and V_j via

$$U_j^{(k+1)} \rightarrow \Psi^{(k)} - \Psi^{(k)} \left(\Psi^{(k)} + \bar{\Gamma}_j^{(k)} + \lambda I \right)^{-1} \Psi^{(k)}$$

$$V_j^{(k+1)} \rightarrow \bar{\Gamma}_j^{(k)} - \bar{\Gamma}_j^{(k)} \left(\Psi^{(k)} + \bar{\Gamma}_j^{(k)} + \lambda I \right)^{-1} \bar{\Gamma}_j^{(k)} \tag{30}$$

5. Update Ψ and Γ using the new variational parameters via

$$\Psi^{(k+1)} \rightarrow \frac{1}{n} \sum_j \left[\boldsymbol{x}_j^{(k+1)} \left(\boldsymbol{x}_j^{(k+1)} \right)^T + U_j^{(k+1)} \right]$$

$$\gamma_{ij}^{(k+1)} \rightarrow \left(s_{ij}^{(k+1)} \right)^2 + \left[V_j^{(k+1)} \right]_{ii}, \forall i, j \tag{31}$$

6. Repeat steps 3 through 5 until convergence. (Recall that $\bar{\Gamma}_j$ is a diagonal matrix formed from the j-th column of Γ.) This process is guaranteed to reduce or leave unchanged the cost function at each iteration.

Note that if we set $U_j^{(k+1)}, V_j^{(k+1)} \rightarrow 0$ for all j, then the algorithm above is guaranteed to (at least locally) minimize the MAP cost function from (5). Additionally, for matrix completion problems (Candès & Recht, 2008), where the support of the sparse errors is known a priori, we need only set each γ_{ij} corresponding to a corrupted entry to ∞. This limiting case can easily be handled with efficient reduced rank updates.

One positive aspect of this algorithm is that it is largely parameter free. We must of course choose some stopping criteria, such as a maximum number of iterations or a convergence tolerance. (For all experiments in Section 5 we simply set the maximum number of iterations at 100.) We must also choose some value for λ, which balances allowable contributions from a diffuse error matrix E, although frequently methods have some version of this parameter, including the PCP algorithm. For all of our experiments we simply choose $\lambda = 10^{-6}$ since we did not include an E component consistent with the original RPCA formulation from Candès et al. (2011).

From a complexity standpoint, each iteration of the above algorithm can be computed in $O(m^3 n)$, where $n \geq m$, so it is linear in the larger dimension of Y and cubic in the smaller dimension. For many computer vision applications (see Section 5 for one example), images are vectorized and then stacked, so Y may be $m =$number-of-images by $n =$ number-of-pixels. This is relatively efficient, since the number of images may be on the order of 100 or fewer (see Wu et al. (2010)). However, when Y is a large square matrix, the updates are more expensive to compute. In the future we plan to investigate various approximation techniques to handle this scenario.

As a final implementation-related point, when given access to a priori knowledge regarding the rank of X and/or sparsity of S, it is possible to bias the algorithm's initialization (from Step 1 above) and improve the estimation accuracy. However, we emphasize that for all of the experiments reported in Section 5 we assumed no such knowledge.

3.3 Alternative Bayesian Methods

Two other Bayesian-inspired methods have recently been proposed for solving the RPCA problem. The first from Ding et al. (2011) is a hierarchical model with conjugate prior densities on model parameters at each level such that inference can be performed using a Gibbs sampler. This method is useful in that the λ parameter balancing the contribution from diffuse errors E is estimated directly from the data. Moreover, the authors report significant improvement over PCP on example problems. A potential downside of this model is that theoretical analysis is difficult because of the underlying complexity. Additionally, a large number of MCMC steps are required to obtain good estimates leading to a significant computational cost even when Y is small. It also uses an estimate of Rank$[X]$ which can effect the convergence rate of the Gibbs sampler.

A second method from Babacan et al. (2011) similarly employs a hierarchial Bayesian model but uses a factorized mean-field variational approximation for inference (Attias, 2000). Note that this is an entirely different type of variational method than ours, relying on a posterior distribution that factorizes over X and S, meaning $p(X, S|Y) \approx q(X|Y)q(S|Y)$, where $q(X|Y)$ and $q(S|Y)$ are approximating distributions learned by minimizing a free energy-based cost function.[4] Unlike our model, this factorization implicitly decouples X and S in a manner akin to MAP estimation, and may potentially produce more locally minimizing solutions (see analysis below). Moreover, while this approach also has a mechanism for estimating λ, there is no comprehensive evidence given that it can robustly expand upon the range of corruptions and rank that can already be handled by PCP.

To summarize both of these methods then, we would argue that while they offer a compelling avenue for computing λ automatically, the underlying cost functions are substantially more complex than PCP or our method rendering more formal analyses somewhat difficult. As we shall see in Sections 4 and 5, the empirical Bayesian cost function we propose is analytically principled and advantageous, and empirically outperforms PCP by a wide margin.

4 ANALYSIS

In this section we will examine global and local minima properties of the proposed method and highlight potential advantages over MAP, of which PCP can also be interpreted as a special case. For analysis purposes and comparisons with MAP estimation, it is helpful to convert the empirical Bayes cost function (20) into (X, S)-space by first optimizing over U_j, V_j, Ψ and Γ, leaving only the unknown coefficient matrices X and S. Using this process, it is easily shown that the estimates of X and S obtained by globally (or locally) minimizing (20) will also globally (or locally) minimize

$$\min_{X,S} \|Y - X - S\|_{\mathcal{F}}^2 + \lambda g_{EB}(X, S; \lambda), \qquad (32)$$

where the penalty function is given by

$$g_{EB}(X, S; \lambda) \triangleq \qquad (33)$$

$$\min_{\Gamma \geq 0, \Psi \succeq 0} \sum_{i=1}^{n} \boldsymbol{x}_j \Psi^{-1} \boldsymbol{x}_j + \boldsymbol{s}_j^T \bar{\Gamma}_j^{-1} \boldsymbol{s}_j + \log \left| \Psi + \bar{\Gamma}_j + \lambda I \right|.$$

Note that the implicit MAP penalty from (5) is nearly identical:

$$g_{map}(X, S) \triangleq \qquad (34)$$

[4] Additional factorizations are also included in the model.

$$\min_{\Gamma\succeq 0,\Psi\succeq 0}\sum_{i=1}^{n}\boldsymbol{x}_j\Psi^{-1}\boldsymbol{x}_j+\boldsymbol{s}_j^T\bar{\Gamma}_j^{-1}\boldsymbol{s}_j+\log|\Psi|+\log\left|\bar{\Gamma}_j\right|.$$

The primary distinction is that in the MAP case the variational parameters separate whereas in empirical Bayesian case they do not. (Note that, as discussed below, we can apply a small regularizer analogous to λ to the log terms in the MAP case as well.) This implies that $g_{map}(X,S)$ can be expressed as some $g_{map}(X)+g_{map}(S)$ whereas $g_{EB}(X,S;\lambda)$ cannot. A related form of non-separability has been shown to be advantageous in the context of sparse estimation from overcomplete dictionaries (Wipf et al., 2011).

We now examine how this crucial distinction can be beneficial in producing maximally sparse, low-rank solutions that optimize (2). We first demonstrate how (32) mimics the global minima profile of (2). Later we show how the smoothing mechanism of the empirical Bayesian marginalization can mitigate spurious locally minimizing solutions.

The original RPCA development from Candès et al. (2011) assumes that $E=0$, which is somewhat easier to analyze. We consider this scenario first.

Theorem 1. Assume that there exists at least one solution to $Y=X+S$ such that $\text{Rank}[X]+\max_j\|\boldsymbol{s}_j\|_0<m$. Then in the limit as $\lambda\to 0$, any solution that globally minimizes (32) will globally minimize (2).

Proofs will be deferred to a subsequent journal publication. Note that the requirement $\text{Rank}[X]+\max_j\|\boldsymbol{s}_j\|_0<m$ is a relatively benign assumption, because without it the matrices X and S are formally unidentifiable even if we are able to globally solve (2). For $E>0$, we may still draw direct comparisons between (32) and (2) when we deviate slightly from the Bayesian development and treat $g_{EB}(X,S;\lambda)$ as an abstract, stand-alone penalty function. In this context we may consider $g_{EB}(X,S;\alpha)$, with $\alpha\neq\lambda$ as a more general candidate for estimating RPCA solutions.

Corollary 1. Assume that $X_{(\lambda)}$ and $S_{(\lambda)}$ are a unique, optimal solution to (2) and that $\text{Rank}\left[X_{(\lambda)}\right]+\max_j\|\left[\boldsymbol{s}_{(\lambda)}\right]_j\|_0<m$. Then there will always exist some λ' and α' such that the global minimum of

$$\min_{X,S}\|Y-X-S\|_{\mathcal{F}}^2+\lambda' g_{EB}(X,S;\alpha'), \tag{35}$$

denoted $X_{(\lambda',\alpha')}$ and $S_{(\lambda',\alpha')}$, satisfies the conditions $\left\|X_{(\lambda',\alpha')}-X_{(\lambda)}\right\|<\epsilon$ and $\left\|S_{(\lambda',\alpha')}-S_{(\lambda)}\right\|<\epsilon$, where ϵ can be arbitrarily small.

Of course MAP estimation can satisfy a similar property as Theorem 1 and Corollary 1 after a minor modification. Specifically, we may define

$$g_{map}(X,S;\alpha)\triangleq \tag{36}$$

$$\min_{\Gamma\succeq 0,\Psi\succeq 0}\sum_{j=1}^{n}\boldsymbol{x}_j\Psi^{-1}\boldsymbol{x}_j+\boldsymbol{s}_j^T\bar{\Gamma}_j^{-1}\boldsymbol{s}_j+\log|\Psi+\alpha|+\log\left|\bar{\Gamma}_j+\alpha\right|$$

and then achieve a comparable result to the above using $g_{map}(X,S;\alpha')$. The advantage of empirical Bayes then is not with respect to global minima, but rather with respect to local minima. The separable, additive low-rank plus sparsity penalties that emerge from MAP estimation will always suffer from the following limitation:

Theorem 2. Let $S_{ij}^{(a)}$ denote any matrix S with $s_{ij}=a$. Now consider any optimization problem of the form

$$\min_{X,S}g_1(X)+g_2(S),\quad\text{s.t. } Y=X+S, \tag{37}$$

where g_1 is an arbitrary function of the singular values of X and g_2 is an arbitrary function of the magnitudes of the elements in S. Then to ensure that a global minimum of (37) is a global minimum of (2) for all possible Y, we require that

$$\lim_{\epsilon\to 0}\frac{g_2\left[S_{ij}^{(\epsilon)}\right]-g_2\left[S_{ij}^{(0)}\right]}{\epsilon}=\infty \tag{38}$$

for all i and j and S. An analogous condition holds for the function g_1.

This result implies that whenever an element of S approaches zero, it will require increasing the associated penalty $g_2(S)$ against an arbitrarily large gradient to escape in cases where this coefficient was incorrectly pruned. Likewise, if the rank of X is prematurely reduced in the wrong subspace, there may be no chance to ever recover since this could require increasing $g_1(X)$ against an arbitrarily large gradient factor. In general, Theorem 2 stipulates that if we would like to retain the same global minimum as (2) using a MAP estimation-based cost function, then we will necessarily enter an inescapable basin of attraction whenever *either* $\text{Rank}[X]<m$ *or* $\|\boldsymbol{s}_j\|_0<m$ for some j. This is indeed a heavy price to pay.

Crucially, because of the coupling of low-rank and sparsity regularizers, the penalty function $g_{EB}(X,S;\lambda)$ does not have this limitation. In fact, we only encounter insurmountable gradient barriers when $\text{Rank}[X]+\|\boldsymbol{s}_j\|_0<m$ for some j, in which case the covariance Σ_{y_j} from (21) becomes degenerate (with λ small), a much weaker condition. To summarize (emphasize) this point then, MAP can be viewed as heavily dependent on degeneracy of the matrices Ψ and Γ

in isolation, whereas empirical Bayes is only sensitive to degeneracy of their summation.

This distinction can also be observed in how the effective penalties on X and S, as imbedded in $g_{EB}(X, S; \lambda)$, vary given fixed values of Γ or Ψ respectively. For example, when Ψ is close to being full rank and orthogonal (such as when the algorithm is initialized), then the implicit penalty on S is minimally non-convex (only slightly concave). In fact, as Ψ becomes large and orthogonal, the penalty converges to a scaled version of the ℓ_1 norm. In contrast, as Ψ becomes smaller and low-rank, the penalty approaches a scaled version of the ℓ_0 norm, implying that maximally sparse corruptions will be favored. Thus, we do not aggressively favor maximally sparse S until the rank has already been reduced and we are in the basin of attraction of a good solution. Of course no heuristic annealing strategy is necessary, the transition is handled automatically by the algorithm.

Additionally, whenever Ψ is fixed, the resulting cost function formally decouples into n separate, canonical sparse estimation problems on each $\boldsymbol{s}_j$ in isolation. With $\lambda = 0$, it not difficult to show that each of these subproblems is equivalent to solving

$$\min_{\boldsymbol{s}_j} \|\boldsymbol{y}_j - \Phi \boldsymbol{s}_j\|_2^2 + g_{EB}(\boldsymbol{s}_j) \tag{39}$$

where

$$g_{EB}(\boldsymbol{s}_j) \triangleq \min_{\boldsymbol{\gamma}_j \geq 0} \sum_{j=1}^{n} \boldsymbol{s}_j^T \bar{\Gamma}_j^{-1} \boldsymbol{s}_j + \log \left| \Phi \bar{\Gamma}_j \Phi^T + I \right| \tag{40}$$

is a concave sparsity penalty on $\boldsymbol{s}_j$ and Φ is any matrix such that $\Phi \Psi \Phi^T = I$.[5] When Φ is nearly orthogonal, this problem has no local minima and a global solution that approximates the hard thresholding of the ℓ_0 norm; however, direct minimization of the ℓ_0 norm will have 2^n local minima (Wipf et al., 2011). In contrast, when Φ is poorly conditioned (with approximately low-rank structure, it has been argued in Wipf et al. (2011) that penalties such as $g_{EB}(\boldsymbol{s}_j)$ are particularly appropriate for avoiding local minima.

Something similar occurs when Γ is now fixed and we evaluate the penalty on X. This penalty approaches something like a scaled version of the nuclear norm (less concave) when elements of Γ are set to a large constant and it behaves more like the rank function when Γ is small. At initialization, when Γ is all ones, we are relatively free to move between solutions of various rank without incurring a heavy penalty. Later as Γ becomes sparse, solutions satisfying $\text{Rank}[X] + \|\boldsymbol{s}_j\|_0 < m$ for some j become heavily favored.

[5] We have assumed here that Ψ is full rank.

As a final point, the proposed empirical Bayesian approach can be implemented with alternative variational bounds and possibly optimized with something akin to simultaneous reweighted nuclear and ℓ_1 norm minimization, a perspective that naturally suggests further performance analyses such as those applied to sparse estimation in Wipf & Nagarajan (2010).

5 EMPIRICAL RESULTS

This section provides some empirical evidence for the efficacy of our RPCA method. First, we present comparisons with PCP recovering random subspaces from corrupted measurements. Later we discuss a photometric stereo application. In all cases we used the the augmented lagrangian method (ALM) from Lin et al. (2010) to implement PCP. This algorithm has efficient, guaranteed convergence and in previous empirical tests ALM has outperformed a variety of other methods in computing minimum nuclear norm plus ℓ_1 norm solutions.

5.1 RANDOM SUBSPACE SIMULATIONS

Here we demonstrate that the empirical Bayesian algorithm from Section 3.2, which we will refer to as EB, can recovery unknown subspaces from corrupted measurements in a much broader range of operating conditions compared to the convex PCP. In particular, for a given value of $\text{Rank}[X]$, our method can handle a substantially larger fraction of corruptions as measured by $\rho = \|S\|_0/(nm)$. Likewise, for a given value of ρ, we can accurately estimate an X with much higher rank. Consistent with Candès et al. (2011), we consider the case where $E = 0$, such that all the error is modeled by S. This allows us to use the stable, convergent ALM code available online.[6]

The first experiment proceeds as follows. We generate a low-rank matrix X with dimensions reflective of many computer vision problems: *number-of-images* $\times$ *number-of-pixels*. Here we choose $m = 20$ and $n = 10^4$, the later dimension equivalent to a 100×100 pixel image. For each trial, we compute an $m \times n$ matrix with iid $\mathcal{N}(0, 1)$ entries. We then compute the SVD of this matrix and set all but the r largest singular values to zero to produce a low-rank X. S is generated with nonzero entries selected uniformly with probability $\rho = 0.2$. Nonzero values are sampled from an iid Uniform[-10,10] distribution. We then compute $Y = X + S$ and try to estimate X and S using the EB and PCP algorithms. Estimation results averaged over multiple trials as r is varied from 1 to 10 are depicted in Figure 1. We plot normalized mean-squared error

[6] `http://perception.csl.uiuc.edu/matrix-rank/`

(MSE) as computed via $\left\langle \|X - \hat{X}\|_{\mathcal{F}}^2 / \|X\|_{\mathcal{F}}^2 \right\rangle$ as well as the average angular error between the estimated and true subspaces. In both cases the average is across 10 trials.

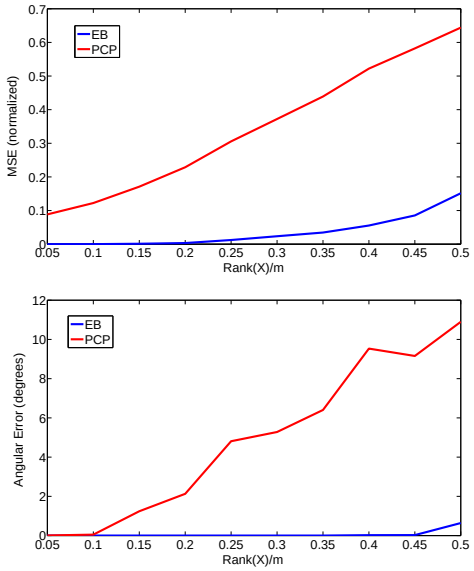

Figure 1: Estimation results where the corruption probability ρ is 0.2 and Rank$[X]/m$ is varied from 0.05 to 0.50, meaning up to 50% of full rank. *Top*: Normalized mean-squared error (MSE). *Bottom*: Average angle (in degrees) between the estimated and true subspaces.

From Figure 1 we observe that EB can accurately estimate X for substantially higher values of the rank. Interestingly, we are also still able to estimate the correct subspace spanned by columns of X perfectly even when the MSE of estimating X starts to rise (compare Figure 1(*Top*) with Figure 1(*Bottom*)). Basically, this occurs because, even if we have estimated the subspace perfectly, reducing the MSE to zero implicitly requires solving a challenging sparse estimation problem for every observation column $\boldsymbol{y}_j$. For each column, this problem requires learning $d_j \triangleq \text{Rank}[X] + \|\boldsymbol{s}_j\|_0$ nonzero entries given only $m = 20$ observations. For our experiment, we can have $d_j > 14$ with high probability for some columns when the rank is high, and thus we may expect some errors in $\hat{S}$ (not shown). However, the encouraging evidence here is that EB is able to keep these corrupting errors at a minimum and estimate the subspace accurately long after PCP has failed. Moreover, if an accurate estimate of X is needed, as opposed to just the correct spanning subspace, then a postprocessing error correction step can potentially be applied to each column individually to improve performance.

The second experiment is similar to the first only now we hold Rank$[X]$ fixed at 4, meaning Rank$[X]/m = 0.2$, and vary the fraction of corrupted entries in S from 0.1 to 0.8. Figure 2 shows that EB is again able to drastically expand the range whereby successful estimates are obtained. Notably it is able to recover the correct subspace even with 70% corrupted entries.

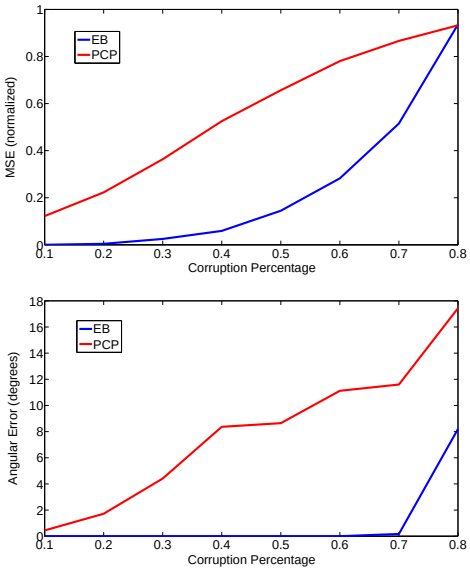

Figure 2: Estimation results with Rank$[X]/m = 0.2$ and ρ varied from 0.1 to 0.8. *Top*: Normalized mean-squared error (MSE). *Bottom*: Average angle (in degrees) between the estimated and true subspaces.

As a final comparison, we tested PCP and EB on a 400×400 observation matrix Y generated as above with a Rank$[X]/m = 0.1$ and $\rho = 0.5$. The estimation results are reported in Table 1. PCP performs poorly since the normalized MSE is above one, meaning we would have been better off simply choosing $\hat{X} = 0$ in this regard. Additionally, the angular error is very near 90 degrees, consistent with the error from a randomly chosen subspace in high dimensions. In contrast, EB provides a reasonably good estimate considering the difficulty of the problem.

Table 1: Estimation results with $m = n = 400$, Rank$[X]/m = 0.1$ and $\rho = 0.5$.

	PCP	**EB**
MSE (norm.)	1.235	0.066
Angular Error	88.50	5.01

5.2 PHOTOMETRIC STEREO

Photometric stereo is a method for estimating surface normals of an object or scene by capturing multiple images from a fixed viewpoint under different lighting conditions (Woodham, 1980). At a basic level, this methodology assumes a Lambertian object surface, point light sources at infinity, an orthographic camera view, and a linear sensor response function. Under these conditions, it has been shown that the intensities of a vectorized stack of images Y can be expressed as

$$Y = L^T N \Upsilon, \tag{41}$$

where L is a $3 \times m$ matrix of m normalized lighting directions, N is a $3 \times n$ matrix of surface normals at n pixel locations, and Υ is a diagonal matrix of diffuse albedo values (Woodham, 1980). Thus, if we were to capture at least 3 images with known, linearly independent lighting directions we can solve for N using least squares. Of course in reality many common non-Lambertian effects can disrupt this process, such as specularities, cast or attached shadows, and image noise, etc. In many cases, these effects can be modeled as an additive sparse error term S applied to (41).

As proposed in Wu et al. (2010), we can estimate the subspace containing N by solving (2) assuming $X = L^T N \Upsilon$ and $E = 0$. The resulting $\hat{X}$, combined with possibly other *a priori* information regarding the lighting directions L can lead to an estimate of N. Wu et al. (2010) propose using a modified version of PCP for this task, where a shadow mask is included to simplify the sparse error correction problem. However, in practical situations it may not always be possible to accurately locate all shadow regions in this manner so it is desirable to treat them as unknown sparse corruptions.

For this experiment we consider the synthetic Caesar image from the INRIA 3D Meshes Research Database[7] with known surface normals. Multiple 2D images with different known lighting conditions can easily be generated using the Cook-Torrance reflectance model (Cook & Torrance, 1981). These images are then stacked to produce Y. Because shadows are extremely difficult to handle in general, as a preprocessing step we remove rows of Y corresponding to pixel locations with more than 10% shadow coverage. Specular corruptions were left unfiltered. We tested our algorithm as the number of images, drawn randomly from a batch of 40 total, was varied from 10 to 40. Results averaged across 5 trials are presented in Figure 3. The error metrics have been redefined to accommodate the photometric stereo problem. We now define the normalized MSE as $\left\langle \|X - \hat{X}\|_{\mathcal{F}}^2 / \|X - Y\|_{\mathcal{F}}^2 \right\rangle$, which measures how much improvement we obtain beyond just using the observation matrix Y directly. Similarly we normalized the angular error by dividing by the angle between Y and the true X for each trial.

[7] http://www-roc.inria.fr/gamma/gamma/download/download.php

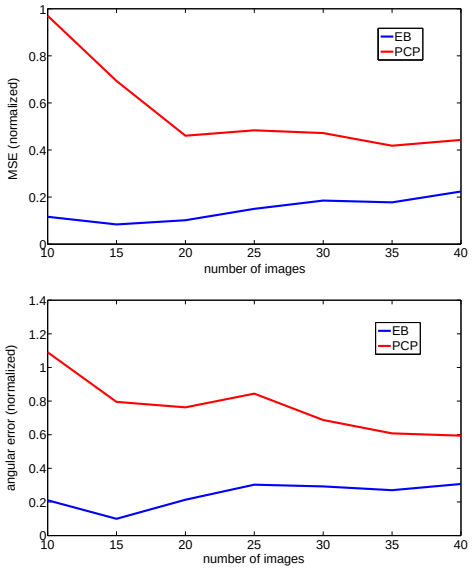

Figure 3: Estimation results using photometric stereo data as the number of images m is varied from 10 to 40. *Top*: Normalized MSE (see altered definition in the main text). *Bottom*: Normalized angle between the estimated and the true subspaces.

From Figure 3 it is clear that EB outperforms PCP in both MSE and angular error, especially when there are fewer images present. It is not entirely clear however why the MSE and angular error are relatively flat for EB as opposed to dropping lower as m increases. Of course these are errors relative to using Y directly to predict X, which could play a role in this counterintuitive effect.

6 CONCLUSIONS

In this paper we have analyzed a new empirical Bayesian approach for matrix rank minimization in the context of RPCA, where the goal is to decompose a given data matrix into low-rank and sparse components. Using a variational approximation and subsequent marginalization, we ultimately arrive at a novel regularization term that couples low-rank and sparsity penalties in such a way that locally minimizing solutions are effectively smoothed while the global optimum matches that of the ideal RPCA cost function.

Abstract

Recently two search algorithms, A* and breadth-first branch and bound (BFBnB), were developed based on a simple admissible heuristic for learning Bayesian network structures that optimize a scoring function. The heuristic represents a relaxation of the learning problem such that each variable chooses optimal parents independently. As a result, the heuristic may contain many directed cycles and result in a loose bound. This paper introduces an improved admissible heuristic that tries to avoid directed cycles within small groups of variables. A sparse representation is also introduced to store only the unique optimal parent choices. Empirical results show that the new techniques significantly improved the efficiency and scalability of A* and BFBnB on most of datasets tested in this paper.

1 Introduction

Bayesian networks are often used to represent relationships among variables in a domain. When the network structure is unknown, we can learn the structure directly from a given dataset. Several exact algorithms for learning optimal Bayesian networks have been developed based on dynamic programming (Koivisto and Sood 2004; Ott, Imoto, and Miyano 2004; Silander and Myllymaki 2006; Singh and Moore 2005; Parviainen and Koivisto 2009; Malone, Yuan, and Hansen 2011), branch and bound (de Campos and Ji 2011), and linear and integer programming (Cussens 2011; Jaakkola et al. 2010).

Recently, Yuan *et al.* (2011) proposed a shortest-path finding formulation for the Bayesian network structure learning problem, in which the shortest path found in an implicit search graph called order graph corresponds to an optimal network structure. An A* search algorithm was developed to solve the search problem. Malone *et al.* (2011) adopted the same formulation, but realized that the search can be performed in a layered, breadth-first order. External memory and delayed duplicate detection are used to ensure completion regardless of the amount of available RAM. This algorithm, named breadth-first branch and bound (BFBnB), was shown to have similar runtimes as A* but scale to many more variables.

A simple admissible heuristic was used in the A* and BFBnB algorithms (Yuan, Malone, and Wu 2011; Malone et al. 2011) to guide the search. Its main idea is to relax the acyclicity constraint of Bayesian networks such that each variable can freely choose optimal parents from all the other variables. The heuristic provides an optimistic estimation on how good a solution can be and, hence, is admissible. However, the simple relaxation behind the heuristic may introduce many directed cycles and result in a loose bound.

This paper introduces a much improved admissible heuristic named *k-cycle conflict heuristic* based on the additive pattern database technique (Felner, Korf, and Hanan 2004). The main idea is to avoid directed cycles within small groups of variables, called patterns, and compute heuristic values by concatenating patterns. Also, a set of exponential-size parent graphs were created by the A* and BFBnB algorithms to retrieve optimal parent choices during the search. We introduce a sparse representation for storing only unique optimal parent sets which can improve both time and space efficiency of the search. Empirical results show that the new techniques significantly improved the efficiency and scalability of A* and BFBnB on most of the benchmark datasets we tested.

The remainder of this paper is structured as follows. Section 2 provides an overview of Bayesian network structure learning and the shortest-path finding formulation of the problem. Section 3 introduces the improved heuristic. Section 4 introduces the sparse representation of optimal parent choices and discusses how to adapt A* and BFBnB algorithms to use the new techniques. Section 5 reports the empirical results on a set of benchmark datasets. Finally, Section 6 concludes the paper with some remarks.

2 Background

This section reviews the basics of score-based methods for learning Bayesian network structures.

2.1 Learning Bayesian network structures

A Bayesian network is a directed acyclic graph (DAG) in which the vertices correspond to a set of random variables $\mathbf{V} = \{X_1, ..., X_n\}$, and the arcs and lack of them represent dependence and conditional independence relations between the variables. The relations are further quantified using a set of conditional probability distributions. We consider the problem of learning a network structure from a dataset $\mathbf{D} = \{D_1, ..., D_N\}$, where D_i is an instantiation of all the variables in $\mathbf{V}$. A scoring function can be used to measure the goodness of fit of a network structure to $\mathbf{D}$. For example, the minimum description length (MDL) scoring function (Rissanen 1978) uses one term to reward structures with low entropy and another to penalize complex structures. The task is to find an optimal structure that minimizes the MDL score. MDL is decomposable (Heckerman 1998), i.e., the score for a structure is simply the sum of the scores for each variable. All algorithms we describe here assume the scoring function is decomposable. The remainder of the paper assumes the use of MDL score, but our method is equally applicable to other decomposable scoring functions, such as AIC, BIC or BDe.

2.2 The shortest-path finding formulation

Yuan *et al.* (2011) formulated the above structure learning problem as a shortest-path finding problem. Figure 1 shows the *implicit* search graph for four variables. The top-most node with the empty set is the *start* search node, and the bottom-most node with the complete set is the *goal* node. An arc from $\mathbf{U}$ to $\mathbf{U} \cup \{X\}$ in the graph represents generating a successor node by adding a new variable $\{X\}$ to the existing variables $\mathbf{U}$; the cost of the arc is equal to the cost of selecting the optimal parent set for X out of $\mathbf{U}$, and is computed by considering all subsets of $\mathbf{U}$, i.e.,

$$BestScore(X, \mathbf{U}) = \min_{PA_X \subseteq \mathbf{U}} score(X|PA_X).$$

With the search graph thus specified, each path from the start node to the goal is an ordering of the variables in the order of their appearance. That is why the search graph is also called an *order graph*. Because each variable only selects optimal parents from the preceding variables, putting together all the optimal parent choices of a particular ordering generates a valid Bayesian network that is optimal for that specific ordering. The shortest path among all possible paths corresponds to a global optimal Bayesian network.

During the search of the order graph, we need to compute the cost for each arc being visited. We use another data

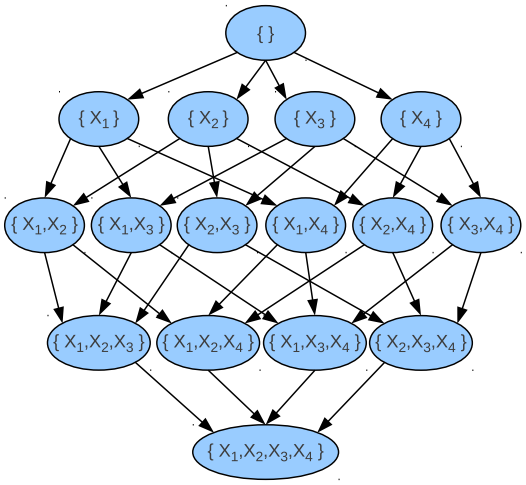

Figure 1: An order graph of four variables

structure called *parent graph* for retrieving the costs. The parent graph for variable X consists of all subsets of $\mathbf{V} \setminus \{X\}$. Figure 2 shows the parent graph for X_1. Figure 2(a) shows a parent graph containing the raw scores for using each subset as the parent set of X_1, while Figure 2(b) shows the optimal scores after propagating the best scores from top to bottom in the graph. For the arc from $\mathbf{U}$ to $\mathbf{U} \cup \{X\}$, we find its score by looking up the parent graph of variable X to find the node that contains $\mathbf{U}$.

Various search methods as well as dynamic programming have been applied to solve the shortest-path finding problem (Malone, Yuan, and Hansen 2011; Malone et al. 2011; Yuan, Malone, and Wu 2011). In (Yuan, Malone, and Wu 2011), an A* search algorithm was proposed based on the following admissible heuristic function.

Definition 1. *Let* $\mathbf{U}$ *be a node in the order graph, its heuristic value is*

$$h(\mathbf{U}) = \sum_{X \in \mathbf{V} \setminus \mathbf{U}} BestScore(X, \mathbf{V} \setminus \{X\}). \quad (1)$$

The A* algorithm is shown to be much more efficient than existing dynamic programming algorithms. However, A* requires all the search information, including parent and order graphs, to be stored in RAM during the search, which makes the algorithm easily run out of memory for large datasets. Malone et al. (2011) developed a breadth-first branch and bound (BFBnB) algorithm to search the order graph in a layered, breadth-first order. By carefully coordinating the parent and order graphs, most of the search information can be stored on disk and are only processed incrementally after being read back to RAM when necessary. The BFBnB algorithm was shown to be as efficient as the A* algorithm but was able to scale to much larger datasets. Theoretically, the scalability of the BFBnB algorithm is only limited by the amount of disk space available.

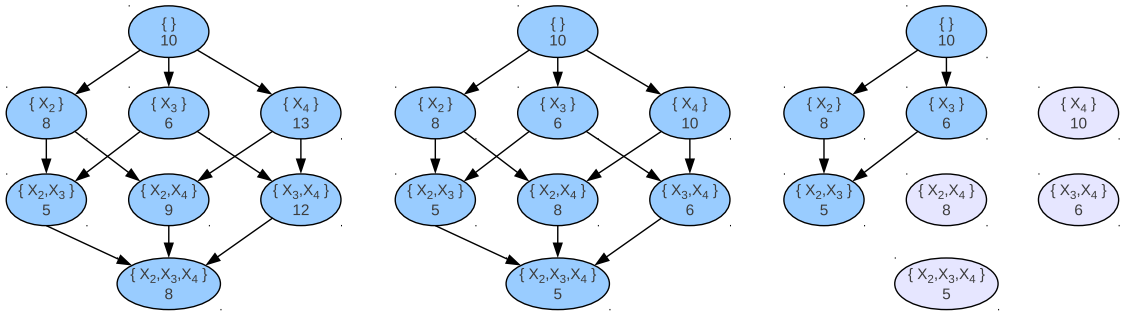

Figure 2: A sample parent graph for variable X_1. (a) The raw scores for all the parent sets. The first line in each node gives the parent set, and the second line gives the score of using all of that set as the parents for X_1. (b) The optimal scores for each candidate parent set. The second line in each node gives the optimal score using some subset of the variables in the first line as parents for X_1. (c) The unique optimal parent sets and their scores. The pruned parent sets are shown in gray. A parent set is pruned if any of its predecessors has an equal or better score.

3 An Improved Admissible Heuristic

The heuristic function defined in Equation 1 is based on a classic approach to designing admissible heuristics. Pearl (1984) pointed out that the optimal solution to a relaxed problem can be used as an admissible bound for the original problem. For structure learning, the original problem is to learn a Bayesian network that is an *acyclic* directed graph (DAG). Equation 1 relaxes the problem by completely ignoring the acyclicity constraint, so all *directed graphs* are allowed. This paper aims to improve the heuristic by enforcing partial acyclicity. We will first motivate our approach using a small example. We then describe the specifics of the new heuristic.

3.1 A motivating example

According to Equation 1, the heuristic estimate of the start node in the order graph allows each variable to choose optimal parents from all the other variables. Suppose the optimal parents for X_1, X_2, X_3, X_4 are $\{X_2, X_3, X_4\}$, $\{X_1, X_4\}$, $\{X_2\}$, $\{X_2, X_3\}$ respectively. These parent choices are shown as the directed graph in Figure 3. Since the acyclicity constraint is ignored, directed cycles are introduced, e.g., between X_1 and X_2. However, we know the final solution cannot have cycles; three scenarios are possible between X_1 and X_2: (1) X_2 is a parent of X_1 (so X_1 cannot be a parent of X_2), (2) X_1 is a parent of X_2, or (3) neither of the above is true. The third case is dominated by the other two cases because of the following theorem.

Theorem 1. *Let* $\mathbf{U}$ *and* $\mathbf{V}$ *be two candidate parent sets for* X*, and* $\mathbf{U} \subset \mathbf{V}$*, then* $BestScore(X, \mathbf{V}) \leq BestScore(X, \mathbf{U})$.

This theorem has appeared in many earlier papers, e.g. (Teyssier and Koller 2005; de Campos and Ji 2010), and simply means that an equal or better score can be obtained if a larger set of parent candidates is available to choose from. The third case cannot provide a better value than the other two cases because one of the variables must have fewer parents to choose from. Between the first two cases it is unclear which one is better, so we take the minimum of them. Consider the first case first: We have to delete the arc $X_1 \rightarrow X_2$ to rule out X_1 as a parent of X_2. Then we have to let X_2 to rechoose optimal parents from $\{X_3, X_4\}$, that is, we must check all the parent sets not including X_1; the deletion of the arc alone cannot produce the new bound. The total bound of X_1 and X_2 is computed by summing together the original bound of X_1 and the new bound of X_2. We call this total bound b_1. The second case is handled similarly; we call that total bound b_2. Because the joint heuristic for X_1 and X_2 must be optimistic, we compute it as the minimum of b_1 and b_2. Effectively we have considered all possible ways to break the cycle and obtained a new but improved heuristic value. The new heuristic is clearly admissible, as we still allow cycles among other variables.

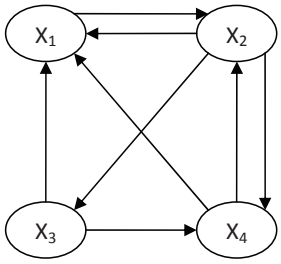

Figure 3: A directed graph representing the heuristic estimate for the start search node.

Often, the simple heuristic introduces multiple cycles. The graph in Figure 3 also has a cycle between X_2 and X_4. This cycle shares X_2 with the earlier cycle; we say they

overlap. Overlapping cycles cannot be broken independently. For example, suppose we break the cycle between X_1 and X_2 by setting the parents of X_2 to be $\{X_3\}$. This effectively breaks the cycle between X_2 and X_4 as well, but introduces a new cycle between X_2 and X_3. As described in more detail shortly, we divide the variables into non-overlapping groups and focus only on avoiding cycles within each group. So if X_2 and X_3 are in different groups, they are allowed to form a cycle.

3.2 The k-cycle conflict heuristic

The idea above can be generalized to compute the joint heuristics for all groups of variables with a size up to k by avoiding cycles within each group. We call the resulting technique the *k-cycle conflict heuristic*. Note that Equation 1 is a special case of this new heuristic, as it simply contains heuristics for the individual variables (k=1). The new heuristic is an application of the *additive pattern database* technique (Felner, Korf, and Hanan 2004). We first have to explain what *pattern database* (Culberson and Schaeffer 1998) is. Pattern database is an approach to computing an admissible heuristic for a problem by solving a relaxed problem. As an example, the 15 sliding tile puzzle can be relaxed to only contain the tiles 1-8 by removing the other tiles. Because of the relaxation, multiple states of the original problem are mapped to one state in the *abstract* state space of the relaxed problem. Each abstract state is called a *pattern*, and the exact costs for solving all the abstract states are stored in a pattern database; each cost can be retrieved as an admissible heuristic for any consistent state in the original state space. Furthermore, we can relax the problem in different ways and obtain multiple pattern databases. If the solutions to a set of relaxed problems are independent, the problems are said to have no interactions between them. Again consider 15-puzzle, we can also relax it to only contain the tiles 9-15. This relaxation can be solved independently from the previous one, as they do not share puzzle movements. The costs of their pattern databases can be *added* together to obtain an admissible heuristic, hence the name additive pattern databases.

In the learning problem, a pattern is defined as a set of variables, and its cost is the joint heuristic of the variables involved. The costs of two patterns sharing no variables can be added together to obtain an admissible heuristic because of the decomposability of the scoring function.

We do not need to explicitly break cycles to compute the k-cycle conflict heuristic. The following theorem offers a straightforward approach to computing the heuristic.

Theorem 2. *The cost of the pattern* $\mathbf{U}$ *is equal to the shortest distance from the node* $\mathbf{V} \setminus \mathbf{U}$ *to the goal node in the order graph.*

The theorem can be proven by noting that avoiding cycles between the variables in $\mathbf{U}$ is equivalent to finding an optimal ordering of the variables with the best joint score, and the different paths from $\mathbf{V} \setminus \mathbf{U}$ to the goal correspond to the different orderings of the variables, among which the shortest path thus corresponds to the optimal ordering. Again consider the example in Figure 3. The joint heuristic for the pattern $\{X_1, X_2\}$ is equal to the shortest distance from the node $\{X_3, X_4\}$ to the goal in Figure 1. Therefore, the new heuristic can be computed by finding the shortest distances from all the nodes in the last k layers of the order graph to the goal. We will describe a backward search algorithm for computing the heuristic in Section 4.2.

Furthermore, the *difference* between the cost of the pattern $\mathbf{U}$ and the simple heuristic of $\mathbf{V} \setminus \mathbf{U}$ indicates the amount of improvement brought by avoiding cycles within the pattern. The differential cost can thus be used as a quality measure for ordering the patterns and for choosing patterns that are more likely to result in a tighter heuristic. Also, we can discard any pattern that does not introduce additional improvement over any of its subset patterns. The pruning can significantly reduce the size of a pattern database and improve the efficiency of accessing the database.

3.3 Computing the heuristic for a search node

Once the k-cycle conflict heuristic is computed, we can use it to calculate the heuristic value for any node during the search. For a node $\mathbf{U}$, we need to partition $\mathbf{V} \setminus \mathbf{U}$ into a set of non-overlapping patterns, and sum their costs together as the heuristic value. There are potentially many ways to do the partition; ideally we want to find the one with the highest total cost, which represents the most accurate heuristic value. The problem of finding the optimal partition can be formulated as *maximum weighted matching* problem (Felner, Korf, and Hanan 2004). For $k = 2$, we can define a graph in which each vertex represents a variable, and each edge between two variables representing the pattern containing the same variables with an edge weight equal to the cost of the pattern. The goal is to select a set of edges from the graph so that no two edges share a vertex and the total weight of the edges is maximized. The matching problem can be solved in $O(n^3)$ time (Papadimitriou and Steiglitz 1982), where n is the number of vertices.

For $k > 2$, we have to add *hyperedges* to the matching graph for connecting up to k vertices to represent larger patterns. The goal becomes to select a set of edges and hyperedges to maximize the total weight. However, the three-dimensional or higher-order maximum weighted matching problem is NP-hard (Garey and Johnson 1979). That means we have to solve an NP-hard problem when calculating the heuristic value for a search node.

To alleviate the potential inefficiency, we elect to use a greedy method to compute the heuristic value. The method sequentially chooses patterns based on their quality. Consider the node $\mathbf{U}$; the unsearched variables are $\mathbf{V} \setminus \mathbf{U}$. We

first choose the pattern with the highest differential cost from all patterns that are subsets of $\mathbf{V} \setminus \mathbf{U}$. We repeat this process by choosing the next pattern for the remaining unsearched variables until all the variables are covered. The total cost of the chosen patterns is used as the heuristic value for the node $\mathbf{U}$.

3.4 Dynamic and static pattern databases

The version of the k-cycle conflict heuristic introduced above is an example of the *dynamically partitioned pattern database* (Felner, Korf, and Hanan 2004), as the patterns are dynamically selected during the search algorithm. We refer to it as *dynamic pattern database* for short. A potential drawback of dynamic pattern databases is that, even using the greedy method, computing a heuristic values is still more expensive than the simple heuristic in Equation 1. Consequently, the running time can be longer even though the tighter heuristic results in more pruning and fewer expanded nodes.

We can resort to another version of the k-cycle conflict heuristic based on the *statically partitioned pattern database* technique (Felner, Korf, and Hanan 2004). The idea is to statically divide all the variables into several groups, and create a separate pattern database for each group. Consider a problem with variables $\{X_1, ..., X_8\}$. We simply divide the variables into two equal-sized groups, $\{X_1, ..., X_4\}$ and $\{X_5, ..., X_8\}$. For each group, say $\{X_1, ..., X_4\}$, we create a pattern database that contains the costs of *all* subsets of $\{X_1, ..., X_4\}$ and store them as a hash table. We refer to this heuristic as the *static pattern database* for short.

It is much simpler to use static pattern databases to compute a heuristic value. Consider the node $\{X_1, X_4, X_8\}$; the unsearched variables are $\{X_2, X_3, X_5, X_6, X_7\}$. We divide these variables into two patterns $\{X_2, X_3\}$ and $\{X_5, X_6, X_7\}$ according to the static grouping. We then simply look up the costs of these two patterns in the pattern databases and sum them together as as the heuristic value for the node. Better yet, every search step only processes one variable and affects one pattern, so computing the heuristic value can be done incrementally.

4 The Search Algorithms

Both computing the k-cycle conflict heuristic and solving the shortest-path finding problem requires us to search the order graph. The searches further require the parent graphs to be calculated in advance or during the search. In this section, we first introduce a sparse representation of the parent graphs. We then discuss how to search the order graph backward to compute the k-cycle conflict heuristic, and forward to solve the shortest path-finding problem by adapting the A* and BFBnB algorithms.

$parents_{X_1}$	$\{X_2, X_3\}$	$\{X_3\}$	$\{X_2\}$	$\{\}$
$scores_{X_1}$	5	6	8	10

Table 1: Sorted scores and parent sets for X_1 after pruning parent sets which are not possibly optimal.

$parents_{X_1}$	$\{X_2, X_3\}$	$\{X_3\}$	$\{X_2\}$	$\{\}$
X_2	1	0	1	0
X_3	1	1	0	0
X_4	0	0	0	0

Table 2: The $parents_X(X_i)$ bit vectors for X_1. A "1" in line X_i indicates that the corresponding parent set includes variable X_i, while a "0" indicates otherwise. Note that, after pruning, none of the optimal parent sets include X_4.

4.1 Sparse representation of parent graphs

The parent graph for each variable X exhaustively enumerates the optimal scores for all subsets of $\mathbf{V} \setminus \{X\}$. Naively, this approach requires storing $n2^{n-1}$ scores and parent sets. Due to Theorem 1, however, the number of *unique* optimal parent sets is often far smaller. For example, Figure 2(b) shows that each score may be shared by several nodes in a parent graph. The parent graph representation will allocate space for this repetitive information, resulting in waste of space.

Instead of storing the complete parent graphs, we propose a sparse representation which *sorts* all the *unique* parent scores for each variable X in a list, and also maintain a parallel list that stores the associated optimal parent sets. We call these sorted lists $scores_X$ and $parents_X$. Table 1 shows the sorted lists for the parent graph in Figure 2(b). In essence, this allows us to store and efficiently process only scores in Figure 2(c). We do not have to create the full parent graphs before realizing some scores can be pruned (post-pruning). For example, we can use the following theorem (Tian 2000) to prune some scores before even computing them (pre-pruning).

Theorem 3. *In an optimal Bayesian network based on the MDL scoring function, each variable has at most* $\log(\frac{2N}{\log N})$ *parents, where* N *is the number of data points.*

Because of the pruning of duplicate scores, the sparse representation requires much less memory than storing all the possible parent sets and scores. As long as $\|scores(X)\| < C(n-1, \frac{n}{2})$, it also requires less memory than the BFBnB algorithm for X. In practice, $\|scores_X\|$ is almost always smaller than $C(n-1, \frac{n}{2})$ by several orders of magnitude. So this approach offers (usually substantial) memory savings compared to previous best approaches. In addition, the sparse representation is also much more efficient to create because of the pre-pruning.

The key operation in parent graphs is querying the opti-

$parents_{X_1}$	$\{X_2, X_3\}$	$\{X_3\}$	$\{X_2\}$	$\{\}$
$valid_{X_1}$	1	1	1	1
$\sim X_3$	0	0	1	1
$valid^{new}_{X_1}$	0	0	1	1

Table 3: The result of performing the bitwise operation to exclude all parent sets which include X_3. A "1" in the $valid_{X_1}$ bit vector means that the parent set does not include X_3 and can be used for selecting the optimal parents. The first set bit indicates the best possible score and parent set.

$parents_{X_1}$	$\{X_2, X_3\}$	$\{X_3\}$	$\{X_2\}$	$\{\}$
$valid_{X_1}$	0	0	1	1
$\sim X_2$	0	1	0	1
$valid^{new}_{X_1}$	0	0	0	1

Table 4: The result of performing the bitwise operation to exclude all parent sets which include either X_3 or X_2. A "1" in the $valid^{new}_{X_1}$ bit vector means that the parent set includes neither X_2 nor X_3. The initial $valid_{X_1}$ bit vector had already excluded X_3, so finding $valid^{new}_{X_1}$ only required excluding X_2.

mal parents for variable X out of a candidate set $\mathbf{U}$. With the sparse representation, we can simply scan the list of X starting from the beginning. As soon as we find the first parent set that is a subset of $\mathbf{U}$, we find the optimal parent set and its score. However, scanning the lists can be inefficient if not done properly. Since we have to do the scanning for each arc, the inefficiency will have a large impact on the whole search algorithm. We therefore propose the following incremental approach. Initially, we allow each variable X to use all the other variables as candidate parents, so the first element in the sorted score list must be optimal. For example, the first score in Table 1 must be $BestScore(X_1, \{X_2, X_3, X_4\})$. Suppose we remove X_2 from consideration as a candidate parent; we scan the list by continuing from where we last stopped and find a parent set which does not include X_2, which must be $BestScore(X_1, \{X_3, X_4\})$ ($\{X_3\}$ in this example). If we further remove X_3, we continue scanning the list until finding a parent set which includes neither X_2 nor X_3 to find $BestScore(X_1, \{X_4\})$ ($\{\}$ it is).

To further improve the efficiency, we propose the following efficient scanning technique. For each variable X, we first initialize an incumbent bit vector of length $\|scores_X\|$ called $valid_X$ to be all 1s. This indicates that all the parent scores in $scores_X$ are usable; the first score in the list will be the optimal score. Then, we create $n-1$ bit vectors also of length $\|scores_X\|$, one for each variable in $\mathbf{V} \setminus \{X\}$. The bit vector for variable Y is denoted as $parents_X(Y)$ and contains 1s for all the parent sets that contain Y and 0s for others. Table 2 shows the bit vectors for Table 1. Then, to exclude variable Y as a candidate parent, we perform the bit operation $valid^{new}_X \leftarrow valid_X \& \sim parents_X(Y)$. The $valid^{new}_X$ bit vector now contains 1s for all the parent sets that are subsets of $\mathbf{V} \setminus \{Y\}$. The *first set bit* corresponds to $BestScore(X, \mathbf{V} \setminus \{Y\})$. Table 3 shows an example of excluding X_3 from the set of possible parents for X_1, and the first set bit in the new bit vector corresponds to $BestScore(X_1, \mathbf{V} \setminus \{X_3\})$. If we further exclude X_2, the bit vector resulting from the last step becomes the incumbent bit vector, and a similar bit operation is applied: $valid^{new}_X \leftarrow valid_X \& \sim parents_{X_1}(X_2)$. The first set bit of the result corresponds to $BestScore(X_1, \mathbf{V} \setminus \{X_2, X_3\})$. Table 4 demonstrates this operation. Also, it is important to note that we exclude one variable at a time. For example, if, after excluding X_3, we wanted to exclude X_4 rather than X_2, we could take $valid^{new}_X \leftarrow valid_X \& \sim parents_X(X_4)$.

4.2 Creating the k-cycle conflict heuristic

We have two versions of the k-cycle conflict heuristic: dynamic and static pattern databases. To compute the dynamic pattern database, we use the *breadth-first search* to do a backward search for k layers in the order graph. The search starts from the goal node and expands the order graph backward layer by layer. A reverse arc from $\mathbf{U} \cup \{X\}$ to $\mathbf{U}$ has a cost equal to $BestScore(X, \mathbf{U})$. The reverse g cost to $\mathbf{U}$ is updated whenever a new path with a lower cost is found. Breadth-first search ensures that node $\mathbf{U}$ will obtain its optimal reverse g cost once the whole layer is processed. Its corresponding pattern $\mathbf{V} \setminus \mathbf{U}$ is pruned if the differential score is equal to that of any subset pattern. Otherwise, it is added to the pattern database together with both its pattern cost and differential cost.

The static pattern databases are calculated differently. For a static grouping $\mathbf{V} = \bigcup_i \mathbf{V_i}$, we need to compute a pattern database for each group $\mathbf{V_i}$, which is basically a full order graph containing all subsets of $\mathbf{V_i}$. We will also use a backward breadth first search to create the graph layer by layer starting from the node $\mathbf{V_i}$. However, the cost for any reverse arc from $\mathbf{U} \cup \{X\}$ to $\mathbf{U}$ in this order graph will be $BestScore(X, (\bigcup_{j \neq i} \mathbf{V_j}) \cup \mathbf{U})$.

4.3 Solving the shortest-path finding problem

After the pattern database heuristics are computed, we solve the shortest-path finding problem using a forward search in the order graph. We adapt both the A* (Yuan, Malone, and Wu 2011) and BFBnB (Malone, Yuan, and Hansen 2011) algorithms to utilize the new heuristic and the sparse parent graphs.

Originally, the A* algorithm first creates the full parent graphs and then expands the order graph in a best-first order starting from the top. For the improved version, we first create the unique score lists and the k-cycle conflict heuristic. During the search, the only difference appears in gener-

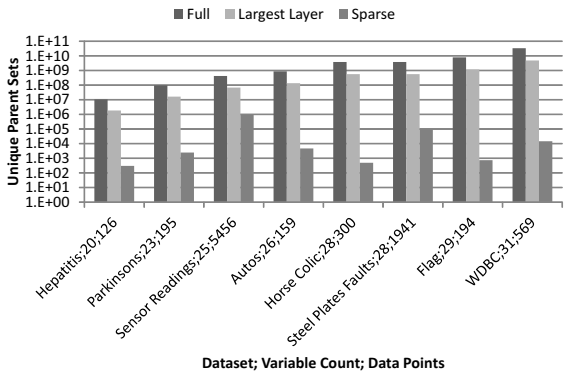

Figure 4: The number of parent sets stored in the full parent graphs ("Full"), the largest layer of the parent graphs ("Largest Layer"), and the sparse representation ("Sparse").

ating the successors of a node. For each successor $\mathbf{U} \cup \{X\}$ of node $\mathbf{U}$, we calculate its heuristic value according to the methods described in Sections 3.3 and 3.4. Looking up the cost $BestScore(X, \mathbf{U})$ for the arc $\mathbf{U} \rightarrow \mathbf{U} \cup \{X\}$ is achieved by using the sparse parent graphs.

The BFBnB algorithm is affected in a similar way. Originally it works by coordinating the expansion of the order graph and parent graphs layer by layer. In the improved version, the unique score lists and the heuristic are calculated first. The search part of the algorithm only needs to expand the order graph, during which generating successors works similarly as in the improved A* algorithm.

5 Empirical Results

We tested our new techniques on the A* and BFBnB algorithms by comparing to their original versions[1]. The experiments were performed on a PC with 3.07 GHz Intel i7 processor, 16 GB of RAM, 500 GB of hard disk space, and running Ubuntu 10.10. We used benchmark datasets from the UCI machine learning repository (Frank and Asuncion 2010) to test the algorithms. For all the datasets, records with missing values were removed. All variables were discretized into two states around their means.

5.1 Memory savings of sparse parent graphs

We first evaluated the memory savings made possible by using the sparse representation in comparison to the full parent graphs. In particular, we compared the maximum number of scores that have to be stored for all variables at once by each algorithm. A typical dynamic programming algorithm stores scores for all possible parent sets of all variables. BFBnB and memory-efficient dynamic programming (Malone, Yuan, and Hansen 2011) (assuming implementation optimizations) store all possible parent sets only in one layer of the parent graphs for all variables, so the size of the largest layer of all parent graphs is an indication of its space requirement. The sparse representation only stores the unique optimal parent sets for all variables at all layers.

Figure 4 shows the memory savings by the sparse representation. The number of unique scores stored by the sparse representation is typically several orders of magnitude smaller than the number of parent sets stored by the full representation. These results agree quite well with previously published results (de Campos and Ji 2010).

Due to Theorem 3, increasing the number of data records increases the maximum number of candidate parents. Therefore, the number of unique candidate parent sets increases as the number of records increases; however, many of the new parent sets are pruned. The number of variables also affects the number of candidate parent sets. Consequently, the number of unique scores increases as a function of the number of records and the number of variables. The amount of pruning is data-dependent, though, and is not easily predictable. In practice, we find the number of records to affect the number of unique scores more than the number of variables. Other scoring functions, such as BDe, exhibit similar behavior.

The results also suggest that the savings increase as the number of variables increases in the datasets. This implies that, while more variables necessarily increases the number of possible parent sets exponentially, the number of unique optimal parent sets increases much more slowly. Intuitively, even though we add more parents, only a small number of them are "good" parents for any particular variable.

5.2 Heuristics vs sparse representation

Both the new heuristic and the sparse representation can be used to improve the A* and BFBnB algorithms. It is beneficial to have an understanding on how much improvement each technique contributes. Also, the new heuristic has two versions: static and dynamic pattern databases; each of them can be parameterized in different ways. We applied various parameterizations of the new techniques to the algorithms on the datasets Autos and Flag. For the dynamic pattern database, we varied k from 2 to 4. For the static pattern databases, we tried groupings 9-9-8 and 13-13 for the Autos dataset and groupings 10-10-9 and 15-14 for the Flag dataset. The results are shown in Table 5.

The sparse representation helped both A* and BFBnB algorithms to achieve much better efficiency and scalability. A* ran out of memory on both of the datasets when using full parent graphs, but was able to solve both Autos (with

[1] A software package named *URLearning* ("you are learning") implementing the A* and BFBnB algorithms can be downloaded at `http://url.cs.qc.cuny.edu/software.html`.

Pattern Database			BFBnB, Full		BFBnB, Sparse		A*, Sparse	
Dataset	Type	Size	Time (s)	Nodes	Time (s)	Nodes	Time (s)	Nodes
Autos	Simple	26	2,690	62,721,601	461	62,721,601	674	35,329,016
Autos	Dynamic, k=2	41	2,722	52,719,774	449	52,719,793	148	6,286,142
Autos	Dynamic, k=3	116	2,720	49,271,793	468	49,271,809	76	2,829,877

Autos	Static, 13-13	16,384	2,747	48,814,324	211	48,814,334	125	4,762,276
Flag	Simple	29	OT	OT	OT	OT	OM	OM
Flag	Dynamic, k=2	45	OT	OT	1,222	132,431,610	824	19,359,296
Flag	Dynamic, k=3	149	OT	OT	788	79,332,390	207	5,355,085
Flag	Dynamic, k=4	858	OT	OT	1,624	84,054,443	350	7,377,817
Flag	Static, 10-10-9	2,560	OT	OT	2,600	249,638,318	OM	OM
Flag	Static, 15-14	49,152	OT	OT	720	88,305,173	136	4,412,232

Table 5: A comparison of the enhanced A* and BFBnB algorithms with various combinations of parent graph representations (full vs. sparse) and the heuristics (simple heuristic, dynamic pattern database with $k = 2$, 3, and 4, and static pattern databases with groupings 9-9-8 and 13-13 for the Autos dataset and groupings 10-10-9 and 15-14 for the Flag dataset). "Size" means the number of patterns stored; "Sparse" means the sparse parent graphs; "Full" means the full parent graphs; "Time" means the running time (in seconds), and "Nodes" means the number of nodes expanded by the algorithms; "OT" means the algorithm fail to finish within a 1-hour time limit set for this experiment; and "OM" means the algorithm used up all the RAM (16G). "A*, Full" is not included because it ran out of memory in all cases.

any heuristic) and Flag (with some of the best heuristics) when using sparse parent graphs. Similarly, BFBnB ran out of time on the Flag dataset within the one hour time limit when using full parent graphs, but was able to solve the dataset using the sparse representation (except when using the simple heuristic); on Autos, the sparse representation helped improve the time efficiency of BFBnB by up to an order of magnitude. One last note here is the numbers of expanded nodes by BFBnB are slightly different when using the two representations; it is only because of the randomness in the local search method used to compute the initial upper bound solution for BFBnB.

Both the static and dynamic pattern databases helped A* and BFBnB algorithms to improve efficiency and scalability. A* with both the simple heuristic and the static pattern database with grouping 10-10-9 ran out of memory on the Flag dataset. The other pattern database heuristics enabled A* to finish successfully. The dynamic pattern database with $k = 2$ helped to reduce the number of expanded nodes significantly for both algorithms on the datasets. Setting $k = 3$ helped even more. However, further increasing k to 4 often resulted in increased running time, and sometimes an increased number of expanded nodes as well. We believe that a larger k always results in a better heuristic; the occasional increase in expanded nodes is because the greedy strategy we used to choose patterns did not fully utilize the larger pattern database. The longer running time is reasonable though because it is less efficient to compute a heuristic value in larger pattern databases, and the inefficiency gradually overtook the benefit brought by the better heuristic. Therefore, $k = 3$ seems to be the best parametrization for the dynamic pattern database in general. For the static pattern databases, we were able to test much larger groups as we do not need to enumerate all groups up to a certain size. The results suggest that larger groupings tend to result in tighter heuristic.

The sizes of the static pattern databases are typically much larger than the dynamic pattern databases. However, they are still negligible in comparison to the number of expanded search nodes in all cases. It is thus cost effective to try to compute larger but affordable-size static pattern databases to achieve better search efficiency. The results show that the best static pattern databases typically helped A* and BFBnB to achieve better efficiency than the best dynamic pattern database, even when the number of expanded nodes is larger. The reason is calculating the heuristic values is more efficient when using static pattern databases.

5.3 Results on other datasets

Since static pattern databases seem to work better than dynamic pattern databases in most cases, we tested A* and BFBnB using static pattern database and sparse representation on all the datasets against the original algorithms. We used the simple static grouping of $\lceil \frac{n}{2} \rceil - \lfloor \frac{n}{2} \rfloor$ for all the datasets, where n is the number of variables. The results are shown in Table 6.

For the BFBnB algorithm, the improved version was around 5 times faster than the original version and sometimes even orders of magnitude faster (e.g. Flag). The reduction in the number of expanded nodes is not as dra-

Dataset				Results

			Nodes	1,353,762,809	273,746,036	OM	OM

Table 6: A comparison on the number of nodes expanded and running time (in seconds) of the A* and BFBnB algorithms enhanced by both static pattern database with grouping $\lceil \frac{n}{2} \rceil - \lfloor \frac{n}{2} \rfloor$, where n is the number of variables, and sparse representation of parent scores (denoted by "SP") against the original versions of these algorithms. "n" is the total number of variables, and "N" is the number of data points.

matic, however. The main reason is that the original BFBnB algorithm interleaves expanding the order graph and the full parent graphs during the search, while the improved version first calculates the sparse representation of parent scores, and then performs the search. It is much more efficient to compute the sparse representation than computing the full parent graphs. However, on the dataset Sensor Readings, the improved BFBnB algorithm runs slower than the original version. There are two potential explanations. First, this particular dataset has a large number of data points, which makes the sparse representation not truly sparse. Second, the new heuristic seems to be not much tighter than the simple heuristic on this dataset, because the numbers of expanded nodes are very similar in both cases.

The benefits of the new techniques are more obvious when applied to A*. For the datasets on which the original algorithm was able to finish, the improved algorithm was up to one order of magnitude faster; the number of expanded nodes is also significantly reduced. In addition, it was able to solve three larger datasets: Sensor Readings, Autos, and Flag. The running time on each of those datasets is pretty short, which indicates that once the memory consumption of the parent graphs was reduced, the A* algorithm was able to use more memory for the order graph and solved the search problems rather easily.

6 Concluding Remarks

The shortest-path finding formulation of the learning problem presented in (Yuan, Malone, and Wu 2011) makes two orthogonal directions of research natural. One is the development of search algorithms for learning optimal Bayesian networks, represented by the A* and BFBnB algorithms developed in (Yuan, Malone, and Wu 2011; Malone et al. 2011). One contribution of this paper is the sparse representation of the parent graphs which only store the unique optimal parent sets and scores. The method improves the time and space efficiency of the parent graph part of the search and thus falls in the first direction.

The second direction, which we believe is equally important, is the development of search heuristics. Another contribution of this paper is a new admissible heuristic called the k-cycle conflict heuristic developed based on the additive pattern databases. We tested the A* and BFBnB algorithms enhanced by the new heuristic and the sparse representation on a set of UCI machine learning datasets. The results show that both of the new techniques contributed to significant improvement in the efficiency and scalability of the algorithms. We therefore believe the new methods represent another significant step forward in exact Bayesian network structure learning.

As future work, we plan to investigate better approaches to obtaining the groupings for the static pattern databases. It could be based on prior knowledge, or some initial estimation of the correlation between the variables. Such groupings are expected to work better than the simple grouping we tested in this paper.

Abstract

Planning in partially observable Markov decision processes (POMDPs) remains a challenging topic in the artificial intelligence community, in spite of recent impressive progress in approximation techniques. Previous research has indicated that online planning approaches are promising in handling large-scale POMDP domains efficiently as they make decisions "on demand" instead of proactively for the entire state space. We present a Factored Hybrid Heuristic Online Planning (FHHOP) algorithm for large POMDPs. FHHOP gets its power by combining a novel hybrid heuristic search strategy with a recently developed factored state representation. On several benchmark problems, FHHOP substantially outperformed state-of-the-art online heuristic search approaches in terms of both scalability and quality.

1 Introduction

Partially observable Markov decision processes (POMDPs) have been widely recognized as a powerful probabilistic model for planning and control problems in partially observable stochastic domains (Kaelbling et al. 1998). Solving POMDP problems exactly can be impossible due to their computational complexity (Madani et al. 1999). In the past decade, researchers have made impressive progress in designing approximate algorithms (Pineau et al. 2006; Kurniawati et al. 2008; Ross et al. 2008a) and have successfully applied them to various realistic robotic tasks (Hoey et al. 2007; Hsu et al. 2008).

Planning algorithms can be categorized as offline planning algorithms and online planning algorithms depending on the ways of solving problems. Offline approaches separate the policy-construction phase and the policy-execution phase. They devote significant pre-processing time to generate a policy over the whole belief space in the policy-construction phase, then use the resulting policy to make decisions during the policy-execution phase. Offline approaches can be beneficial for repeated POMDP planning tasks as the pre-processing time can be amortized over the various runs. In contrast, online approaches are a viable alternative for urgent or one-off POMDP planning tasks. They do not allocate significant time to pre-processing, but alternate between a time-limited policy-construction step for the current state and a policy-execution step (Ross et al. 2008a). Instead of finding policies that generalize to all possible situations, they focus on computing good local policies at each policy-construction step, and therefore can potentially produce a sequence of actions with high reward while spending much less overall time for policy construction and policy execution compared to offline algorithms.

In this paper, we aim to accelerate online POMDP planning algorithms by taking advantage of a more efficient heuristic search strategy and a factored state representation.

Our work on heuristics originates from the insight that lower bounds on the optimal value function have not been well exploited in current online algorithms. Current online algorithms maintain both the lower and upper bounds as a heuristic to find good policies. One key problem that determines the overall performance of current approaches is how to approximate the optimal policy according to the lower and upper bounds. In previous work (Ross et al. 2008a), the upper bound was usually more popular than the lower bound in the calculation. The search toward the action with the highest upper bound guarantees that an ϵ-optimal action can be found within finite time theoretically. In contrast, the lower bound is more difficult to be exploited since it can easily trap search into local optima. For example, the result of always exploring toward the action branch with the highest lower bound only makes us believe that this action branch is optimal, although it tends not to be so. However, the lower bound can guarantee the quality of policy, which is an advantage that the upper bound does not have. Thus, online algorithms typically return the best

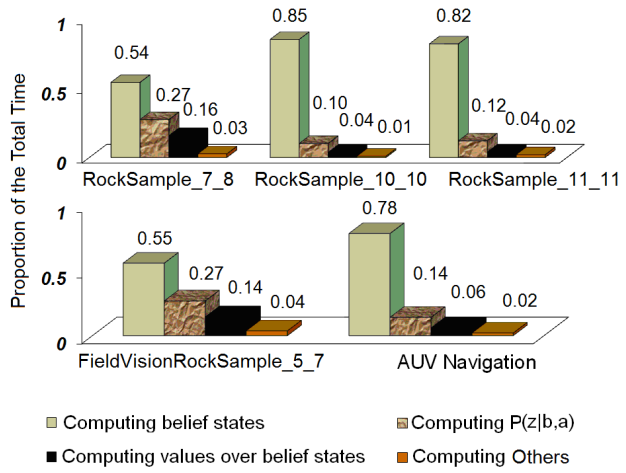

Figure 1: AEMS2's computational profile on several benchmark problems. The plot shows, for example, that on RockSample_7_8 AEMS2 spends 54%, 27% and 16% of its running time in computing new belief states, $P(z|b,a)$, and values over belief states given a value function, respectively. See text for further explanations.

action with the highest lower bound but not with the highest upper bound. In this paper, we discuss how to take full advantage of both the lower and upper bound in a novel hybrid way and avoid their disadvantages. The role of the lower bound in our heuristic method is to guide the search toward a set of promising policies whose quality may be better than the current best policy.

Our work on factorization was inspired by profiling data on several typical benchmark problems like those in Figure 1. Ignoring the details of the tasks for the time being, we can see that in all cases the anytime error minimization search 2 (AEMS2) algorithm, one of the most efficient online heuristic search algorithms (Ross and Chaib-draa 2007; Ross et al. 2008a), spends more than 95% of its overall running time in computing: (1) new belief states; (2) $P(z|b,a)$, the probabilities of observing z after taking action a at belief state b; and (3) values over belief states given a value function. These dramatic observations drive us to decrease overall computation time by reducing the time on these three operations. We show theoretically and empirically that it is possible to do so by taking advantage of the mixed observability MDP (MOMDP) representation (Ong et al. 2010). The MOMDP representation can be considered as an instance of a dynamic Bayesian network (DBN). It exploits mixed observability where some state variables are always observed and others are hidden to reduce the time complexity of state related operations.

We refer to our new algorithm based on the above two insights as Factored Hybrid Heuristic Online Planning (FHHOP). Experimental results reveal that FHHOP substantially outperformed the AEMS2 algorithm on all test problems. Especially, on some well-known benchmark problems, FHHOP has achieved more than an order of magnitude improvement in terms of runtime.

The remainder of the paper is organized as follows. Section 2 provides an overview of the POMDP model, online algorithms and the MOMDP representation. Section 3 describes the details in the FHHOP algorithm, which is our key contribution. Section 4 describes a set of experiments showing the efficacy of the FHHOP algorithm in terms of both runtime and solution quality. We conclude and discuss future work in Section 5.

2 Background and Related Work

In this section, we briefly introduce the POMDP model, online algorithms, and the MOMDP representation.

2.1 POMDP Model

POMDPs provide a very powerful mathematical model for an agent's decision making in partially observable domains. A discrete and discounted POMDP model can be formally defined by a tuple $(S, A, Z, T, \Omega, R, \gamma)$. In the tuple, S, A and Z are the finite and discrete state space, action space and observation space, respectively, $T(s,a,s') : S \times A \times S \to [0,1]$ is the state transition function ($P(s'|s,a)$), $\Omega(a,s',z) : A \times S \times Z \to [0,1]$ is the observation function ($P(z|a,s')$), $R(s,a) : S \times A \to \mathbb{R}$ is the reward function, and $\gamma \in (0,1)$ is the discount factor on the summed sequence of rewards. Because the agent's current state is not fully observable, the agent could have to rely on the complete history of past actions and observations to select a desirable current action. In the context of decision making, the *belief state* b is a sufficient statistic for the history of actions and observations (Smallwood and Sondik 1973). A belief state b is a discrete probability distribution over the state space, whose element $b(s)$ gives the probability that the agent's state is s. Let $\mathcal{B}$ be the space of all possible belief states and b_0 be the agent's *initial belief state*. Thus, $\mathcal{B}$ is an $|S|$-dimensional space, where $|S|$ is the number of states. In a so-called flat POMDP, all operations on beliefs and value functions are performed at the level of $|S|$-dimensional belief states.

When the agent takes action a at a belief state b and receives observation z, it will arrive at a new belief state $b^{a,z}$:

$$b^{a,z}(s') = \frac{1}{\eta}\Omega(a,s',z)\sum_{s\in S} T(s,a,s')b(s), \qquad (1)$$

where η is a normalizing constant (Kaelbling et al. 1998). The constant is the probability of receiving z after the agent

takes a at b and can be specified as:

$$P(z|b,a) = \sum_{s' \in S} \Omega(a,s',z) \sum_{s \in S} T(s,a,s')b(s). \quad (2)$$

A key goal in solving POMDPs is to find an *optimal policy* π^* that maximizes the *expected discounted reward* $V^\pi(b_0) = E[\sum_{t=0}^{\infty} \gamma^t R(s_t,a_t)|b_0,\pi]$, where π denotes a policy that maps from belief states to actions, and s_t and a_t are the agent's state and action at time step t, respectively. The maximal expected discounted reward starting from any initial belief state in the whole belief space is captured by the optimal value function V^*, which can be defined via the fixed point of Bellman's equation (Bellman 1957):

$$V^*(b) = \max_{a \in A} Q^*(b,a), \quad (3)$$

where $Q^*(b,a) = R(b,a) + \gamma \sum_{z \in Z} P(z|b,a)V^*(b^{a,z})$ and $R(b,a) = \sum_{s \in S} R(s,a)b(s)$. The function V^* can be approximated infinitely closely by a piecewise linear and convex function:

$$V(b) = \max_{\alpha \in \Gamma} (\alpha \cdot b) = \max_{\alpha \in \Gamma} \sum_{s \in S} \alpha(s)b(s), \quad (4)$$

where Γ is a finite set of $|S|$-dimensional hyperplanes, called α-vectors, over $\mathcal{B}$ (Smallwood and Sondik 1973). The piecewise linear and convex property makes several exact and approximate value iteration algorithms feasible for solving POMDPs (Kaelbling et al. 1998; Kurniawati et al. 2008). Once V^* has been identified, computing the optimal policy π^* is a straightforward application of $\pi^*(b) = \text{argmax}_{a \in A} Q^*(b,a)$.

2.2 Approximate Online Algorithms

Online POMDP algorithms can be classified into three categories: branch-and-bound pruning, Monte-Carlo sampling and heuristic search (Ross et al. 2008a). In this paper, we only focus on one category, heuristic search online algorithms. The central idea in heuristic search online algorithms is to maintain lower and upper bounds on the value function, $\underline{V}(b) \leq V^*(b) \leq \bar{V}(b)$, and to iteratively improve these bounds at the current belief state b_c by expanding an AND/OR tree of reachable belief states from b_c. We denote $\underline{Q}(b,a)$ and $\bar{Q}(b,a)$, respectively, as the lower and upper bounds over $Q^*(b,a)$. Each OR-node in the tree represents a belief state and each AND-node represents an action choice from the belief state (node) above it, given the tree is drawn growing downwards. By abuse of notation, we will use b to represent a belief node in the tree and its associated belief state.

Algorithm 1 is a generic POMDP solver. It accepts three parameters: b_0, τ and ϵ, where b_0 is the initial belief state, τ is a bound on computation time allowed per policy-construction step, and ϵ is the desired precision on $V(b_c)$.

Algorithm 1: Generic Online POMDP Solver

Function OnlinePOMDPAlgorithm(b_0,τ,ϵ)
1: Initialize the bounds by offline algorithms;
2: $b_c = b_0$;
3: Build an AND/OR tree to contain b_c at the root;
4: **while** b_c is not a goal state
5: a =Search(b_c,τ,ϵ);
6: Take action a and receive a new observation z;
7: $b_c = b_c^{a,z}$;
8: Update the tree so that b_c is the new root;
9: **end while**

Algorithm 2: Policy Construction

Function Search(b_c,τ,ϵ)
1: StartTimer();
2: **while** ElapsedTime() $\leq \tau$ and $\bar{V}(b_c) - \underline{V}(b_c) > \epsilon$
3: b^* =ChooseBestNodetoExpand();
4: Expand(b^*);
5: UpdateAncestors(b^*);
6: **end while**
7: return $\text{argmax}_{a' \in A} \underline{Q}(b_c,a')$;

Online algorithms use this tree to alternate between policy construction and policy execution. The policy execution procedure (see Lines 6–8 in Algorithm 1) is consistent across all online algorithms.

Algorithm 2 is a general online policy-construction function. The ChooseBestNodetoExpand() procedure uses efficient heuristic search strategies to select a useful belief node to expand among the leaf nodes. The Expand() procedure expands a belief node, improving its lower and upper bound over V^* in the process. The UpdateAncestors() procedure concentrates on updating the bounds of a belief node's ancestors. On Line 7 of Algorithm 2, it returns the action branch at the root with the highest lower bound of $Q(b_c,a')$. We define the current best policy π_{best} to be the policy of always selecting the action $\pi_{best}(b) = \text{argmax}_{a' \in A} \underline{Q}(b,a')$.

To better describe our work on heuristics, we first use Figure 2 as an example to further illustrate how online algorithms work. Suppose that b_{c+k} is the leaf belief node that ChooseBestNodetoExpand() returns. Let b_{c+k} be a leaf node that is reachable from the root belief node b_c by following a k-step action-observation sequence, $a_0 z_1 a_1 z_2 \ldots a_{k-1} z_k$. After expanding b_{c+k}, an improved $\underline{V}(b_{c+k})$ and $\bar{V}(b_{c+k})$ can be obtained. Furthermore, the invocation of UpdateAncestors() results in the improved bounds at all belief nodes and Q nodes along this path. In other words, given that b_{c+k} is reachable from b_c by following some policy π, the execution of Line 3–5 in Algorithm 2 will lead to improved $\underline{V}^\pi(b_c)$ and $\bar{V}^\pi(b_c)$,

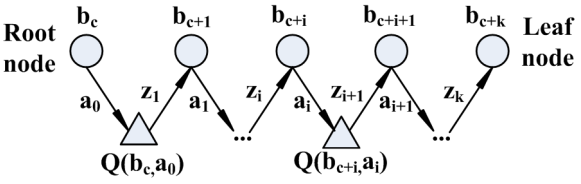

Figure 2: A path from the root belief node b_c to the leaf belief node b_{c+k}.

the lower and upper bounds on the expected discounted reward generated by following π at b_c. If $\underline{V}^{\pi_{best}}(b_c)$ in the previous round is surpassed by the new improved $\underline{V}^{\pi}(b_c)$, then a policy with higher lower bound will be found.

2.3 Heuristics in Current Online Algorithms

In current heuristic search online algorithms, each leaf belief node has an associated heuristic value. The invocation of ChooseBestNodetoExpand() returns the leaf belief node with the maximal heuristic value. If an oracle provides us with the optimal value function V^*, a heuristic function over a leaf node b_{c+k} with good theoretical guarantees can be defined as follows (Ross et al. 2008b):

$$H^*(b_{c+k}) = e^*(b_{c+k}) \prod_{t=0}^{k-1} \omega^*(b_{c+t}, a_t)\omega(b_{c+t}, a_t, z_{t+1}), \tag{5}$$

where $e^*(b_{c+k}) = V^*(b_{c+k}) - \underline{V}(b_{c+k})$, $\omega(b_{c+t}, a_t, z_{t+1}) = \gamma P(z_{t+1}|b_{c+t}, a_t)$, and

$$\omega^*(b_{c+t}, a_t) = \begin{cases} 1 & \text{if } a_t \in \operatorname{argmax}_{a' \in A} Q^*(b_{c+t}, a'), \\ 0 & \text{otherwise.} \end{cases} \tag{6}$$

In such a heuristic function, each quantity plays an important role in expanding the leaf nodes: $e^*(b_{c+k})$ encourages exploration of leaf nodes with loose bounds, $\omega^*(b_{c+t}, a_t)$ focuses the exploration toward the leaf nodes that are reachable from b_c under the optimal policy, and $\omega(b_{c+t}, a_t, z_{t+1})$ guides the search toward belief nodes that are likely to be encountered in the future. Empirical results in prior work (Ross et al. 2008a) teach us that ignoring some quantities in Equation 5 would damage the overall performance of online approaches. For example, the lack of $\omega(b_{c+t}, a_t, z_{t+1})$ in the BI-POMDP algorithm (Washington 1997) may explain its poor performance on some POMDP problems with large observation spaces.

However, the optimal policy or value function is not available for constructing H^*. Thus, the finding of a set of "promising" policies is one of the core issues for improving the speed of online algorithms. The approach of Satia and Lave (Satia and Lave 1973) assumes the set of promising policies are all possible optimal policies. In this approach, little heuristic information about $\underline{V}$ and $\bar{V}$ is exploited to focus its search toward actions that look promising, and therefore the approach of Satia and Lave is not able to scale well to large-scale POMDPs. The AEMS1 algorithm (Ross et al. 2008a) takes both $\underline{V}$ and $\bar{V}$ into account by favoring exploration of action branches with high average values of $\underline{Q}(b, a)$ and $\bar{Q}(b, a)$. Such an algorithm loses its competitive capability in large-scale POMDP problems partially because its search strategy does not use the highest lower or upper bound well. In contrast to AEMS1, the BI-POMDP and AEMS2 algorithms use $\bar{V}$ as an estimated substitute for V^*. $H_U(b_{c+k})$ is the AEMS2 algorithm's heuristic:

$$H_U(b_{c+k}) = e(b_{c+k}) \prod_{t=0}^{k-1} \omega(b_{c+t}, a_t)\omega(b_{c+t}, a_t, z_{t+1}), \tag{7}$$

where $e(b_{c+k}) = \bar{V}(b_{c+k}) - \underline{V}(b_{c+k})$ and

$$\omega(b_{c+t}, a_t) = \begin{cases} 1 & \text{if } a_t \in \operatorname{argmax}_{a' \in A} \bar{Q}(b_{c+t}, a'), \\ 0 & \text{otherwise.} \end{cases} \tag{8}$$

From the definition of $\omega(b_{c+t}, a_t)$, we can see AEMS2 assumes that the action with the maximal upper bound is in fact the optimal action. Such a definition, sometimes called the IE-MAX heuristic (Smith and Simmons 2004), leads AEMS2 to find an ϵ-optimal action within finite time (Ross et al. 2008b). The action branch according to the highest lower bound is deliberately ignored in AEMS2 simply because choosing leaf nodes under such an action branch to expand could only cause its lower bound to rise, and therefore, easily trap search in local optima. However, $\underline{Q}(b, a)$ may be a very useful heuristic in finding a better policy. A direct insight is that the action that Algorithm 1 returns is the action corresponding to the maximal $\underline{Q}(b, a)$ but not the maximal $\bar{Q}(b, a)$. One of our contributions is to suggest that using the lower bound could provide improvements compared to the heuristics used in AEMS2.

2.4 MOMDPs

A MOMDP can be generally specified as a tuple $(\mathcal{X}, \mathcal{Y}, A, Z, T_{\mathcal{X}}, T_{\mathcal{Y}}, \Omega, R, \gamma)$, where $\mathcal{X}$ is the set of fully observable state variables, $\mathcal{Y}$ is the set of partially observable state variables, $S = \mathcal{X} \times \mathcal{Y}$, $T_{\mathcal{X}}(x, y, a, x') : \mathcal{X} \times \mathcal{Y} \times A \times \mathcal{X} \to [0, 1]$ and $T_{\mathcal{Y}}(x, y, a, x', y') : \mathcal{X} \times \mathcal{Y} \times A \times \mathcal{X} \times \mathcal{Y} \to [0, 1]$ are the two corresponding probabilistic state-transition functions ($P(x'|x, y, a)$ and $P(y'|x, y, a, x')$), $\Omega(a, x', y', z) : A \times X \times Y \times Z \to [0, 1]$ is the observation function ($P(z|a, x', y')$), $R(x, y, a) : \mathcal{X} \times \mathcal{Y} \times A \to \mathbb{R}$ is the reward function, and the other quantities are the same as a POMDP model's elements. Since x is fully observable, a belief state b on the underlying state $s = (x, y)$ can be represented as $(x, b_{\mathcal{Y}}(x))$. Let $\mathcal{B}_{\mathcal{Y}}$ be the belief space over $\mathcal{Y}$, and $\mathcal{B}_{\mathcal{Y}}(x) = \{(x, b_{\mathcal{Y}}(x))|b_{\mathcal{Y}}(x) \in \mathcal{B}_{\mathcal{Y}}\}$, then $\mathcal{B} =$

$\bigcup_{x\in\mathcal{X}} \mathcal{B}_\mathcal{Y}(x)$. Thus, computations involving updating beliefs and value functions can be restricted to one of $|\mathcal{Y}|$-dimensional subspaces, $\mathcal{B}_\mathcal{Y}(x)$. Please note that $\mathcal{B}$ has $|\mathcal{X}||\mathcal{Y}|$ dimensions, while $\mathcal{B}_\mathcal{Y}$ has only $|\mathcal{Y}|$ dimensions, where $|\mathcal{X}|$ and $|\mathcal{Y}|$ are the number of fully and partially observable state variables, respectively.

After taking a and receiving z from $(x, b_\mathcal{Y}(x))$, a new belief $(x^{a,z}, b_\mathcal{Y}(x^{a,z}))$ results. The variable $x^{a,z}$ can be directly inferred from z, and $b_\mathcal{Y}(x^{a,z})$ can be computed as follows:

$$b_\mathcal{Y}(x^{a,z}, y') = \frac{1}{\eta}\Omega(a, x^{a,z}, y', z) \sum_{y\in\mathcal{Y}} T_{\mathcal{X}\mathcal{Y}} b_\mathcal{Y}(x, y), \quad (9)$$

where $T_{\mathcal{X}\mathcal{Y}} = T_\mathcal{X}(x, y, a, x^{a,z}) T_\mathcal{Y}(x, y, a, x^{a,z}, y')$ and η, the probability of receiving z after taking a at $(x, b_\mathcal{Y}(x))$ is

$$P(z|x, b_\mathcal{Y}(x), a, x^{a,z}) = \sum_{y'\in\mathcal{Y}} \Omega(a, x^{a,z}, y', z) \sum_{y\in\mathcal{Y}} T_{\mathcal{X}\mathcal{Y}} b_\mathcal{Y}(x, y). \quad (10)$$

For any given x, $V^*(x, b_\mathcal{Y}(x))$ can be accurately approximated by a finite set of $|\mathcal{Y}|$-dimensional vectors $\Gamma_\mathcal{Y}(x)$ over $\mathcal{B}_\mathcal{Y}(x)$:

$$V(x, b_\mathcal{Y}(x)) = \max_{\alpha\in\Gamma_\mathcal{Y}(x)} (\alpha \cdot b_\mathcal{Y}(x)). \quad (11)$$

From the description of MOMDPs, we can see any MDP can be written as a MOMDP and any POMDP can be written as a MOMDP. That is because the MDP states can reside in the fully observable part of the MOMDP description and the POMDP states can reside in the partially observable part of a MOMDP description. Similarly, any MOMDP can be written as a POMDP by treating all states as partially observable (Ong et al. 2010).

3 Factored Hybrid Heuristic Online Planning

In this section, we describe the FHHOP algorithm in detail. First, we construct a novel hybrid heuristic strategy by combining a new heuristic function using the lower bound with an existing heuristic function using the upper bound to improve the heuristic search mechanism in the ChooseBestNodetoExpand() procedure. Then, we concentrate on the reason that the MOMDP representation is useful to reduce the running time in the Expand() and UpdateAncestors() procedures. Finally, we discuss the convergence property of the FHHOP algorithm.

3.1 Constructing a Heuristic Function Using the Lower Bound

As mentioned in the last paragraph of Section 2.2, to find a better policy, we need to select a policy π and expand the leaf belief nodes that are reachable from b_c by following the policy π. Our goal here is to use the lower bound as a heuristic to select a set of promising policies so that the exploration toward them will lead to find an even better policy as quickly as possible. Our idea is to elicit a set of policies π from all possible policies, whose $\underline{V}^\pi(b_c)$ are close to $\underline{V}^{\pi_{best}}(b_c)$, according to the lower bound.

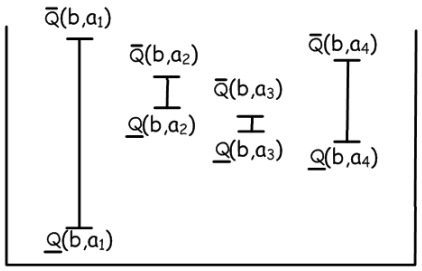

Figure 3: An example of action branches at b. $A_L = \{a_2\}$, $A_S = \{a_1, a_4\}$, and current second-best action is a_4. The action branch a_3 is not included in A_S because $\bar{Q}(b, a_3)$ is smaller than $\underline{Q}(b, a_2)$.

First, define $\omega_1(b, a)$, a term that guides the exploration toward belief nodes that are reachable from b_c under the current best policy, as follows:

$$\omega_1(b, a) = \begin{cases} 1 & \text{if } a \in \operatorname{argmax}_{a'\in A} \underline{Q}(b, a'), \\ 0 & \text{otherwise.} \end{cases} \quad (12)$$

Then, we consider the action branches at a single belief node b. We assume $A_L = \operatorname{argmax}_{a'\in A} \underline{Q}(b, a')$ and $A_S = \{a \in A \setminus A_L | \bar{Q}(b, a) > \max_{a'\in A} \underline{Q}(b, a')\}$. Thus, A_L is a current best action branch at b and A_S is a set of actions without both A_L and suboptimal action branches. The condition $\bar{Q}(b, a) > \max_{a'\in A} \underline{Q}(b, a')$ is used to prune suboptimal action branches at b, just like the branch-and-bound pruning technique in the approach of Satia and Lave. Then, we define

$$\omega_2(b, a) = \begin{cases} 1 & \text{if } a \in \operatorname{argmax}_{a'\in A_S} \underline{Q}(b, a'), \\ 0 & \text{otherwise,} \end{cases} \quad (13)$$

where $\operatorname{argmax}_{a'\in A_S} \underline{Q}(b, a')$ is called the current second-best action at b. So, $\omega_2(b, a)$ is a term that encourages the exploration toward belief nodes that are reachable from b's second-best action branch. We use Figure 3 to provide a direct explanation of these notions. The current second-best action looks a bit like the action branch with the second highest upper bound in this figure, but they actually have nothing to do with each other.

Finally, we figure out the way of eliciting a set of promising policies according to the lower bound. Obviously, the nodes that are reachable from b_c by following the set of promising policies constitute of a subtree of the current AND/OR tree. We are interested in all leaf nodes of

this subtree reachable from b_c through **one and only one** current second-best action branch and all other current best action branches. Such a strategy can be well depicted by $\omega_{1,2}(b_{c+k})$:

$$\omega_{1,2}(b_{c+k}) = \max_{i\in\{0,1,\ldots,k-1\}} \omega_2(b_{c+i}, a_i) \prod_{\substack{t=0 \\ t\neq i}}^{k-1} \omega_1(b_{c+t}, a_t), \tag{14}$$

where b_{c+i} is the only belief node in which its current second-best action branch is chosen. When $\omega_{1,2}(b_{c+k})$ equals 1, the leaf node b_{c+k} is reachable from b_c by following one of such a set of promising policies. We construct a new heuristic $H_L(b)$ for each leaf node using $\omega_{1,2}(b_{c+k})$ as follows:

$$H_L(b_{c+k}) = e(b_{c+k})\omega_{1,2}(b_{c+k}) \prod_{t=0}^{k-1} \omega(b_t, a_t, z_{t+1}). \tag{15}$$

From Equation 15, we can see that the leaf nodes being selected to expand using $H_L(b)$ are not reachable from b_c under the current best policy. However, they are reachable from b_c under a set of promising policies that are very similar to the current best policy since they have only one action branch that is different from the current best action branch. Such a heuristic $H_L(b)$ has several advantages, as follows:

- First, a better policy according to the lower bound would be quickly found using $H_L(b)$ only if the improved Q-value at the second-best action branch is greater than the Q-value at the current best action branch.
- Second, it focuses search toward a set of promising policies but not a single policy. The main drawback of expanding the leaf nodes that are reachable under a single policy is that the time of expanding is wasted if such a single policy is not better than the current best policy. Since $H_L(b)$ selects a set of promising policies, suboptimal policies will be eliminated as the depth of its leaf nodes increases. In other words, $H_L(b)$ favors exploration toward the highest potential policy among the set of promising policies as time goes on.
- Third, such a set of promising policies is only a very small subset in the set of all possible policies. Therefore, the technique can avoid exploring a large policy space to satisfy the requirement of real-time limitations in online algorithms.

However, such a heuristic may still be at the risk of trapping the search into local optima if the optimal policy is outside of the set of promising policies and the current best policy. Thus, our new heuristic function $H_L(b)$ might be only a greedy heuristic and not lead to optimal behavior in the end.

3.2 Constructing a Hybrid Heuristic Strategy

Before we construct a hybrid strategy, recall the strength and weakness of $H_L(b)$ and $H_U(b)$. $H_L(b)$ is a heuristic that depends on the lower bound. Its advantage is to guide search toward finding a better policy with a higher lower bound guarantee quickly. However, $H_L(b)$ limits its search effort to a set of promising policies. If both the current policy and the set of promising policies are suboptimal, the search led by $H_L(b)$ might become trapped in a local optimum. $H_U(b)$ is a heuristic strategy that depends on the upper bound. It favors exploration toward an ϵ-optimal action branch. The ϵ-optimal action can be found theoretically even if $H_L(b)$ is not used. However, the process of finding an ϵ-optimal action is usually very slow, especially in POMDP domains with large action and observation spaces. Because their strengths are complementary, it seems to be reasonable to combine them for obtaining a hybrid heuristic search strategy that leverages the advantages of both heuristics.

We suggest a way of constructing a hybrid strategy. Let $\mathcal{L}$ be a set of leaf belief nodes in the AND/OR tree,

$$b_U = \operatorname*{argmax}_{b\in\mathcal{L}} H_U(b) \tag{16}$$

and

$$b_L = \operatorname*{argmax}_{b\in\mathcal{L}} H_L(b). \tag{17}$$

Then, our hybrid strategy selects b^* by Equation 18:

$$b^* = \begin{cases} b_U & \text{if } C_U H_U(b_U) > C_L H_L(b_L), \\ b_L & \text{otherwise,} \end{cases} \tag{18}$$

where C_i denotes expected change value of both $\underline{V}(b_c)$ and $\bar{V}(b_c)$ if b_i is chosen to be expanded. We use the following formula to compute C_i in our experiments:

$$C_i = \frac{I_i + 1}{N_i + 1}, \tag{19}$$

where $i = U$ or L, I_i denotes the accumulative total change value of both $\underline{V}(b_c)$ and $\bar{V}(b_c)$ caused by expanding b_i for N_i times, and N_i represents the number of expanding b_i. Both I_i and N_i are recalculated at the beginning of each policy-construction step. The overhead of computing C_i is negligible in comparison to the Expand() and UpdateAncestors() procedures. Here, b_U (or b_L) refers to all belief nodes generated when $C_U H_U > C_L H_L$ (or otherwise), and expanding b_i once means calling Expand(b_i) and UpdateAncestors(b_i) once. The ones appearing in both numerator and denominator are used to make C_U and C_L equal 1 at the beginning of the online algorithm's run. C_U and C_L are variables for adjusting the importance of $H_U(b)$ and $H_L(b)$, respectively, in heuristic search. For example, imagine the expansions of b_U (in a period) brought no or only small change in both $\underline{V}(b_c)$ and

$\bar{V}(b_c)$. As time goes on, the value of C_U will decrease, and the probability of selecting b_U to expand will also drop.

Note that there are many other possible hybrid methods that combine $H_L(b)$ and $H_U(b)$. Here is only one feasible way. A further research in this direction may lead to a more efficient hybrid method.

3.3 Leveraging the MOMDP Representation

Now, we analyze why the MOMDP representation is a useful tool to reduce the time complexity of the operations related with belief-state computation and value-function computation. Reconsidering Equations 1, 2 and 4 in the context of POMDPs, we can see that computing $b^{a,z}$, $P(z|b,a)$ and $V(b)$ takes $|\mathcal{X}|^2|\mathcal{Y}|^2 + 2|\mathcal{X}||\mathcal{Y}|$, $|\mathcal{X}|^2|\mathcal{Y}|^2$ and $|\Gamma||\mathcal{X}||\mathcal{Y}|$ multiplications, respectively. However, by applying the MOMDP-specific versions of these equations—Equations 9, 10 and 11—these costs can be reduced to $2|\mathcal{Y}|^2 + 2|\mathcal{Y}|$, $2|\mathcal{Y}|^2$ and $|\Gamma_{\mathcal{Y}}(x)||\mathcal{Y}|$ multiplications, respectively. That is, the time complexity of computing $b^{a,z}$, $P(z|b,a)$ and $\underline{V}(b)$ can be reduced by $\frac{|\mathcal{X}|^2|\mathcal{Y}|^2+2|\mathcal{X}||\mathcal{Y}|}{2|\mathcal{Y}|^2+2|\mathcal{Y}|}(= \mathcal{O}(|\mathcal{X}|^2))$, $\frac{|\mathcal{X}|^2}{2}$ and $\frac{|\mathcal{X}||\Gamma|}{|\Gamma_{\mathcal{Y}}(x)|}$ times. Since $|\Gamma| = \sum_{x\in\mathcal{X}} |\Gamma_{\mathcal{Y}}(x)|$, the expectation $E_{x\sim\mathcal{X}}[\frac{|\Gamma|}{\Gamma_{\mathcal{Y}}(x)}]$ is $|\mathcal{X}|$. Thus, the MOMDP representation reduces each of the three operations' complexity by a factor of $\mathcal{O}(|\mathcal{X}|^2)$.

3.4 Convergence of FHHOP

The new online heuristic search algorithm using the hybrid heuristics in Section 3.2 and the POMDP representation in Section 3.3 is the FHHOP algorithm. Note that there are substantial differences between our hybrid strategy and the strategy included in AEMS1. AEMS1 merges $\underline{V}$ and $\bar{V}$ at the beginning of designing the action selection strategy in its heuristic function. However, FHHOP first separates $\underline{V}$ and $\bar{V}$ in order to define two almost independent heuristic functions, then merges the two heuristic functions with the goal of taking full advantage of each heuristic function. As a final note, Proposition 1 states the convergence property of the FHHOP algorithm.

Proposition 1. *Let $\epsilon > 0$ and b_c the current belief state. Then, the FHHOP algorithm is guaranteed to find an ϵ-optimal action for b_c within finite time.*

Proof. Because the FHHOP algorithm exploits the MOMDP representation to accelerate the computation of $b^{a,z}$, $P(z|b,a)$ and $\underline{V}(b)$ without losing accuracy, following Theorem 2 in (Ross et al. 2008b), we only need to prove that the probability of choosing b_U to expand in the FHHOP algorithm is always greater than 0 in this algorithm. The following is the proof by contradiction.

Suppose that after the M^{th} expansion of b_U or b_L, the FHHOP algorithm never selects b_U to expand, namely, $C_U H_U(b_U) \leq C_L H_L(b_L)$. Thus, I_U and N_U will never change, and therefore, C_U and $H_U(b_U)$ will never change after the M^{th} expansion. Let $\underline{V}_0(b)$ and $\bar{V}_0(b)$ be b's initialized lower and upper bounds, and $e_0(b) = \bar{V}_0(b) - \underline{V}_0(b)$. Then, we have

$$H_L(b_L) \leq e(b_L) \leq \max_{b\in\mathcal{B}} e_0(b),$$

and $I_L \leq e_0(b_c)$. Now, let

$$N_L > \max\{M, \frac{[e_0(b_c)+1]\max_{b\in\mathcal{B}} e_0(b)}{C_U H_U(b_U)} - 1\}.$$

Then,

$$\begin{aligned} C_U H_U(b_U) &> \frac{[e_0(b_c)+1]\max_{b\in\mathcal{B}} e_0(b)}{N_L+1} \\ &\geq \frac{I_L+1}{N_L+1} H_L(b_L) \\ &= C_L H_L(b_L). \end{aligned}$$

There is a contradiction. □

4 Experimental Results

In this section, we present detailed empirical results designed to test the performance of the FHHOP algorithm. In all test domains, we use the blind policy and the FIB method (Hauskrecht 2000) to initialize the lower and upper bounds, respectively. Except where stated otherwise, all experiments were run on an AMD dual core processor 3600+ 2.00GHz with 2GB memory. We implemented FHHOP and AEMS2 using C++, within APPL-0.93[1], an efficient POMDP solver. Results about SARSOP without attribution appeared in Table 1 were also obtained using APPL-0.93 in our experimental platform.

4.1 Benchmark Problems

a) *Hallway:* The Hallway domain (Littman et al. 1995) models a robot navigating in an office environment. The task of the robot in this problem is to arrive in a single goal location. The state of the robot is comprised of its current position and its current orientation. However, neither attribute is fully observable. There is a set of 5 actions for movements:{Forward, Turn-left, Turn-right, Turn-around, Stay-in-place}. The robot can partially observe the existence of walls in four directions using four independent, short-range, and noisy sensors.

b) *Tag:* The Tag problem was first described in (Pineau et al. 2003). In this environment, a mobile robot moves in a grid map with 29 positions with the goal of tagging an

[1]The software package is available from the web-page: http://bigbird.comp.nus.edu.sg/pmwiki/farm/appl/. All test problems in the MOMDP representation conform to the syntax of pomdpx specified on the same web site.

opponent that intentionally moves away. Both the robot and the opponent are located initially in independently selected random positions. The robot can choose either to move into one of four adjacent positions by actions {North, South, East, West} or to tag the opponent by a "Catch" action. The effect of the robot's action is deterministic. The robot can know its current position exactly, but the opponent's position is not observable for the robot unless they are in the same position. The robot tries to catch the opponent as quickly as possible to receive a good reward since each move for the robot is expensive. In the MOMDP representation for Tag, the fully observable state variable x represents the robot's position. The partially observable state variable y is the opponent's position.

c) *RockSample:* The RockSample domain was originally presented in (Smith and Simmons 2004) and has been frequently used in recent work to test new POMDP algorithms (Ross et al. 2008a; Bonet and Geffner 2009; Ong et al. 2010; Silver and Veness 2010). This domain models a planetary robot that has to explore an area represented as a grid map and sample rocks with a scientific value. The robot receives a positive or negative reward depending on whether the sampled rock has a scientific value. RockSample_n_k is a family of problems in the RockSample domain with a map size $n \times n$ and k rocks. In these problems, the robot's action set consists of $k + 5$ actions: {North, South, East, West, Sample, Check$_1$,... Check$_k$}. The robot always knows its own position and rock positions in the map exactly. That is rock locations are fixed and encoded in the map and need not be encoded in state variables. However, whether rock m has a scientific value is only partially observed via the action Check$_m$. The Check$_m$ action is responsible for gathering information about rock m using a noisy long-range sensor. The accuracy of the information gathered depends on the distance between the robot and the rock checked. In the MOMDP representation for this domain, the x variable is the robot's position, and the y variable is a Boolean that indicates whether a particular rock has a scientific value.

d) *FieldVisionRockSample:* The FieldVisionRockSample domain was initially introduced in the work on AEMS2 (Ross and Chaib-draa 2007). This domain can be viewed as a variant of the RockSample domain. The only difference between them is the way of perceiving the rocks in the environment. In contrast to perform a check action on a specific rock to observe its state in RockSample, in FieldVisionRockSample the states of all rocks are observed after any action by the same noisy sensor. Consequently, the robot can only perform 5 actions: {North, South, East, West, Sample}, and has an observation space with size 2^k for the problem with k rocks. What is different from the RockSample domain is that, in the MOMDP model for this task, the y variable represents k Boolean values, each of which indicates whether a rock has a scientific value.

e) *AUV Navigation:* The AUV Navigation problem first appeared in (Ong et al. 2009). This problem models a 3-D oceanic environment with 4 levels and a 7×20 grid map at each level. An autonomous underwater vehicle (AUV) can achieve reward by navigating from some uncertain starting position to some goal positions and avoiding rock formations. The AUV can perform 6 actions: {Forward, Stay, Left, Right, Up, Down}. All of them are stochastic due to control uncertainty or ocean currents. The AUV is equipped with an accurate pressure senor, an accurate compass, and a global positioning system (GPS), whose signals can only be received when the AUV is located at the surface level. In the MOMDP representation, the x variable models the AUV's depth and orientation, and the y variable models the AUV's horizonal location.

These benchmark problems were selected to illustrate specific characteristics. First, the Tag problem has a dynamic environment that changes over time even if the robot does not take any action. Second, the RockSample domain has a larger action space but smaller observation space, while the other domains have smaller action spaces but larger observation spaces. Third, the Hallway problem does not include the mixed observation structure. Fourth, all test problems except Hallway have large state spaces ranging from about 10^3 to 10^5 dimensions. Thus, we hope including problems with different features helps test FHHOP's overall performance thoroughly.

4.2 Performance Comparison

We applied FHHOP and existing state-of-the-art online and offline algorithms to these benchmark problems. Table 1 compares them in terms of the following characteristic metrics (Ross et al. 2008a): expected discounted reward (Reward), upper bound of online time per policy-construction step (τ) (seconds), offline time (seconds). Looking at the comparison between our implementation of AEMS2 and FHHOP, we can find that FHHOP obtains higher values in terms of reward on all test problems with online time less or equal to AEMS2's. Furthermore, at least on the Tag, RockSample and AUVNavigation domains, FHHOP has achieved more than an order of magnitude improvement compared to AEMS2. These empirical results suggest that FHHOP tends to have a better scalability especially in large-scale POMDP domains.

Previously published results for SARSOP, except those on the Hallway and FieldVisionRockSample domains from our experimental platform, are provided in the table for comparison. Through the comparison can be found that the FHHOP algorithm is very competitive, sometimes even better, in terms of expected discounted reward, and meanwhile have advantages such as a small initial offline planning time and a small re-planning time between action

Table 1: Multi-algorithm performance comparison on several benchmark problems. See text for explanations.

executions. Note that there also exists other state-of-the-art offline algorithms (Smith and Simmons 2004; Pineau et al. 2006; Shani et al. 2007; Bonet and Geffner 2009). Here, we only use SARSOP as a representative offline algorithm to compare with our online algorithms.

In addition, published results on the partially observable Monte-Carlo planning (POMCP) algorithm (Silver and Veness 2010) for some RockSample problems are also presented. POMCP is a promising online Monte-Carlo algorithm, especially in large-scale POMDP problems. From these data, we can see FHHOP exceeds POMCP in terms of both overall running time and qualities of generated policies on these RockSample problems.

5 Conclusion and Future Work

This paper presents FHHOP, a novel factored hybrid heuristic online planning algorithm for large POMDPs. To the best of our knowledge, FHHOP is the most efficient online heuristic search algorithm, on the whole, yet proposed amongst existing fully implemented domain-independent online POMDP solvers. A major contribution of this algorithm is a new hybrid heuristic search strategy that takes full advantage of both lower and upper bounds on the optimal value function. Its foundation stone is a clever way of constructing a heuristic function using the lower bound. A minor contribution of this algorithm is to integrate MOMDP, a recently developed factored state representation, with a cutting-edge online algorithm and reveal its efficacy empirically. Experimental results reported here provide a comprehensive picture of FHHOP and state-of-the-art online and offline approaches on five popular benchmark domains.

There are some interesting directions for future work. First, we noticed some efficient structure learning algorithms had been proposed in factored state MDPs (Li et al. 2008; Diuk et al. 2009). An interesting research direction is to extend these existing algorithms to automatically learn the mixed observation structure in POMDPs. Second, we believe it should be possible to use other cutting-edge data structures, such as algebraic decision diagrams (Poupart 2005) or topology (Brunskill and Russell 2010), in FHHOP to succinctly represent more complex structures. Third, reparameterization (Ong et al. 2009) may give POMDPs without the mixed observation structure a chance to benefit from the MOMDP representation. Fourth, we could leverage the graph structure instead of the AND/OR tree in FHHOP to avoid redundant computations on duplicate belief states. Finally, we would also like to investigate further hybrid heuristic strategies for better performance.

Abstract

It is often the case that, within an online recommender system, multiple users share a common account. Can such shared accounts be identified *solely on the basis of the user-provided ratings*? Once a shared account is identified, can the different users sharing it be identified as well? Whenever such user identification is feasible, it opens the way to possible improvements in personalized recommendations, but also raises privacy concerns. We develop a model for composite accounts based on unions of linear subspaces, and use subspace clustering for carrying out the identification task. We show that a significant fraction of such accounts is identifiable in a reliable manner, and illustrate potential uses for personalized recommendation.

1 Introduction

Online commerce services such as Netflix provide personalized recommendations by collecting user ratings about a universe of items, to which we refer here as 'movies'. Typically, multiple people within a single household (family members, roommates, *etc.*) may share the same account for both viewing and rating movies. Service providers are avoid deploying multiple accounts as log-in screens are perceived as a nuisance and a barrier to using the service. This is especially true on a keyboard-less devices, such as televisions or gaming platforms. Account sharing persists even when providers offer the option of registering secondary accounts, as the latter may have access to a subset of the services enjoyed by the primary account. Finally, sharing might be regarded as a partial (if unconscious) privacy protection mechanism, hindering the release of the household's composition and demographics.

The use of a single account by multiple individuals poses a challenge in providing accurate personalized recommendations. Informally, the recommendations provided to a "composite" account, comprising the ratings of two dissimilar users, may not match the interests of either of these users. More concretely, as discussed in Section 3, collaborative filtering methods such as matrix factorization assume that ratings follow a linear model of user and movie profiles of small dimension. Though such methods may perform well for most cases, they can fail on composite accounts, as we show in Section 6. This is because "mixing" ratings from different users may yield a rating set that can no longer be explained by a linear model.

Can composite accounts within a recommender system be identified? Can the individuals sharing such an account be identified? Can accurate profiles of different users' behaviors be learnt? We address these questions in the most challenging setting, namely when no information is available apart from the ratings users provide. Our contributions are as follows:

(a) We develop a model of composite accounts as unions of linear subspaces. This allows us to apply a number of *linear subspace clustering* algorithms (Ma et al., 2008) to the present problem.

(b) Based on this model, we develop a statistical test that can be used as indicator of 'compositeness', and a model selection procedure to determine the number of users sharing the same account. We systematically apply and evaluate these methods on real datasets.

(c) In particular, we show that a significant fraction of composite accounts can be reliably identified. In a dataset made of both single-user and composite accounts, a subset S of accounts can be selected that comprises roughly 70% of the composite accounts, while only 40% of the accounts in S are single-user accounts.

(d) The users sharing an account can be identified

with good accuracy. For the accounts in the above set, more than 60% of the movies were identified correctly (a result that we estimate to be significant with $p < 0.05$).

(e) We apply these mechanisms on 54K Netflix users that rated more than 500 movies, and identify 4 072 composite users with high confidence.

(f) Finally, we demonstrate how the above methods can be applied to improve recommendations.

We consider this ability to identify multiple users behind an account quite surprising, in view that no information is used apart from users' ratings. In particular, *all publicly available datasets are susceptible to this identification*. Beyond personalized recommendations, this ability is useful/worrisome for a number of reasons. On one hand, it can aid in determining the household's demographics. Such information can be subsequently monetized, *e.g.*, through targeted advertising. On the other hand, user identification can be considered as a privacy breach, and calls for a careful privacy assessment of recommender systems.

The remainder of this paper is organized as follows. Section 2 briefly reviews related work. Section 3 develops our statistical model. Sections 4 and 5 apply and evaluate our new methods to recommender system datasets. Finally, Section 6 uses these methods to improve personalized recommendations.

2 Related Work

The problem of user identification from ratings has received attention only recently. The 2nd Challenge on Context-Aware Movie Recommendation (Said et al., 2011) addressed a "supervised" variant. Movie ratings generated by users in the same household as well as the ids of the users was provided as a training set. The test set included movie ratings attributed to households, and contestants were asked to predict which household members rated these movies. In contrast, we study an unsupervised version of the problem, where the mapping of movies to users is not a priori known.

To the best of our knowledge, we are the first to study user identification as a subspace clustering problem. Beyond EM and GPCA, several subspace clustering algorithms have been recently proposed (Elhamifar and Vidal, 2009; Liu et al., 2010; Soltanolkotabi and Candes, 2011; Eriksson et al., 2011). Preliminary simulations using these methods did not yield significant improvements.

3 Statistical Modeling

Consider a dataset of ratings on M movies provided by N accounts, each corresponding to a different household. Ratings are available for a subset of all $N \times M$ possible pairs: we denote by $\mathcal{M}_H \subseteq [M]$, where $m_H \equiv |\mathcal{M}_H|$, the set of movies rated by account/household H, and by $r_{Hj} \in \mathbb{R}$ the rating of movie $j \in \mathcal{M}_H$.

Each movie $j \in [M]$ is associated with a feature vector $\mathbf{v}_j \in \mathbb{R}^d$, where $d \ll N, M$. We use matrix factorization to extract the latent features for each movie, as described in Section 3.3. If explicit information (*e.g.*, genres or tags) is available, this can be easily incorporated in our model by extending the vectors $\mathbf{v}_j$.

Each household H may comprise one *or more* users that actually rated the movies in $\mathcal{M}_H$. Abusing notation, we denote by H the set of users in this household, and by $n_H = |H|$ the household size. For each $i \in H$, we denote by $A_i^* \subseteq \mathcal{M}_H$ the set of movies rated by i, and by $I^*(j) \in H$ the user that rated $j \in \mathcal{M}_H$.

Note that neither the household size n_H nor the mapping $I^* : \mathcal{M}_H \to H$ are a priori known. We would like to perform the following inference tasks.

(a) *Model Selection*: determine the household size n_H. A closely related problem is the one of determining whether the account is *composite* (*i.e.*, $|H| > 1$) or not.

(b) *User Identification:* identify movies that have been viewed by the same user—*i.e.*, recover I^*, up to a permutation, and use this knowledge to profile the individual users.

We also explore the impact of user identification on targeted recommendations. The 'dual' impact on user privacy will be the object of a forthcoming publication.

3.1 Linear Model

We focus now on a single household, and omit the index H hereafter. We thus denote by n the household size, $\mathcal{M}$ and m the set of movies rated by this household and its size, respectively, and by r_j the rating given to movie $j \in \mathcal{M}$.

Our main modeling assumption is that the rating r_j generated by a user $i \in H$ for a movie $j \in \mathcal{M}$ is determined by a linear model over the feature vector $\mathbf{v}_j$. That is, for each $i \in H$ there exists a vector $\mathbf{u}_i^* \in \mathbb{R}^d$ and a real number $z_i^* \in \mathbb{R}$ (the *bias*), such that

$$r_j = \langle \mathbf{u}_i^*, \mathbf{v}_j \rangle + z_i^* + \epsilon_j, \quad \text{for all } j \in A_i^*, i \in H, \quad (1)$$

where $\epsilon_j \in \mathbb{R}$ are i.i.d. Gaussian random variables with mean zero and variance σ^2. Such linear models are

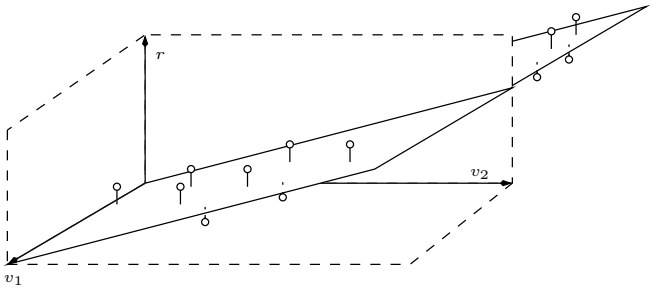

Figure 1: For all movies $j \in A_i$ rated by user $i \in H$, the points $\mathbf{x}_j = (\mathbf{v}_j, 1, r_j) \in \mathbb{R}^{d+2}$ lie slightly off a hyperplane whose normal is $(\mathbf{u}_i, z_i, -1) \in \mathbb{R}^{d+2}$.

used extensively by rating prediction methods that rely on matrix factorization (Srebro and Jaakkola, 2003; Srebro et al., 2005; Koren et al., 2009), and are known to perform very well in practice.

Assuming that the household size is known, the model parameters of (1) are (a) the *user profiles* $\boldsymbol{\Theta}^* = \{\boldsymbol{\theta}_i^*\}_{i \in H} \in \mathbb{R}^{n \times d+1}$, where $\boldsymbol{\theta}_i^* = (\mathbf{u}_i^*, z_i^*) \in \mathbb{R}^{d+1}$, $i \in H$, as well as (b) the mapping $I^* : \mathcal{M} \to H$. Given two estimators $\boldsymbol{\Theta}, I$ of $\boldsymbol{\Theta}^*, I^*$, the log-likelihood of the observed sequence of pairs $\{(\mathbf{v}_j, r_j)\}_{j \in \mathcal{M}}$, is given by

$$L(\boldsymbol{\Theta}, I) = -\frac{1}{2\sigma^2} \sum_{j \in \mathcal{M}} \big(r_j - z_{I(j)} - \langle \mathbf{u}_{I(j)}, \mathbf{v}_j \rangle\big)^2. \quad (2)$$

Estimating the maximum likelihood model parameters thus amounts to minimizing the mean square error:

$$\min_{\boldsymbol{\Theta}, I} \ \mathrm{MSE}(\boldsymbol{\Theta}, I) = \frac{1}{m} \sum_{j \in \mathcal{M}} \big(r_j - z_{I(j)} - \langle \mathbf{u}_{I(j)}, \mathbf{v}_j \rangle\big)^2, \quad (3)$$

where $\boldsymbol{\Theta} \in \mathbb{R}^{n \times d+1}$, $I \in \mathcal{I}$, the set of all mappings from $\mathcal{M}$ to H. Note that (3) is not convex. Nevertheless, as discussed in Section 4.1, fixing I results in a quadratic program, while fixing $\boldsymbol{\Theta}$ results in a combinatorial problem solvable in $O(nm)$ time.

3.2 Subspace Arrangements

We obtain an insightful geometric interpretation of the minimization (3) by studying the points $\mathbf{x}_j = (\mathbf{v}_j, 1, r_j) \in \mathbb{R}^{d+2}$, *i.e.*, the $d+2$-dimensional vectors resulting from appending $(1, r_j)$ to the movie profiles. Eq. (1) implies that although the points x_j live in an ambient space of dimension $d+2$, they actually lie on a lower-dimensional manifold: the union of n hyperplanes, *i.e.*, $d+1$-dimensional linear subspaces of $\mathbb{R}^{d+2}$.

To see this, let $\mathbf{n}_i^* = (\mathbf{u}_i, z_i, -1) \in \mathbb{R}^{d+2}$ be the vector obtained by appending the bias z_i^* and -1 to $\mathbf{u}_i^*$. Then, $|\langle \mathbf{n}_i^*, x_j \rangle| = |\langle \mathbf{u}_i^*, \mathbf{v}_j \rangle + z_i^* - r_j| = |\epsilon_j|$, for every $j \in A_i$. Hence, provided that the variance σ^2 is small, the points $\mathbf{x}_j$ lie very close to the hyperplane with normal $\mathbf{n}_i^*$ that crosses the origin (see Figure 1).

A union of such affine subspaces is called a *subspace arrangement*. Given that the data x_j, $j \in \mathcal{M}$, "almost" lie on such a manifold, minimizing the MSE has the following appealing geometric interpretation. First, mapping a movie j to a user amounts to identifying the hyperplane to which x_j is closest to. Second, once movies are thus mapped to users, profiling a user amounts to computing the normal to its corresponding hyperplane. Finally, identifying the number of users in a household amounts to determining the number of hyperplanes in the arrangement.

These tasks are known collectively as the *subspace estimation* or *subspace clustering* problem, which has numerous applications in computer vision and image processing (Vidal, 2010). In Section 4.1, we exploit this connection to apply algorithms for subspace clustering on user identification (namely, EM and GPCA).

3.3 Datasets

We test our algorithms on two datasets:

CAMRa2011 dataset. The CAMRa2011 dataset was released at the Context-Aware Movie Recommendation (CAMRa) challenge at the 5th ACM International Conference on Recommender Systems (RecSys) 2011. This dataset consists of 4 536 891 5-star ratings provided by $N = 171\,670$ users on $M = 23\,974$ movies, as well as additional information about household membership for a subset of 602 users. The 290 households comprise 272, 14 and 4 households of size 2, 3 and 4 users, respectively. We use the entire dataset to compute the movie profiles $\mathbf{v}_j$ through matrix factorization, using $d = 10$ (found to be optimal through cross validation). In the sequel, we restrict our attention to the 544 users belonging to households of size 2. To simulate a composite account, we merge the ratings provided by users belonging to the same household. The original mapping of ratings to household members serves as the ground truth.

Netflix Dataset. The second dataset contains 5-star ratings given by $N = 480\,189$ users for $M = 17\,770$ movies. We again obtain the movie profiles $\mathbf{v}_j$ through matrix factorization on the entire dataset, with $d = 30$. We then restrict our attention to the subset of 54 404 users who rated at least 500 movies. We also generate 300 'synthetic' households of size 2 by pairing the ratings of 600 randomly selected users; we select these among the accounts that our model-selection methods, described in Section 5.3, classify as non-composite.

Matrix factorization is likely to be unreliable for extracting account feature vectors, as the latter may be

composite. On the other hand, it appears to perform well for movies. We use the OptSpace algorithm of Keshavan et al. (2010) in both datasets for matrix factorization, which will not be further discussed.

4 User Identification

In this section, we address the user identification problem assuming that the household size n is a priori known. This amounts to obtaining estimators of I^* and $\boldsymbol{\theta}_i^* = (\mathbf{u}_i^*, z_i^*)$ for each user $i \in H$. We first describe four algorithms for solving this problem and then evaluate them on our two datasets. We present methods for determining the size n in Section 5.

In the absense of any additional information, we cannot distinguish between two mappings $I : \mathcal{M} \to H$ that partition $\mathcal{M}$ identically. As such, we have no hope of identifying the correct "label" $i \in H$ of a user; we thus assume in the sequel, w.l.o.g., that $H = [1, \ldots, n]$.

4.1 Algorithms

Clustering. Our first approach consists of two steps. First, we obtain a mapping $I : \mathcal{M} \to [n] = H$ by clustering the rating events $(\mathbf{v}_j, r_j) \in \mathbb{R}^{d+1}$, $j \in \mathcal{M}$ into n clusters. Second, given I, we estimate $\boldsymbol{\theta}_i = (\mathbf{u}_i, z_i)$, $i \in [n]$, by solving the quadratic program:

$$\min_{\boldsymbol{\Theta}} \mathrm{MSE}(\boldsymbol{\Theta}, I), \tag{4}$$

where MSE is given by (3). This is separable in each $\boldsymbol{\theta}_i$, so the latter can be obtained by solving

$$\min_{(\mathbf{u}_i, z_i)} \sum_{j \in A_i} (r_j - \langle \mathbf{u}_i, \mathbf{v}_j \rangle - z_i)^2. \tag{5}$$

where $A_i = \{j \in \mathcal{M} : I(j) = i\}$, which amounts to linear regression w.r.t. the model (1).

We perform the clustering in the first step using either (a) K-means or (b) spectral clustering. Each yields a distinct mapping; we denote the resulting two user identification algorithms by K-Means and Spectral, respectively. Intuitively, these methods treat the rating as "yet another" feature, and tend to attribute movies with very similar profiles $\mathbf{v}$ to the same user, even if they receive quite distinct ratings.

Expectation Maximization. The EM algorithm (Dempster et al., 1977) identifies the parameters of mixtures of distributions. It naturally applies to subspace clustering—technically, this is "hard" or "Viterbi" EM. Proceeding over multiple iterations, alternately minimizing the MSE in terms of the movie-user mapping I and the user profiles $\boldsymbol{\Theta}$. Initially, a mapping $I^0 \in \mathcal{I}$ is selected uniformly at random; at step $k \geq 1$, the profiles and the mapping are computed as follows.

$$\boldsymbol{\Theta}^k = \operatorname*{arg\,min}_{\boldsymbol{\Theta} \in \mathbb{R}^{n \times (d+1)}} \mathrm{MSE}(\boldsymbol{\Theta}, I^{k-1}) \tag{6a}$$

$$I^k = \operatorname*{arg\,min}_{I \in \mathcal{I}} \mathrm{MSE}(\boldsymbol{\Theta}^k, I) \tag{6b}$$

The minimization in (6a) can be solved as in (4) through linear regression. Eq. (6b) amounts to identifying the profile that best predicts each rating, *i.e.*,

$$I^k(j) = \arg\min_{i \in H} (r_j - z_i^k - \langle \mathbf{u}_i^k, \mathbf{v}_j \rangle)^2, \quad j \in \mathcal{M}. \tag{7}$$

which can be computed in $O(nm)$ time.

Generalized PCA. The Generalized Principal Components Analysis (GPCA) algorithm, originally proposed by Vidal et al. (2005), is an algebraic-geometric algorithm for solving the general subspace clustering problem, as defined in section 3.2.

To give some insight on how GPCA works, we consider first an idealized case where the noise ϵ_j in the linear model (1) is zero. Then, the points $\mathbf{x}_j = (\mathbf{v}_j, 1, r_j)$, $j \in A_i^*$, lie exactly on a hyperplane with normal $\mathbf{n}_i^* = (\mathbf{u}_i^*, z_i^*, -1)$. Thus, every $\mathbf{x}_j$, $j \in \mathcal{M}$, is a root of the following homogeneous polynomial of degree n:

$$\begin{aligned} P_{\mathbf{c}}(\mathbf{x}) &= \prod_{i \in H} \langle \mathbf{n}_i^*, \mathbf{x} \rangle = \prod_{i \in H} \sum_{k=1}^{d+2} n_{ik}^* x_{jk} \\ &= \sum_{k_1 + \ldots + k_{d+2} = n, \forall l \;\; k_\ell \geq 0} c_{k_1, \ldots, k_{d+2}} x_1^{k_1} \ldots x_{d+2}^{k_{d+2}} \end{aligned} \tag{8}$$

We denote by $\mathbf{c} \in \mathbb{R}^{K(n,d)}$, where $K(n,d) = \binom{n+d+1}{n}$, the vector of the monomial coefficients $c_{k_1, \ldots, k_{d+2}}$. Note that $P_{\mathbf{c}}$ is uniquely determined by $\mathbf{c}$. Moreover, provided that $m = |\mathcal{M}| \geq K(n,d) = O(\min(n^d, d^n))$, $\mathbf{c}$ can be computed by solving the system of linear equations $P_{\mathbf{c}}(\mathbf{x}_j) = 0$, $j \in \mathcal{M}$.

Knowledge of $\mathbf{c}$ can be used to *exactly recover* I^*, up to a permutation. This is because, by (8), for any $j \in A_i^*$, the gradient $\nabla P_{\mathbf{c}}(x_j)$ is proportional to the normal $\mathbf{n}_i^*$. Hence, the partition in of points $\{A_i^*\}$ can be recovered by grouping together points with co-linear gradients (Vidal et al., 2005).

Unfortunately, this result does not readily generalize in the presence of noise (see, *e.g.*, Ma et al. (2008)). In this case, one approach is to estimate $\mathbf{p}$ by solving the (non-convex) optimization problem

$$\begin{aligned} \text{Minimize:} \quad & \sum_{j \in [m]} ||\mathbf{x}_j - \widehat{\mathbf{x}}_j||_2^2 \\ \text{subject to:} \quad & P_{\mathbf{c}}(\widehat{\mathbf{x}}_j) = 0 \end{aligned} \tag{9}$$

We use the heuristic of Ma et al. (2008) for solving (9) through a first order approximation of $P_{\mathbf{c}}$ and cluster gradients using the "voting" method also by Ma et al.

4.2 Evaluation

We evaluate the four algorithms, namely K-Means, Spectral, EM, and GPCA over CAMRa2011 and Netflix. In the CAMRa2011, we focus on the 272 composite accounts obtained by merging the ratings of users belonging to households of size 2. In Netflix, we focus on the 300 composite accounts obtained by pairing 600 users. For each composite account H, the original mapping $I^* : \mathcal{M} \to \{1, 2\}$ serves as ground truth.

Similarity and RMSE. We measure the performance of each algorithm two ways. First, we compare the mapping $I : \mathcal{M} \to \{1, 2\}$ obtained to the ground truth through the following *similarity* metric:

$$s(I, I^*) = \max_{\pi \in \Pi(\{1,2\})} \frac{1}{m} \sum_{j \in \mathcal{M}} \mathbb{1}\{\pi(I(j)) = I^*(j)\}$$

where $\Pi(\{1, 2\})$ is the set of permutations of $\{1, 2\}$. In other words, the similarity between I and I^* is the fraction of movies in $\mathcal{M}$ which I and I^* agree, up to a permutation. Notice that, by definition $s(I, I^*) \geq 0.5$. Second, we compute how well the obtained profiles $\boldsymbol{\Theta} = \{\boldsymbol{\theta}_i\}_{i \in H}$ fit the observed data by evaluating the root mean square error: $\text{RMSE}(\boldsymbol{\Theta}, I) = \sqrt{\text{MSE}(\boldsymbol{\Theta}, I)}$, where MSE is given by (3).

Figures 2a and 2b show the cumulative distribution function (CDF) of the similarity metric s across all CAMRa2011 and Netflix composite accounts, respectively. Spectral performs the best in terms of similarity with EM (in CAMRa2011) and K-Means (in Netflix) being close seconds. The fact that clustering methods perform so well, in spite of treating ratings as "yet another" feature, suggests that users in these composite accounts indeed tend to watch different types of movies. Nevertheless, though K-Means and Spectral are comparable to EM in terms of s, they exhibit roughly double the RMSE of EM, as seen in Figure 2c. This is because, by grouping together similar movies with dissimilar ratings, these methods partition $\mathcal{M}$ in sets in which the linear regression (5) performs poorly.

Statistical Significance. In order to critically assess our results, we investigated the statistical significance of user identification performance under EM. We generated a null model by converting each of the 544 (600) users in the CAMRa2011 (Netflix) dataset into a composite account, by splitting the movies they rated into two random sets, thereby creating two fictitious users. Our random selection was such that the size ratio between the two sets in this partition followed the same distribution as the corresponding ratios in the real composite accounts. Our construction thus corresponds to a random "ground truth" that exhibits similar statistical properties as the original dataset. We subsequently ran EM over these 544 (600) fictitious composite accounts, and computed the similarity w.r.t. the random ground truth.

The resulting similarity metric CDF is indicated on Figures 2a and 2b as "Random EM". In CAMRa2011 (resp. Netflix), this curve indicates that any similarity $s > 0.59$ in CAMRa2011 (resp. $s > 0.52$) yields a p-value (probability of the similarity being larger or equal to s under the null hypothesis) below 0.05. This corresponds to 41% and 88% of the composite accounts, respectively in each dataset. For these households, we can be confident that the high similarity performance is not due to random fluctuations.

Precision at the Tail. The similarity metric captures the performance of user identification in the aggregate across all movies in $\mathcal{M}$. Nevertheless, even when the similarity metric is extremely low, we can still attribute some movies to distinct users with very high confidence. As we will see in Section 5.3, this is important, because identifying even a few movies that a user has watched can be quite informative.

Let $(\mathbf{u}_i, z_i)$, $i \in \{1, 2\}$, be the profiles computed by EM for a given household H. Figure 3 shows histograms of the difference

$$\Delta_j = |r_j - \langle u_1, v_j \rangle - z_2| - |r_j - \langle u_2, v_j \rangle - z_2|, \quad (10)$$

for $j \in \mathcal{M}$, for three different composite accounts in CAMRa2011. Note that EM classifies j as a movie rated by user 1 when $\Delta_j < 0$, and as a movie rated by user 2 otherwise. The three figures show the histograms of Δ_j for three households with high (0.90), intermediate (0.68), and low (0.50) similarity, respectively. The blue and green colors of each bar indicate the number of movies truly rated by user 1 and user 2, respectively. The total height of each bar corresponds to the total number of movies with that value of Δ_j.

The household in Figure 3a exhibits a clear separation between the two users; indeed, Δ_j is negative for most movies rated by user 1 and positive otherwise. In contrast, in Figures 3b and 3c the distribution of

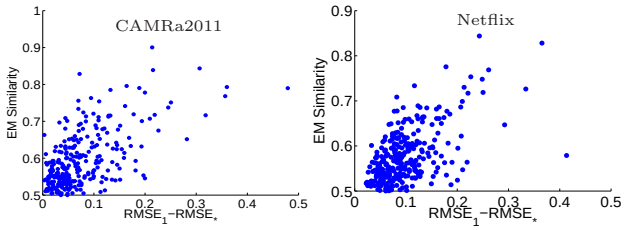

Figure 4: EM Similarity vs. gap in RMSE.

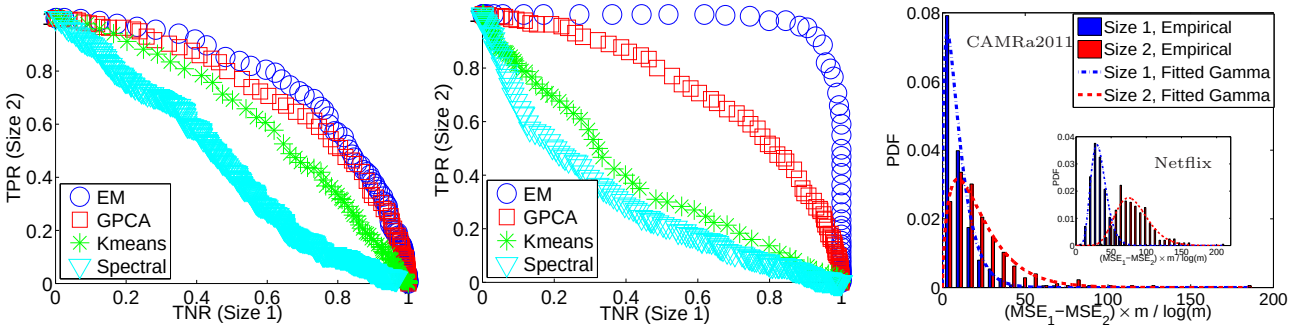
Δ_j is concentrated at zero. Intuitively, a large number of movies are difficult to classify between users 1 and 2. Nevertheless, the tails of this distribution are overwhelmingly biased towards one of the two users. In other words, when labeling movies that lie on the tails of these distributions, our confidence is very high. We determine formally the tails of these curves by fitting a Gaussian on these histograms, after discarding points whose distance from the mean exceeds 1.5 standard deviations. Indeed, mapping the tails above these curves to distinct users identifies them accurately.

Similarity Correlation to Diversity. For each composite account, we computed the RMSE assuming that *all ratings were generated by a single user*: *i.e.*, we obtained a single profile $\boldsymbol{\theta}_1$ solving the regression (5), assuming that $I(j) = 1$ for all $j \in \mathcal{I}$, and used this to obtain an RMSE, denoted by RMSE_1. We also computed the RMSE assuming that *the mapping of ratings to users is known*: *i.e.*, we obtained two profiles $\boldsymbol{\theta}_1^*$ and $\boldsymbol{\theta}_2^*$ by solving the regression (5), assuming that $I = I^*$, and used these profiles to obtain a new RMSE, denoted by RMSE_*.

Figure 4 shows the similarity metric $s(I, I^*)$ for each composite account, computed using EM, versus the gap $\text{RMSE}_1 - \text{RMSE}_*$ for a particular household. We observe a clear correlation between the two values for both datasets. Intuitively, the EM method fails to identify users precisely on households where users *have similar profiles*, and for which distinguishing the users has little impact on the RMSE. The method performs well when users are quite distinct, and a single profile does not fit the observed data well.

5 Model Selection

The user identification methods presented in the previous section assume a priori knowledge of the number of users sharing a composite account. However, this information may not be readily available; in fact, determining if an account is composite or not is an interesting problem in itself. In this section, we propose and evaluate algorithms for this task.



(a) CAMRa2011 (b) Netflix (c) Normalized MSE Gap Distribution for CAMRa2011 and Netflix (inset).

Figure 5: (a)-(b): ROC curves, where TPR (TNR) is the number households correctly labeled as size two (one) over the number of households labeled as size two (one). (c): Normalized MSE gaps for sizes 1 and 2

5.1 Model Selection

The problem of estimating the number of unknown parameters in a model is known as *model selection*—see, *e.g.*, Hansen and Yu (2001). Denoting by $\mathbf{\Theta}_n \in \mathbb{R}^{n\times(d+1)}, I_n \in \mathcal{I}$ the estimators of the parameters $\mathbf{\Theta}^*, I^*$ of the linear model (1) for size n, the general method for model selection amounts to determining n that minimizes $-\frac{1}{m}L(\mathbf{\Theta}_n, I_n) + \frac{C(\mathbf{\Theta}_n, I_n)}{m}$ where $L(\mathbf{\Theta}_n, I)$ is the log-likelihood of the data, given by (2), and C is a metric capturing the *model complexity*, usually as a function of the number of parameters n. Several different approaches for defining C exist; we report our results only for the *Bayesian Information Criterion* (BIC), by Schwarz (1978), as we observed that it performs best over our datasets.

The BIC for a household H of size $|H| = n$ is given by

$$BIC_n := \frac{1}{2\sigma^2}\text{MSE}(\mathbf{\Theta}_n, I_n) + \frac{2n(d+1)\log m}{m}. \quad (11)$$

where σ^2 is the variance of the Gaussian noise in (1). Note that different methods for obtaining the estimators $\mathbf{\Theta}_n, I_n$ lead to different values for BIC_n.

We tested BIC on our two datasets as follows. For the CAMRa2011 (Netflix) dataset, we created a combined dataset comprising the 272 (300) composite accounts of $n = 2$ as well as as the 544 (600) individuals of size $n = 1$ that are included in these households, yielding a total of 816 (900) accounts. For each of these accounts, we first computed the MSE under the assumption that $n = 1$; this amounted to solving the regression 5 for a single profile $\boldsymbol{\theta}_1 = [\mathbf{u}_1, z_1]$ under $I(j) = 1$, for all $j \in \mathcal{M}$, obtaining an MSE we denote by MSE_1. Subsequently, we used each of the four identification methods (EM, GPCA, K-Means, and Spectral) to obtain a mapping $I : \mathcal{M} \to H$, and vectors $\boldsymbol{\theta}_i = (\mathbf{u}_i, z_i)$, $i \in \{1, 2\}$: each of these yielded an MSE for $n = 2$, denoted by MSE_2.

Using these values, we constructed the following classifier: we labeled an account as composite when

$$(MSE_1 - MSE_2) - \tau \log m/m > 0 \quad (12)$$

By varying τ, we can make the classifier more or less conservative towards declaring accounts as composite. For $\tau = 2\sigma^2(d+2)$, this classifier coincides with BIC.

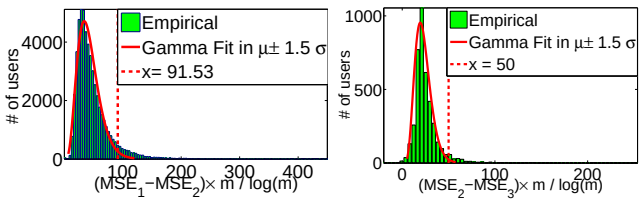
5.2 ROC Curves

The ROC curves obtained under different estimator functions for the model parameters can be found in Figure 5a for CAMRa2011. There is a clear ordering of the performance of different estimators as follows: EM (AUC=0.7711), GPCA (0.7455), K-Means (0.6111) and Spectral (0.4458). In particular, EM and GPCA yield very good classifiers. The performance on Netflix (Figure 5b) is even more striking, where EM (AUC=0.9796) significantly outperforms GPCA (0.7287), while K-Means (0.3879) and Spectral (0.2934) perform very poorly.

In Figure 5c, we plot the distribution of the normalized gap $(\text{MSE}_1 - \text{MSE}_2) \times m/\log m$ under EM for accounts of size 1 and 2, respectively. We see that in both datasets the distributions are well approximated by gamma distributions. Most importantly, accounts of size 2 exhibit a heavier tail. This is why labeling the outliers in the normalized gap distribution as households of size 2 as in (12) performs well.

5.3 Finding Composite Accounts on Netflix

Model Selection in Netflix. Armed with the above classification method, we turn our attention to the 54 390 users of the Netflix dataset that rated more than 500 movies. A natural question to ask is how many users in this dataset are in fact composite.



(a) Gap 1–2 in Netflix (b) Gap 2–3 in Netflix

Figure 6: PDF of RMSE gap in 54K Netflix users that rated more than 500 movies.

We first applied BIC with EM as a user identification method on these users. That is, we applied EM under the assumption the household size is n =1,2, and 3, and labeled a household with the value n that minimized BIC_n. We estimated the noise variance σ^2 through the mean square error of the matrix factorization applied on the entire dataset. The resulting classification labeled 36 832, 14 789, and 2 769 accounts as of size 1, 2, and ≥ 3, respectively.

We also applied an alternative method (akin to the empirical Bayes approach of Efron (2009)). First, we plotted the histogram of the normalized gap in the MSE from a model of 1 to 2 users (Figure 6a). We then identified the outliers of this curve, and labeled them as accounts of size 2 and above. To identify the outliers, we fitted a gamma distribution to the portion of the histogram that lies within 1.5 standard deviations from the mean. Superimposing the two distributions, we found the normalized gap value (91.53) at which the tail of the original distribution (which has a heavier tail) had twice the value of the fitted gamma distribution; all accounts with a higher normalized gap were labeled as outliers. To identify accounts with size 3 and above, we repeated the above process only on the outliers, using now the normalized gap between models of 2 and 3 users (Figure 6b).

The resulting classification is compared to the classification under BIC in the following table:

BIC\Outl.	1	2	≥ 3	Tot.
1	36832	0	0	36832
2	12712	2071	6	14789
≥ 3	774	1805	190	2769
Tot.	50318	3876	196	54390

Note that the above method of outliers is more conservative when labeling accounts as composite, labeling only 4 072 users as composite. Nevertheless, we know that this method performs well over the datasets on which we have ground truth (c.f. Figure 5c).

Visual Inspection. Though we cannot assess the accuracy of this classification (we lack ground truth), a visual inspection of the accounts that were labeled as composite yield some interesting observations. Recall that, in each composite account, there are a few movies that we can assign to different users with very high confidence: these are precisely the movies that lie close to one of the two hyperplanes computed by EM and far from the other (*c.f.* Figure 3).

User 1	User 2
TLOTR: The Fellowship of the Ring†(5), TLOTR: The Return of the King†(5), TLOTR: The Two Towers†(5), The Whole Nine Yards(4), Immortal†(1), The Deep End(2), Toys†(4), The Addams Family(5)	H.R. Pufnstuf(5), Sex and the City: Season 5$^{\heartsuit}$(1), Me Myself & Irene(1), All the Real Girls$^{\heartsuit\triangle}$(5), Titanic$^{\heartsuit}$(5), George Washington$^{\triangle}$(5), The Siege(1), In the Bedroom$^{\triangle}$(5)
User 1	**User 2**
Monsters Inc.$^{\diamondsuit}$(5), Finding Nemo$^{\diamondsuit}$(5), Whale Rider(5), Con Air(4), Lilo and Stitch$^{\diamondsuit}$(4), Ice Age$^{\diamondsuit}$(5), Ring of Fire(4), Star Trek: Nemesis(3),	In America$^{\spadesuit}$(2), Super Size Me(2), A Very Long Engagement$^{\spadesuit}$(1), Bend It Like Beckham(2), 21 Grams$^{\spadesuit}$(1), Airplane II: The Sequel(4), Spun$^{\spadesuit}$(1), Fahrenheit 9/11(1)

Table 1: Movies rated by accounts labeled as composite in the Netflix dataset. We split each account using EM and show movies j with most positive and most negative Δ_j. Symbols indicate labels from the Netflix website: $\dagger$ = "Sci-Fi & Fantasy", $\heartsuit$ = "Romantic", $\triangle$ = "Understated", $\diamondsuit$ = "Children & Family Movies", $\spadesuit$ = "Drama"

Using this intuition, we ran EM on several accounts declared as composite (size 2) by both BIC and the outlier method, and computed Δ_j, given by (10) for each movie j rated by these accounts. Table 1 shows the titles of the 8 most positive and 8 most negative movies for 2 such accounts. Looking up these titles on the Netflix website indicates clearly that these accounts exhibit a bimodal behavior. In the first account, 5/8 movies rated by User 1 are labelled as "Sci Fi & Fantasy", while 5/8 movies rated by User 2 are labelled either "Romantic" or "Understated". Similarly, in the second household, 4/8 movies rated by User 1 are labelled "Children & Family Movies", while 4/8 movies rated by User 2 are labelled as "Dramas", suggesting movies viewed by a child and an adult, respectively.

In many accounts we inspected, sequels (*e.g.*, "Lord of the Rings", "Star Wars", *etc.*) or seasons of the same TV show (*e.g.* "Sex and the City", "Friends", *etc.*) were grouped together (*i.e.*, attributed to the same user). The first account in Table 1 illustrates this.

We stress that we did not use any labeling or title information in our classification, as neither was available for both datasets. Nevertheless, as noted Section 3, such information can be incorporated in our model by extending v_j to include any additional features.

6 Targeted Recommendations

In this section, we illustrate how knowledge of household composition can be used to improve recommen-

dations. In a typical setup, a user accesses the account and the recommender system suggests a small set of movies from a catalog, recommending movies that are likely to be rated highly. However, even if the recommender knows the household composition and the user profiles, it still does not know who might be accessing the account at a given moment. In the absence of side information, we can circumvent this problem as follows. Assume the recommender has a budget of K movies to be displayed; it can then recommend the union of the K/n movies that are most likely to be rated highly by each of the n users. This exploits household composition, without requiring knowledge of who is presently accessing the account.

To investigate the benefit of user identification, we performed a 5-fold cross validation in each of the 272 households in CAMRa2011, whereby user profiles where trained in 4/5ths of $\mathcal{M}$ (the training set), and used to predict ratings in the remaining 1/5th (the test set). As, in the real-life setting, we can circumvent identifying which user is accessing an account when recommending movies, we focus on predicting the ratings of users accurately. Ideally, we would like to assess our rating prediction over the test set for both users; unfortunately, we have the true rating of only one user for each movie. As a result, we assume that the mapping of movies to users is priori known on the test set (but *not* on the training set): to generate a prediction for a movie in the test set, we generate a single rating using the profile of the user that truly generated it.

We tested the following 4 methods. The first, termed *Single*, ignores the household composition; a unique profile $\boldsymbol{\theta}_S = (\mathbf{u}_i, z_i)$ is computed over the training set for both users through ridge regression over (5) using $I(j) = 1$ for all j in the training set. The regularization parameter is chosen through cross validation. The second method, termed *Oracle*, assumes that the mapping of movies to users is known in the trainset; profiles $\theta_i^* = (\mathbf{u}_i^*, z_i^*)$, $i \in \{1, 2\}$ are obtained on the trainset using again ridge regression over (5) using $I = I^*$.

The third method, termed EM, uses the EM method outlined in Section 4 to obtain user profiles $\boldsymbol{\theta}_i = (\mathbf{u}_i, z_i)$. The EM algorithm is modified by adding regularization factor to the MSE, and using ridge rather than linear regression in each step. Finally, the last method, termed CNV for "convex", uses as a profile a linear combination of the common profile computed by Single and the specialized profile computed by EM. *I.e.* the profile of user i is given by $\alpha\boldsymbol{\theta}_S + (1-\alpha)\boldsymbol{\theta}_i$, with α computed through cross validation.

We evaluate the performance of these methods in terms of two metrics. The first is the RMSE of the predicted ratings on the test set. The second, which we call *overlap*, is computed by generating a list of 6 movies and calculating the number of common elements with the 3 top rated movies by each user in the test set. For Single, the list is generated by picking the 6 movies in the test set with the highest predicted rating. For the remaining methods, we generate the list by picking the 3 movies in the test set with the highest predicted rating for each user, and combining these two lists.

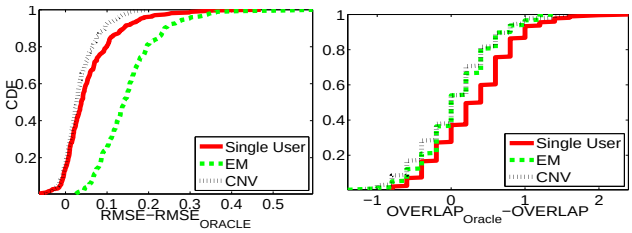


Figure 7: RMSE and OVERLAP performance compared to an oracle for the 272 composite users of CAMRa2011, when using (a) a single profile, (b) EM, and (c) a convex combination of the two.

Figure 7 shows the CDFs of the perfromance of the three mechanisms w.r.t. the distance of each metric from the corresponding metric under Oracle. We first observe that Oracle outperforms all other methods for the majority of the households, having an RMSE 0.60 and overlap 1.87, on average. This indicates that fitting a single profile to a composite account leads to poor predictions, which improve when the household composition is known. EM clearly outperforms Single w.r.t. the overlap metric, having a 14% higher overlap on average; however, it does worse w.r.t. RMSE also by roughly 14%. This is because, as observed in Figure 3, the bulk of movies are rated similarly by users, which dominates behavior in the RMSE; EM performs better on metrics that depend on the performance of outliers, such as overlap. In both metrics, CNV yields an improvement on both EM and Single, showing that the relative benefits of both methods can be combined.

7 Conclusion

We proposed methods for user identification solely on the ratings provided by users based on subspace clustering. Evaluating such methods in the presence of additional information is a potential future direction of this work. We also believe modeling rating data as a subspace arrangement can provide insight on a variety of applications, including privacy in recommender systems. In particular, altering or augmenting one's rating profile to *appear* as a composite user, with the purpose of obscuring, *e.g.*, one's gender, is an interesting research topic.
